What is the form of an ideal Bayesian observer that performs the detection task using only the VSDI signals from the monkey's V1? We have already characterized the stimulus-evoked response (figure 29.3) and the variability (figure 29.5). Given that the spatial profiles of the stimulus-evoked response at different contrasts are scaled versions of each other and that the variability is additive Gaussian noise with significant spatial correlations, the ideal observer should use a linear summation rule of the form

$$x_{pooled} = \sum_{i=1}^n w_i x_i \quad (1)$$

where w_i is the weight given to response x_i from site i (Chen et al., 2006; Duda, Hart, & Stork, 2001). This pooled response is the *decision variable* that is used to determine whether the target is present or absent on a given trial. The optimal set of weights, $\mathbf{w} = \langle w_1, \dots, w_n \rangle$, is given by

$$\mathbf{w} = \Sigma^{-1} \mathbf{s} \quad (2)$$

where Σ^{-1} is the inverse of the response covariance matrix Σ and \mathbf{s} is the mean difference in response between the target-present and target-absent trials (Chen et al., 2006; Duda et al., 2001).

An equivalent way to obtain the optimal set of weights is to derive a *whitening* or *decorrelation* spatial filter that, when convolved with the population response, produces variability that is independent over space. Figure 29.7A shows a one-dimensional slice through the whitening filter matched to the properties of the spatial correlations in the VSDI signals (figure 29.5C). This filter has a sharp positive peak and a small negative trough. By applying this filter to the fitted response profile (figure 29.3A), we obtained the linear weights used by the optimal spatial decoder (figure 29.7B) (Chen et al., 2006).

The optimal weights contain a central positive region and a larger negative surround. The reason these weights have a center-surround structure is that the spatial correlations fall off more slowly over space than the signal does. Because variability in the surround, where stimulus-evoked signals are weak or absent, is still highly correlated with variability in the center, the optimal strategy is to estimate the common noise from the surround and subtract it from the center.

The detection sensitivity of the optimal decoder can be determined by measuring its performance in the detection task (Chen et al., 2006). We can also evaluate the detection

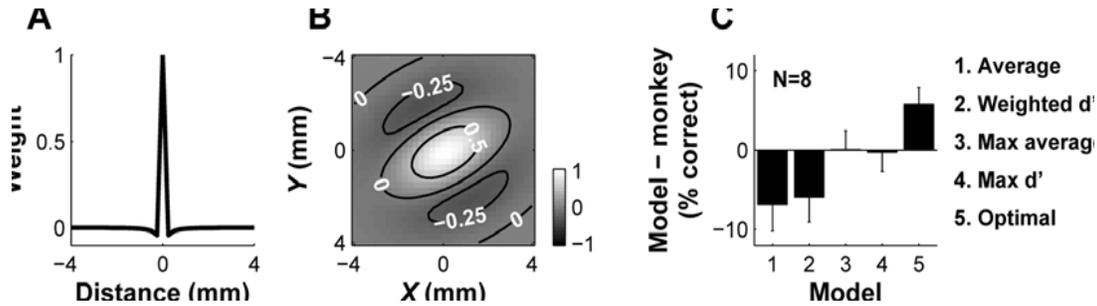

FIGURE 29.7 Optimal spatial pooling of VSDI responses in a detection task. (A) A one-dimensional cut through a two-dimensional spatial decorrelation (whitening) filter that removes the spatial correlations in the population responses (figure 29.5C). (B)

sensitivity of other previously proposed spatial pooling rules; for example, a rule that gives equal weight to all locations (average rule, analogous to the rule used by Shadlen, Britten, Newsome, and Movshon (1996)) or a rule that weights each location based on its sensitivity (weighted d' , analogous to the rule used by Geisler and Albrecht (1997)). Similarly, we can evaluate pooling rules that consider only a small region such as the location with the peak average response or the location with the highest sensitivity (maximal d').

Figure 29.7C shows the average difference in performance of the optimal and four suboptimal pooling rules from the performance of the monkey in eight VSDI experiments. This figure shows two surprising results. First, the optimal rule does significantly better than the monkey, demonstrating the sensitivity of the VSDI technique and showing that there are more signals in V1 than the monkey uses. Second, the two rules that pool over a large area with positive weights (average and weighted d') perform significantly worse than the monkey, while the two rules that consider only a single location perform comparably to the monkey.

The rules that pool over a large area with positive weights perform poorly, owing to the spatial correlations (figure 29.5C). Because the pool contains both highly sensitive and weakly sensitive neurons, averaging these together reduces signal without reducing the correlated noise. Thus when the noise is highly correlated, pooling over a small area may be better than pooling with positive weights over a larger area, even if the larger area contains signals. The only way to improve performance beyond the performance of a rule such as maximal d' is to use negative weights to cancel some of the noise. Importantly, rules that rely on a single-site perform poorly if the site is significantly smaller than $0.25 \times 0.25 \text{ mm}^2$. With smaller sites, independent noise dominates the response, leading to reduced performance.

TEMPORAL DECODING OF NEURAL POPULATION RESPONSES

Next, consider the optimal Bayesian temporal decoder for detecting the target from V1 population responses in a reaction time task. Here we ignore the spatial dimension and

simply consider the time course in a $1 \times 1 \text{ mm}^2$ region centered on the most sensitive location. This optimal decoder evaluates V1 responses and decides, on a moment-by-moment basis, whether and when sufficient evidence that the target is present has accumulated.

To optimally decode neural population responses over time, temporal correlations in the population responses must first be removed. Analogous to space, temporal correlations can be removed by a decorrelation filter that, when convolved with the responses in single trials, produces responses that are independent across frames. To be biologically plausible, however, this filter must be causal; that is, the output of the filter at time t must depend only on the response up to time t . The whitening filter is shown in figure 29.8A; it has a sharp positive peak, immediately followed by a smaller and slightly longer-lasting negative peak. Such a filter could be implemented biologically with rapid excitation followed by time-lagged inhibition. The whitening operation emphasizes the response onset (and offset) relative to the sustained response (figure 29.8B). In other words, there is more information per unit time in the initial rising edge of the response than in the sustained response. This occurs because the response onset contains high temporal frequencies and most of the power in the correlated noise is in the low temporal frequencies.

The optimal temporal decoder takes the whitened VSDI signal in single trials and computes the dynamic posterior probability of each possible stimulus, given the observed responses (Chen et al., 2008). It then reports “target present” if the posterior probability for target presence exceeds a fixed criterion (the horizontal line in figure 29.8C) that is selected to maximize accuracy. The optimal temporal pooling model performed more accurately than the monkey (figure 29.8D). In addition, the “reaction times” of the optimal temporal pooling model (the time at which the posterior probability for target presence reached the criterion) were much faster, on average, than the monkey’s reaction times (figure 29.8E). These results indicate that population responses provide reliable information that could guide behavior even in brief

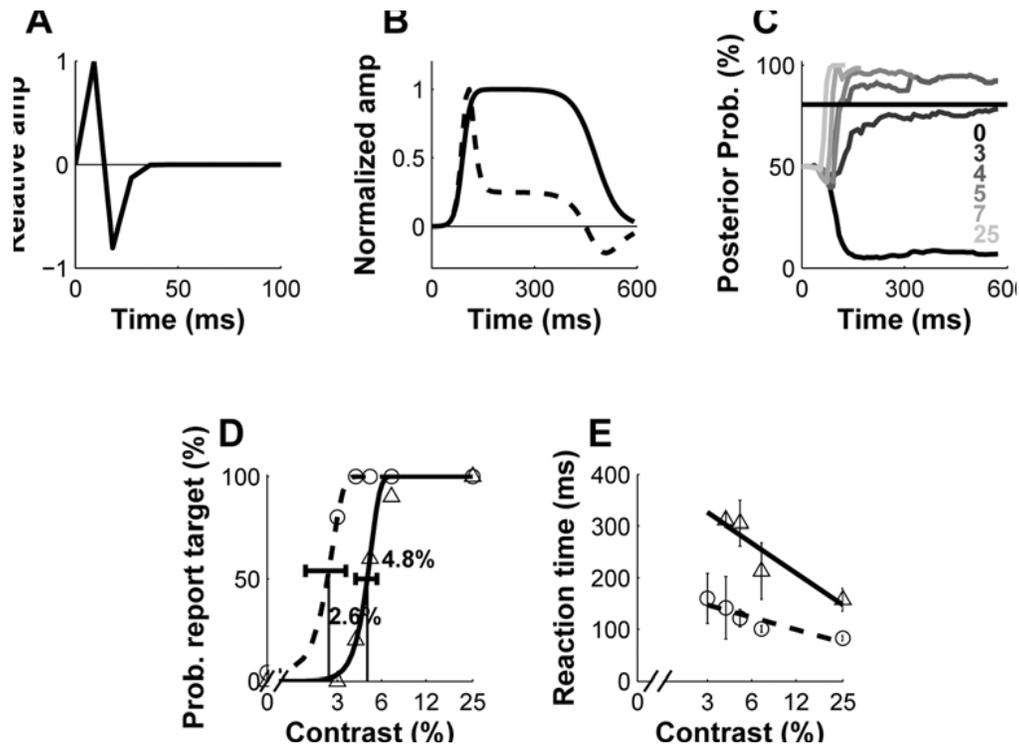

FIGURE 29.8 Optimal temporal pooling of neural population responses in a reaction-time detection task. (A) A causal temporal whitening filter that removes the temporal correlations in the population responses (figure 29.5D). (B) Normalized fitted time course of the response at 5% target contrast in one VSDI experiment before (solid curve) and after (dashed curve) whitening using the filter in A. (C) Posterior probability of target presence as a function of time averaged across all trials and plotted separately for each possible target contrast, including contrast zero (target absent). The horizontal black line indicates the position of the criterion on the

posterior probability. (D) Fraction of trials in which the observer (monkey: triangles, ideal temporal decoder: circles) reported that the target was present as a function of target contrast in the same experiment as in panel C. The curves indicate best-fit Weibull functions. The numbers are the stimulus contrasts required for an accuracy of 75% correct. (E) Average and standard deviation of reaction time of monkey (triangles) and ideal observer (circles) as a function of target contrast. The reaction time of the ideal observer was taken as the time the posterior probability for target presence exceeded the threshold.

temporal intervals (~ 100 ms). The mean and the variance of both the ideal observer's and the monkey's reaction times increase with decreasing target contrast, but at a faster rate for the monkey than for the ideal observer (figure 29.8E).

As with spatial pooling, one advantage of deriving the optimal decoder is that it can serve as a benchmark to which suboptimal models can be compared. We evaluated the performance of a simple model in which the VSDI responses are summed until a fixed threshold is reached. This model performs significantly worse than the monkey. We also evaluated an optimally shaped “running integrator” model that integrates the whitened responses over a window of about 100 ms. Because most of the information in our task was concentrated in the rising edge of the response and because the temporal profiles of the response at different contrasts differ only in latency and amplitude, this running integrator model performed almost as well as the ideal observer.

Note that the ideal observer would have performed much better had the responses been statistically independent over time, demonstrating that in our task, the detrimental effect

of temporal correlations cannot be entirely overcome by optimal pooling. Finally, note that the performance of the optimal temporal decoder (and running integrator decoder) can be improved further by combining signals over space using the optimal spatial pooling rule rather than averaging the signals in a 1.0-mm^2 region (Chen et al., 2008).

Discussion

This chapter began with two central claims that are relevant to the goal of understanding encoding and decoding by neural populations in the mammalian cortex. First, emergent properties in large neural populations make it essential to augment single-neuron recording with techniques that measure the responses of large populations of neurons simultaneously. Second, in formulating and testing hypotheses for population encoding/decoding, it can be highly beneficial to derive and evaluate optimal encoding and decoding strategies. To illustrate the first claim, we reviewed some emergent properties that have been observed in V1: widespread

responses even from maximally localized stimuli, highly sparse representations with most of the population response arising from weakly responding neurons, rapid response dynamics over large areas of cortex, additive but not multiplicative population noise, and large spatial and temporal noise correlations. To illustrate the second claim, we described the optimal decoding strategy for VSDI signals recorded from behaving monkeys in a reaction-time detection task and how this optimal decoder provides insight into specific questions about neural decoding.

Although progress is being made, the rigorous study of population responses in sensory and motor areas of the cortex is just beginning; indeed, the results obtained to date raise more questions than they answer. Next we discuss some of the relevant issues.

WEAKLY VERSUS STRONGLY RESPONDING NEURONS An important emergent property of large population responses in V1 is the dominance of relatively weakly responding neurons in the total population activity (figure 29.4). An open question is whether the weakly responding neurons are ignored or used by subsequent decoding mechanisms. It is not uncommon from the perspective of single-neuron electrophysiology to assume that those neurons that are most sensitive to a stimulus are the ones that carry most of the information used by the brain, but this need not be the case. For example, magnocellular neurons in the LGN are much more sensitive to contrast than are parvocellular neurons, and hence one might expect them to dominate performance in contrast detection, but in fact, the much more numerous but weaker responding parvocellular neurons dominate in most contrast detection tasks (Merigan, Katz, & Maunsell, 1991).

To further illustrate the potential significance of weakly responding neurons, consider the study of choice probability (trial-by-trial correlations between neural and behavioral variability) at the single-neuron level. If a large pool of weakly responding neurons were contributing as much to a subject's choice as a small pool of strongly responding neurons, recording from a single strongly responding neuron could easily yield a measurable correlation with behavior, whereas recording from a single weakly responding neuron could easily yield no measurable correlation. Obviously, it would be a mistake to interpret the lack of correlation in the weakly responding neuron as evidence against a major role for the weakly responding neurons in the subject's choice.

These considerations provide an additional illustration of a central theme of this chapter: that effects that are very weak at the single-neuron level could have a dominant role at the level of the pool. Therefore a general conclusion is that one should be cautious when making predictions based on single-unit measurements.

SOURCES OF CORRELATED NOISE Another important emergent property in V1 is the widespread and large spatial and temporal correlations in the variability of the population response. These correlations can have profound consequences for decoding, and they are entirely expected when a large number of neural inputs, having weakly correlated noise, are summed. Thus, it is important to identify and characterize the sources responsible for the small correlated noise that is shared between the neurons in a population. For example, it is possible that weak correlated noise must always be present, owing to the inevitable sharing of inputs between neurons. If so, then every time a large amount of convergence is required in a neural circuit, there will be the need for a decorrelating mechanism that can cancel most of the correlated noise.

DECODING A NEURAL POPULATION RESPONSE WITH A NEURAL POPULATION In the description of optimal and suboptimal candidate decoders, we were not explicit about how they might be implemented. In all likelihood, the decoding of population responses is implemented with another neural population. In fact, it is likely that, at every step along a sensorimotor pathway (from sensory encoding, to decision computation, all the way to the activation of muscle fibers), the stimulus and/or motor response is represented by the activity of a large neural population, because that is the obvious way to obtain robust behavior without ever requiring any specific neuron to be as robust as the behavior.

DECODING POPULATION RESPONSES IN DIFFERENT CORTICAL AREAS Given the similarities in neural anatomy across the cortex, it is quite possible that in all sensory and motor areas (as in V1), even the most localized inputs are encoded by population activity that extends over at least several square millimeters. However, there may also be some substantial differences in the properties of population responses across areas. For example, it is possible that early sensory areas contain a more sparse representation than higher sensory areas because they must represent many stimulus dimensions within the same area. This could have important consequences for the properties of population responses and hence for subsequent decoding.

DECODING POPULATION RESPONSES IN DIFFERENT TASKS The ideal Bayesian spatial decoder developed for our detection task (figure 29.7B) can be extended to other detection and discrimination tasks. As long as the variability is consistent with an additive Gaussian noise, the optimal weights are given by equation 2. Because the variability is additive, the only factor that determines the task-dependent component of the optimal weights is the difference in the mean response between the two stimulus conditions, \mathbf{s} .

Recall that the correlated noise is dominated by low spatial frequencies (figure 29.5C); therefore the whitening operation of the ideal observer amounts to high-pass filtering of \mathbf{s} . Figure 29.9 illustrates the expected impact of this whitening operation on the optimal weights for three detection tasks and one discrimination task. The upper row in figure 29.9 shows the stimuli; the middle row shows \mathbf{s} , the difference in the mean hypothetical responses for each task; and the bottom row the optimal weights. In the detection tasks (figures 29.9A–29.9C), the difference in response to the stimulus and blank is dominated by low spatial frequencies; therefore the optimal weights are strongly affected by the whitening operation. On the other hand, in the discrimination task (figure 29.9D), the difference in response to the two oriented stimuli is dominated by high spatial frequencies (i.e., comparable to the spatial frequency of orientation columns in macaque V1). In this case, the whitening operation has little impact on the optimal weights because the subtraction in \mathbf{s} , by itself, is sufficient to remove the long-

range spatial correlations. However, even in this case, temporal whitening with time lagged inhibition would still be beneficial for minimizing the impact of the temporal correlation.

FEEDBACK WITHIN AND ACROSS POPULATIONS The role of feedback in encoding and decoding by populations of neurons is still largely unknown. Feedback can play an important role in optimizing encoding of sensory stimuli for the specific demands of the task (e.g., Li, Piech, & Gilbert, 2004). Feedback can also play an active role in the decoding process through dynamic interactions between the encoding and decoding stages. One potential signature of feedback effects could be delayed modulations of the stimulus-evoked responses and/or the response variability. In our reaction-time detection task, however, both the evoked response and the response variability were relatively constant throughout stimulus presentation, suggesting that feedback does not play a strong role in this task.

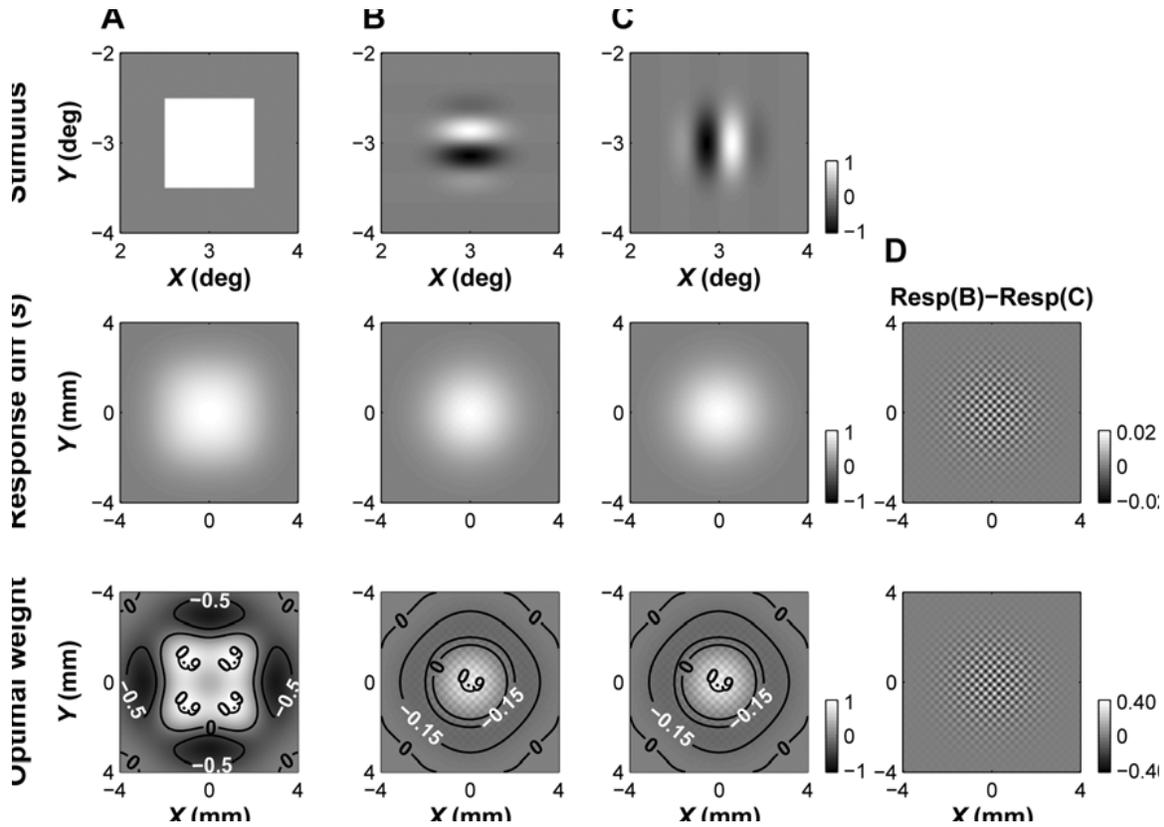

FIGURE 29.9 Optimal linear weights in three different perceptual tasks based on hypothetical population responses. (A) Detection of a low-contrast square. (B) Detection of a low-contrast horizontal Gabor patch. (C) Detection of a low-contrast vertical Gabor patch. (D) Discrimination between the Gabor patches in panels B and C. (A–C) top panel: stimulus; middle panel: hypothetical response in an $8 \times 8 \text{ mm}^2$ patch of cortex; bottom panel: optimal linear weights obtained by applying the whitening filter in figure 29.7A to the

population responses in the middle panel. (D) top panel: response to the horizontal Gabor in panel B minus the response to the vertical Gabor in panel C. The orientation-selective response was modeled as a high-spatial-frequency activation pattern (2.5 cycles/mm) with amplitude that is 10% of the amplitude of the Gaussian envelope of the population response. (D) bottom panel: optimal linear weights for discriminating between the Gabor patches at the two orientations.

IDENTIFYING THE ACTUAL NEURAL CODE AND DECODER The goal of an ideal observer analysis is to determine how population responses *should* be pooled over space and time to perform a specific task optimally. As was discussed before, this approach can, in principle, be used to reject possible combinations of codes and decoders if their sensitivity falls significantly short of the subject's sensitivity. The fact that the ideal observer does better than the monkeys in our detection task shows that in this task, there is no need to assume an actual code with a finer spatial and/or temporal resolutions than the one provided by VSDI. An important goal for future research is to determine whether this holds in other tasks. For example, it is possible that in an orientation discrimination task, an ideal observer using VSDI signals from V1 would perform significantly worse than the subject, owing to the coarse spatial pooling that is inherent to this technique.

The finding that an ideal observer performs significantly better than the subject does not necessarily imply that the subject is using a suboptimal decoding strategy. Population responses could be pooled by using the optimal pooling strategy but be degraded by subsequent sources of noise. For a more complete discussion of why the monkeys might perform suboptimally in our detection task, see Chen and colleagues (2006, 2008).

Ultimately, the goal of this line of research is to determine what are the *actual code* and *actual decoder* used by the observer. We are a long way from being able to address this question even in the simplest perceptual and motor tasks. Next, we briefly mention two approaches that could be used to address these questions.

One potential approach is to examine the trial-by-trial covariations between neural and behavioral responses (choice probability). Previous studies of neural and behavioral performances near psychophysical threshold demonstrated weak but significant covariation between the activity of single neurons and behavioral responses (e.g., Britten, Newsome, Shadlen, Celebrini, & Movshon, 1996; Cook & Maunsell, 2002; Palmer et al., 2007; Purushothaman & Bradley, 2005). If such correlations can be measured at the population level, their nature could provide useful information regarding the decoding mechanisms used by the subject.

A second approach that could be used to study the actual decoder is to perturb population responses in specific ways that are designed to distinguish between possible decoding mechanisms (e.g., Lee, Rohrer, & Sparks, 1988). Combining careful behavioral and neurophysiological measurements with better techniques for selectively perturbing brain activity at the population level (e.g., genetic-based techniques: Tan et al., 2006; Zhang et al., 2007) is a promising direction for testing candidate decoding models.

Conclusions

This chapter reviewed recent progress in understanding neural population coding in the mammalian cortex. This research area is clearly in its infancy. Making further progress will necessitate improving existing techniques, as well as developing new techniques, for monitoring and manipulating neural population responses in behaving subjects. It is unlikely that any single technique will provide access to the real-time activity of all the neurons in a given cortical area that could potentially contribute to behavior. Therefore it is important to develop a quantitative understanding of the relationships between the measurements of neural populations obtained with different techniques at different spatial scales. Analyzing simultaneous measurements of population responses and behavioral performance, within a Bayesian ideal-observer framework, is a powerful approach for addressing fundamental issues of population encoding and decoding.

ACKNOWLEDGMENTS We thank W. Bosking, C. Michelson, C. Palmer, and Z. Yang for discussions, and T. Cakic for technical support. NOTE

1. Note that this measure of information is related to, but differs from, traditional measures in information theory (Cover & Thomas, 2006). For example, Shannon information (mutual information) is appropriate for characterizing the potential bit rate of information transfer through a noisy channel when the goal is input reconstruction, but mutual information is not monotonically related to the trial-by-trial accuracy of an ideal observer in a discrimination or classification task (Geisler, Albrecht, Salvi, & Saunders, 1991). Fisher information can be monotonically related to the performance of the ideal observer, although the ideal observer provides the more general measure.

30 Perceptual Filling-in: From Experimental Data to Neural Network Modeling

RAINER GOEBEL AND PETER DE WEERD

ABSTRACT Recognizing objects, performing goal-directed actions, and navigating the environment are capabilities that crucially depend on the ability to correctly segregate and perceive surfaces. Surface perception results from computations that involve multiple processing levels in the visual system. The nature of these computations has been a matter of persistent debate. The contribution of this chapter to this debate is threefold. In the first part (“Reconstructive Processes Contributing to Surface Perception”), an overview is given of empirical studies that inform and constrain computational models of surface reconstruction. In the second part (“A Computational Model for Modal Texture Filling-in”), empirically supported principles of surface perception and known architecture of early visual areas are used to build a computational model of neural activity corresponding to visual filling-in of surface texture in early visual areas. The model explicitly simulates subthreshold and suprathreshold activity and therefore generates predictions not only for the activity distributions of spiking neurons, but also for functional magnetic resonance imaging (fMRI). The third part, “Insights, Limitations, and Future Research Directions,” provides a discussion of the main insights following from the modeling results. The model demonstrates the consequences of subthreshold neural spread of the BOLD signal for the activity distribution obtained with stimuli typically used to investigate perceptual filling-in, and it provides insight into the divergent data from human fMRI and neurophysiological experiments in animals. The model’s architecture, in which surface-related activity in low-level regions is validated by recurrent loops involving higher-order areas, is in line with theories of conscious perception. Limitations of the model will be discussed, and future research directions will be proposed.

Reconstructive processes contributing to surface perception

THE PROBLEM OF SURFACE PERCEPTION

A brief theoretical background The question how surfaces are represented follows from the normalization of the visual image by antagonistic filters in retina and LGN (Grossberg, 2003a). Normalization leads to a strong emphasis on discontinuities in the light distribution on the retina and a severe loss of signal related to regions of homogenous stimulation. Although that loss is not complete (see the section entitled “Features of Early Visual System Compatible with Active Interpolation”), it raises the question how the vivid experience of surfaces arises in the visual system. This has remained a matter of intense debate (Pessoa & Neumann, 1998; Pessoa, Thompson, & Noë, 1998; Komatsu, 2006), and three classes of mechanisms can be distinguished.

According to *active interpolation theory*, surface reconstruction involves active interpolation of surface features from a surface’s edges inward. The neural substrate of surface-related spreading activation is hypothesized to exist in early visual areas that are retinotopically organized. In this view, boundary representations initiate and contain the spreading of surface information (Walls, 1954; Gerrits, de Haan, & Vendrik, 1966; Gerrits & Vendrik, 1970; Grossberg, 2003a). First, contour interpolation mechanisms use local discontinuities to construct boundary representations. Second, surface interpolation mechanisms use measurements close to the contours as seeding points for the spread of surface feature, and inhibitory signals emanating from boundary representations contain spreading activity within a surface’s cortical projection. Computational models that incorporate an interaction between boundary and surface-related mechanisms perform well in explaining a wide range of visual illusions (Grimson, 1982; Grossberg, 1987a, 1987b, 1997, 2003a, 2003b; Todorovic, 1987; Grossberg & Todorovic, 1988; Arrington, 1994; Gove, Grossberg, & Mingolla, 1995; Grossberg & Raizada, 2000; Raizada & Grossberg, 2001).

Second, *multiscale spatial frequency filtering theory* suggests that surface representations can be derived directly from low-spatial-frequency information (McCourt, 1982; Stromeyer et al., 1984; Purves, Shimpi, & Lotto, 1999; Blakeslee, Pasieka, & McCourt, 2005, Blakeslee & McCourt, 2008; Dakin & Bex, 2003). This theory is compatible with a correlate of surface perception in retinotopic visual areas. However, because low spatial frequencies are processed prior to higher ones, surface representations might emerge before the completion of precise boundary representations, which require processing of high spatial frequencies (Hughes, Nozawa, & Kitterle, 1996).

Third, and in contrast to the previous two proposals, Denett (1991) proposed a *symbolic encoding theory* in which surface qualities are not encoded in retinotopic areas but are encoded implicitly (symbolically) as a lack of discontinuities in between identified surface boundaries. No activity is expected in lower visual areas corresponding to the perceived aspects of surfaces, and surface encoding might take place entirely at a higher, nonretinotopic level in the visual system, where surface representations might be an integral aspect of object representations (Desimone & Ungerleider, 1989; Wang, Tanaka, & Tanifuji, 1996; Biederman, 2000; Haxby et al., 2001; Kayaert, Biederman, & Vogels, 2003).

We take the viewpoint that the perceptual quality of surfaces is at least partly reconstructed from local cues in the retinal image, and in this first part of the chapter, we review evidence that is directly relevant for the active interpolation theory. However, evidence for active interpolation does not exclude contributions of low-spatial-frequency filtering and of feedback from high-level areas.

Experimental paradigms Two types of paradigm have been used to investigate whether active interpolation mechanisms exist (for a review, see Martinez-Conde, 2006). One approach is to directly study the perception of surfaces under normal viewing conditions, in intact or damaged visual systems (Bender & Teuber, 1946; Sergent, 1988), and to test whether surface perception would be associated with a (relatively) fast-spreading mechanism. An alternative approach entails the use of image stabilization, which produces filling-in illusions that (despite their delay from stimulus onset) are believed to yield insight into mechanisms of normal surface perception. When the image is stabilized artificially (e.g., using contact lenses), perceptual filling-in of the stabilized images occurs within a few hundred milliseconds. This has been demonstrated for color as well as brightness (Riggs & Ratliff, 1952; Ditchburn & Ginsborg, 1962; Riggs, Ratliff, Cornsweet, & Cornsweet, 1953; Gerrits et al., 1966; Yarbus, 1967). Taking advantage of the near-perfect stabilization of entopic images, Coppola and Purves (1996) demonstrated

filling-in within as little as 80 ms. By contrast, when the image is stabilized by using a strategy of maintained fixation away from a figure (Troxler, 1804), perceptual filling-in of the figure by the background can take many seconds, the length of the delay depending on the exact stimulus conditions (e.g., De Weerd et al., 1998). This delayed type of filling-in has been demonstrated for color, brightness, and (dynamic) texture (Ramachandran & Gregory, 1991; Spillmann & Kurtenbach, 1992; Ramachandran, Gregory, & Aiken, 1993; Fujita, 1993).

The different onset time of filling-in in the different paradigms fits with the active interpolation model, in which boundary construction precedes surface filling-in, so the spreading activation related to surface filling-in can be contained by inhibition from boundary representations. According to this model, in the brief periods in between saccades during which an observer's eyes rest on a specific point of interest during normal vision, surface interpolation takes place within roughly 100 ms of the completion of boundary representations (the exact time interval depending on surface size). An absence of retinal input within the confines of a cortical surface representation would not affect the cortical interpolation mechanisms, hence the quasi-instantaneous filling-in of the blind spot (Fiorani, Rosa, Gattass, & Rocha-Miranda, 1992; Komatsu & Murakami, 1994; Matsumoto & Komatsu, 2005) and retinal scotomas (Murakami, Komatsu, & Kinoshita, 1997). However, when the image is stabilized on the retina by artificial means or maintained fixation, the ensuing filling-in of a figure by the background is delayed by a time period that corresponds to the time for figure boundary mechanisms to adapt (Clarke, 1957). After a release from inhibition resulting from adaptation, surface feature from the background is interpolated into the area previously occupied by the figure (Tremere, Pinaud, & De Weerd, 2003).

Definitions of filling-in and adaptation *Perceptual filling-in* refers to the spreading of surface feature across a region in the visual field where that feature is physically absent. The term *filling-in* does not always aptly describe the percept, as in some paradigms, feature mixing can be experienced (e.g., Hsieh & Tse, 2006) rather than one region becoming filled in by another. We use the term *filling-in* with that caveat in mind. Furthermore, the term *filling-in* is used to refer to the perceptual phenomenon, and the term *interpolation* or *spreading activation* to refer to the underlying neural mechanism.

The term *adaptation* in a Troxler paradigm is likely to be related to more than the adaptation of local boundary representations and includes more global mechanisms that process the organization of visual scenes and that determine which image areas are labeled as *figure* and *background*. Nevertheless, for the purpose of computational modeling, the

concept of adaptation will be linked with the weakening of boundary representations over time, and the concept of filling-in will be linked with inward flow of background feature into the former figure region.

FEATURES OF EARLY VISUAL SYSTEM COMPATIBLE WITH ACTIVE INTERPOLATION

A possible anatomical basis for boundary and surface processing mechanisms in V1, V2, and V4 An essential aspect of active interpolation models of surface perception is the distinction between networks that analyze boundaries and networks that produce surfaces (Walls, 1954; Gerrits & Vendrik, 1970; Grossberg, 1987a, 1987b, 2003a). This distinction is loosely based upon *functional differences between anatomically defined compartments in V1, V2, and V4*. By using cytochrome oxidase staining, V1 can be subdivided into regions of dense staining (blobs) and less dense staining (interblobs). Blobs in V1 project to thin stripes in V2, and interblobs in V1 project to interstripes as well as thick stripes in V2 (Livingstone & Hubel, 1983; Roe & Ts'o, 1995; Sincich & Horton, 2005) (figure 30.14). Interestingly, V2 thin stripes and interstripes project to separate domains in V4 (Nakamura, Gattass, Desimone, & Ungerleider, 1993; Yoshioka & Dow, 1996; Xiao, Zych, & Felleman, 1999). The data suggest the existence of two processing streams within early to midlevel visual cortex. Both arise from a mix of parvocellular (P) and magnocellular (M) thalamic inputs arriving in layers 4Cb and 4Ca of V1, respectively (Blasdel & Lund, 1983; Nealey & Maunsell, 1994). Furthermore, although feedforward connectivity is predominantly specific within the two streams, feedback (Livingstone & Hubel, 1983; Roe & Ts'o, 1999; Angelucci et al., 2002; Xiao & Felleman, 2004; Angelucci & Bressloff, 2006), as well as lateral connectivity (Gilbert & Wiesel, 1989; McGuire, Gilbert, Rivlin, & Wiesel, 1991; Lund, Yoshioka, & Levitt, 1993; Malach, Tootell, & Malonek, 1994; Yoshioka, Blasdel, Levitt, & Lund, 1996; Yabuta & Callaway, 1998b) shows a mix of specificity and cross-stream connectivity, with the best specificity in layer III and less specificity outside (Ts'o & Gilbert, 1988; Farias, Gattass, Piñon, & Ungerleider, 1997; Shipp & Zeki, 2002). Hence the hypothesized processing streams in early visual cortex are strongly interconnected, and their signals likely interact.

Because of the mixing of P and M inputs in V1, the perceptual contribution of different compartments in early visual areas cannot be inferred from the functional properties of P and M cells, and early proposals that attempted to assign discrete functions such as shape, color, and motion to different anatomical compartments have proven incorrect (for a review, see Sincich & Horton, 2005). Nevertheless, the anatomically defined compartments tend to be character-

ized by different functional properties. Relevant for the present review is that V1 blobs (Friedman, Zhou, & von der Heydt, 2002; Roe, Lu, & Hung, 2005) and V2 thin stripes (Roe & Ts'o, 1995; Ts'o, Roe, & Gilbert, 2001; Wang, Xiao, & Feldman, 2007) contain neurons that are well stimulated by large chromatic and achromatic homogenous surfaces overlaying their receptive fields (RFs). Other studies that did not link recording sites to anatomical compartments confirmed the presence of responses to homogenous surfaces in monkey V1 (Kayama, Riso, Bartlett, & Doty, 1979; Maguire & Baizer, 1982; Kinoshita & Komatsu, 2001; Huang & Paradiso, 2008) and in cat area 17 (Bonhoeffer, Kim, Malonek, Shoham, & Grinvald, 1995; Shoham, Hübener, Schulze, Grinvald, & Bonhoeffer, 1997). By contrast, V1 interblob and V2 interstripe regions contain neurons that show preferential responses to chromatic and achromatic oriented lines and edges (Blasdel, Lund, & Fitzpatrick, 1985; DeYoe & Van Essen, 1988; Blasdel, Obermayer, & Kiorpes, 1995; Fitzpatrick, Lund, & Blasdel, 1985; Hubel & Livingstone, 1987, 1990; Bartfeld & Grinvald, 1992; Blasdel, 1992; Yabuta & Callaway, 1998a; Landisman & Ts'o, 2002; Lu & Roe, 2008). Furthermore, V1 interblobs, as well as V2 thick stripes and interstripes contribute to the analysis of local motion and stereo cues (DeYoe & Van Essen, 1988), but the contribution of these cues to surface segregation and interpolation falls outside the scope of this chapter (Grimson, 1982; Buckley, Frisby, & Mayhew, 1989; Frisby et al., 1995; Treue, Andersen, Ando, & Hildreth, 1995; Hillis, Watt, Landy, & Banks, 2004). On the basis of anatomy and physiological data with stimuli defined by luminance and color, we suggest that there are separate (but interacting) processing streams for contour and surface processing, extending from V1 and V2 into V4.

A possible anatomical basis for spreading activation: Retinotopy and lateral connectivity Early visual cortex shows retinotopic organization (Gattass, Gross, & Sandell, 1981; Gattass, Sousa, & Gross, 1988; Sereno et al., 1995) and therefore provides a substrate for isomorphic spreading activation, while the lack of retinotopy in higher-order cortex (beyond V4) limits its contribution to isomorphic representations. In retinotopic areas, both feedback and lateral connectivity could contribute to spreading. However, psychophysical estimates of the speed of spreading activation fit better with the transmission speed of lateral connectivity (0.2 m/s or 10–30 ms/degree) than with feedback, which is an order of magnitude faster (for review, see Angelucci & Bressloff, 2006). We therefore suggest that the *speed of surface-related spreading activation is set by properties of lateral connectivity*.

Further, cortical compartments with differentiable functions are *intertwined* in each retinotopic map, often at a sub-millimeter scale (figure 30.14). This implies that functional

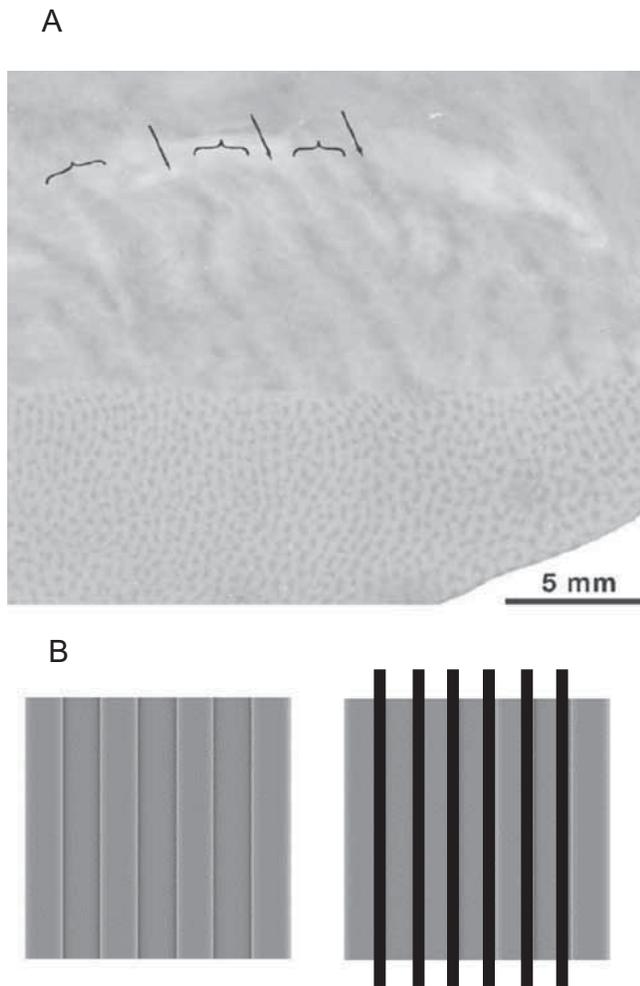

FIGURE 30.1 Cytochrome oxidase staining in V1 and V2, and Craik O'Brian Cornsweet stimulus. (A) Results from cytochrome oxidase staining in V1 (bottom half) and V2 (top half) reveal different anatomical subcompartments. Darker regions in V1 are blobs, lighter regions in V1 are interblobs. In V2, a striped pattern of staining can be discerned, consisting of thin stripes (arrows), thick stripes (brackets), and interstripes (least densely stained). (Reproduced from Sincich & Horton, 2005.) (B) Brightness illusion in the Craik O'Brian Cornsweet stimulus. The illusory brightness difference in the stimulus (on the left) is determined by the luminance at the edges of each patch. This can be appreciated by blocking the edges from view (on the right). Thin stripes (A) may play an important role in the perception of brightness spread as induced in the Craik O'Brian Cornsweet stimulus (see text).

clusters that are involved in spreading of surface properties are mixed with others that are involved in other functions. This has important implications for human functional magnetic resonance imaging (fMRI) studies, in which signal from neighboring clusters is pooled. This can make it difficult to link fMRI activity with specific neural computations during surface perception.

Recurrent loops in a hierarchical system Within each stream, there is evidence for *hierarchical processing*. A series of seminal

papers (von der Heydt, Peterhans, & Baumgartner, 1984; Peterhans & von der Heydt, 1989; von der Heydt & Peterhans, 1989; Heider, Meskaneite, & Peterhans, 2000) indicated that V2 interstripe neurons integrate local measurements into neural signals that are relevant for contour perception, while such integration is absent in V1. Similarly, Roe and colleagues (2005) demonstrated that the activity of V2 interstripe neurons reflects the brightness percept in the Craik O'Brian Cornsweet (COC) stimulus (figure 30.1B), while V1 blob neurons do not. Hung, Ramsden, Chen, and Roe (2001) reported related data for the cat. The presence of activity in V2 more closely linked to perception than in V1 does not imply that processing takes place in a purely feedforward manner. Instead, *recurrent feedforward/feedback loops* are thought to validate local analysis in low-level areas by a more global analysis of the visual scene in higher-level areas.

A strong candidate for sending feedback relevant for surface perception to areas V1 and V2 is area V4, which maintains a segregation of processing streams emanating from V1 and V2 (Nakamura et al., 1993; Yoshioka & Dow, 1996; Xiao et al., 1999). V4 neurons have RFs with large surrounds (Desimone & Schein, 1987; Schein & Desimone, 1990), and they display complex stimulus selectivity, which suggests a role both in global aspects of boundary construction and figure-ground segregation (Pasupathy & Connor, 2002) and in the encoding of more complex aspects of surfaces, such as statistics of low-level features (Hanazawa & Komatsu, 2001; Tanabe, Doi, Umeda, & Fujita, 2005) that can help to determine perceived depth, slant, and curvature. V4 is therefore well placed to be involved in feedback that is relevant for both contour and surface networks in V1 and V2. First, with respect to contour processing, a recurrent loop involving V1, V2, and V4 may help to construct boundaries from local discontinuities and may assign special status to boundaries belonging to the foreground (border ownership), based on occlusion cues, stereo cues, and others (Zhou, Friedman, & von der Heydt, 2000; Qiu & von der Heydt, 2005). Second, with respect to surface processing, feedback from V4 that takes boundary status into account may determine whether a spreading process within boundary representations produces a "visible" surface or not (see the third part of the chapter). Although the processing levels in the model proposed in the second part of the chapter are limited to areas V1, V2, and V4, areas other than V4 are likely to provide relevant feedback to V1 and V2 (e.g., see Hupe, James, Girard, & Bullier, 2001; Hupé et al., 2001).

In summary, the strongest evidence for surface-related spreading processes points to thin-stripe modules in V2. Although a contribution of V1 to surface representation is likely, we hypothesize that spreading activation directly relevant for surface perception takes place predominantly in V2 thin stripes and related modules in higher-order extrastriate cortex (V4). The spreading is hypothesized to be

contained by inhibitory processes related to boundary representations in interstripe modules in V2 and related modules in V4. Feedback from area V4 to V2 and V1 is hypothesized to be instrumental for boundary representation and segregation as well as for the gating of spreading activity that leads to “visible” surfaces.

EVIDENCE FOR ACTIVE INTERPOLATION THEORY IN EARLY VISUAL AREAS

Explicit activity related to surfaces Huang and Paradiso (2008) observed that monkey V1 neurons respond to large homogeneous luminance surfaces overlapping with their RFs. Other studies combining single-unit recording and optical imaging demonstrated surface-related activity for COC stimuli in monkey V1 and V2 (Roe et al., 2005) and in cat areas 17 and 18 (Hung et al., 2001). These studies indicated that perceptual attributes of luminance-defined surfaces were encoded in extrastriate cortex. Interestingly, Perna, Tosetti, Montanaro, and Morrone (2005), using fMRI in human subjects, failed to find any correlate of perceived brightness in the COC illusion in lower-order visual areas. Mendola, Conner, Sharma, Bahekar, and Lemieux (2006) found nonretinotopic deactivation during static brightness filling-in in V1.

Several neurophysiological recording studies found neural correlates of brightness induction in single neurons of monkey V1 (Kinoshita & Komatsu, 2001) or cat area 17 (Rossi & Paradiso, 1996, 1999), although a recent fMRI study failed to replicate these findings in human subjects (Cornelissen, Wade, Vladusich, Dougherty, & Wandell, 2006; see the third part of the chapter). Neural responses related to color filling-in across the blind spot have been demonstrated in monkey V1 (Murakami et al., 1997; Matsumoto & Komatsu, 2005; Komatsu, Kinoshita, & Murakami, 2000), and using fMRI, Sasaki and Watanabe (2004) found a correlate of neon color spreading in human V1.

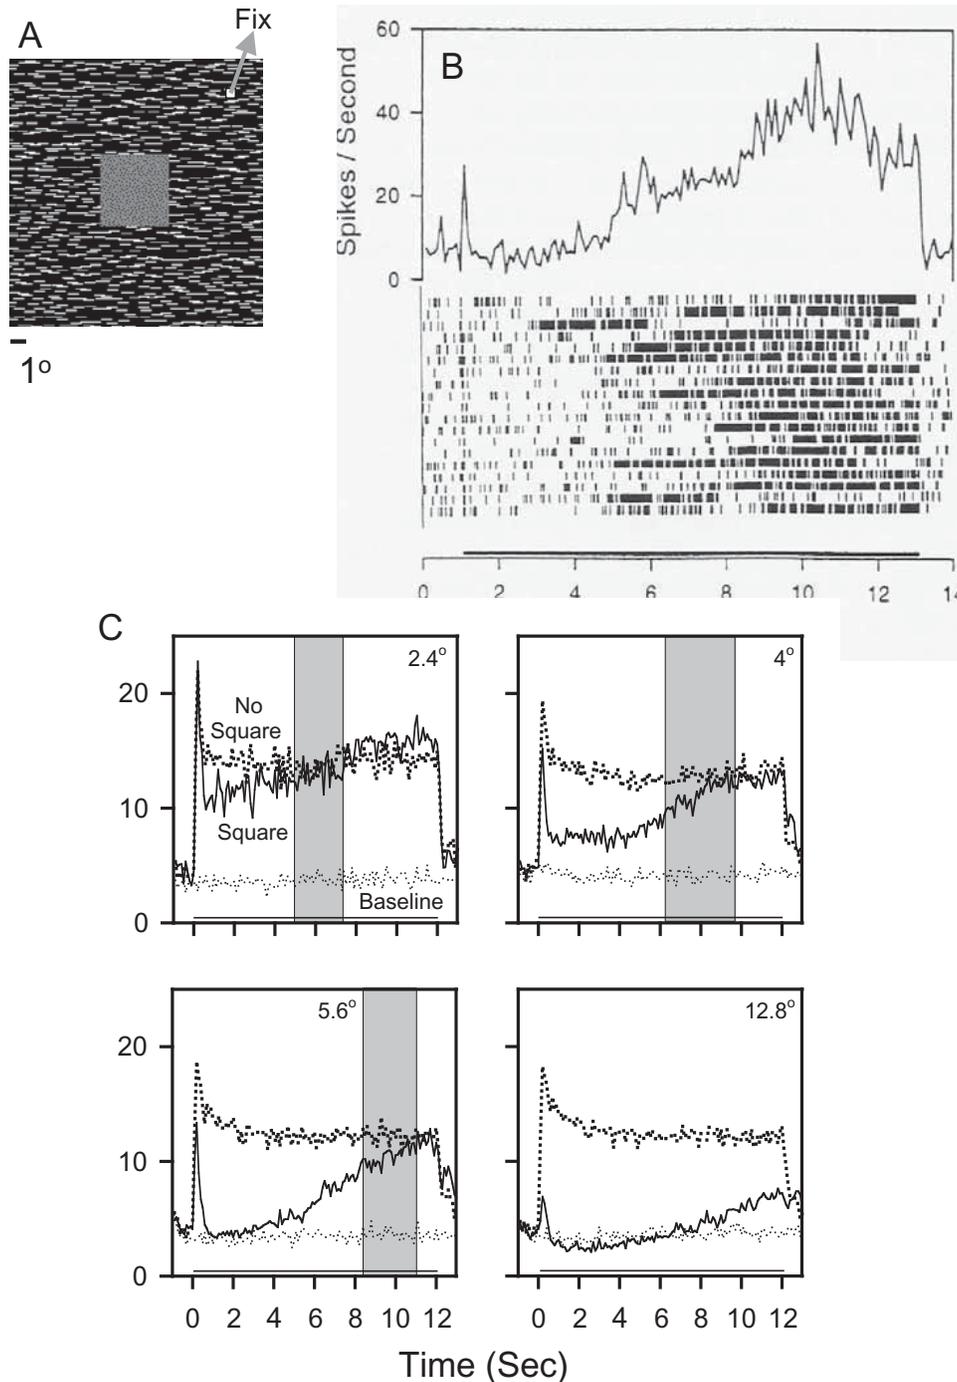

Using texture stimuli in a Troxler fading paradigm (figure 30.2A), De Weerd, Gattass, Desimone, and Ungerleider (1995) demonstrated increased responses in monkey V2 and V3 neurons whose RFs overlapped with a gray square surrounded by texture after several seconds of maintained fixation away from the square (figure 30.2B). When the response increase in monkey extrastriate neurons reached a level that was indistinguishable from activity obtained when the RFs were filled physically with the background, human subjects perceived filling-in under the same stimulus conditions (figure 30.2C). Furthermore, the time delay before filling-in of a gray figure by surrounding texture during maintained fixation away from the figure depended on the projection area in retinotopically organized visual areas (De Weerd, Desimone, & Ungerleider, 1998) and was related to adaptation of an inhibitory signal (Tremere et al., 2003; De

Weerd, 2006), possibly related to boundary adaptation. In line with findings with the COC stimulus (Roe et al., 2005), there were no activity increases in V1 neurons with RFs over the gray square, suggesting that V1 does not represent the perceptual quality of texture surfaces. Weil, Watkins, and Rees (2008) reported a reduction in fMRI activity in the V1 and V2 representations of a small, flickering target, while subjects reported filling-in of the target by surrounding dynamic texture.

Direct measurements of neural spread related to surface perception by recording from multiple electrodes in a surface’s cortical representation have not yet been performed. However, several psychophysical studies managed to visualize spread of brightness (Paradiso & Nakayama, 1991; Paradiso & Hahn, 1996) and texture (Motoyoshi, 1999). Estimates of the speed of brightness spread based on psychophysical data have been on the order of 50 ms/degree in the COC stimulus (Davey, Maddess, & Srinivasan, 1998), and 10 ms/degree in the brightness-masking paradigm (Paradiso & Nakayama, 1991).

The data show strong neurophysiological support for neuronal correlates of brightness, color, and texture spreading in extrastriate areas. At the same time, support from fMRI studies is weak. One of the goals of our modeling effort is to achieve a better understanding of the divergences between fMRI and neurophysiological techniques.

Importance of boundary representations in controlling spread The role of boundary representations in controlling surface feature spread finds support in a number of studies. The optical recording data from Roe and colleagues (2005) in V2 and a similar study in the cat (Hung et al., 2001) confirm the importance of surface information at boundaries in determining surface percepts. Furthermore, a psychophysical study from Salmela and Laurinen (2007) suggests that brightness spread is facilitated when edges are sharp and that the blurring of edges prevents brightness spread. Hence full boundary representations including sufficiently high spatial frequencies (Marr, 1982; Morrone & Burr, 1988) might be required to induce and contain brightness spread within a figure region, and blurred boundaries might not permit adequate surface representation. Other studies using figures on a texture background in a Troxler paradigm confirmed the importance of local differences at the border (De Weerd et al., 1998; Stürzel & Spillmann, 2001; Yokota & Yokota, 2004, 2005; Welchman & Harris, 2001); larger differences tending to prolong the “survival” of the figure (and thus delaying the initiation of perceptual filling-in). Furthermore, blurring facilitates perceptual filling-in of a figure with its background (Zhang & von der Heydt, 1995; Friedman, Zhu, & von der Heydt, 1999; von der Heydt, Friedman, & Zhou, 2003), except when stimuli are placed too peripherally for blurring to have an effect (Welchman & Harris, 2001, 2003).

Direct evidence for the primacy of boundary representations comes from recording study in the cat (Hung, Ramsden, & Roe, 2007), in which responses from simultaneously recorded cell pairs were compared, one RF being over a surface boundary and another inside the surface. They observed a border-to-surface shift in the relative timing of spiking activity for both real and illusory (COC) brightness contrast stimuli. Interestingly, the difference between boundary and surface-related signals was observed predominantly

in area 17–18 pairs and was weaker in area 17–17 pairs. Further, the reduction of inhibition observed in neurons with RFs in a figure surrounded by dynamic texture during Troxler fading (De Weerd, 2006) suggests that boundary adaptation permits the recorded neurons to become driven by excitatory input from the texture background. This is in agreement with the role of boundary representations in controlling neural spreading activation related to surface perception.

FIGURE 30.2 Stimulus used to induce Troxler fading and associated neuronal responses. (A) Dynamic texture stimulus with gray figure used by De Weerd and colleagues (1995, 1998) to induce perceptual filling-in of the figure by the textured surround. The picture shows a single frame of the dynamic texture stimulus. The homogeneous region in the center was approximately equiluminous with the average luminance of the surrounding dynamic texture and with the gray background upon which the texture was presented (23 cd/m^2). Since the position of the line elements was randomized in each frame of the movie, playing the movie (at 20 Hz) created a stimulus with continuously jittering line elements on the dark texture background. The small white square corresponds to the position of the fixation point (Fix). The illustration is approximately to scale except for the fixation spot, which is exaggerated in size for purposes of illustration. (B) Response from a single monkey V3 neuron with RF centered over the peripheral gray square (4 degrees) surrounded by texture, during passive fixation of a fixation spot away from the square (from Spillmann & De Weerd, 2003). The stimulus and square size shown in panel A was used, in which humans start to perceive filling-in approximately 6–10 s after stimulus onset. A recording trial started with the collection of 1 s of baseline activity in absence of a stimulus. Stimulus presentation is indicated by the solid bar at the bottom of the graph. The cell's RF straddled the square's edges, causing a brief onset response. The top panel shows the cumulative histogram demonstrating increased activity toward the end of stimulus presentation. Activity is expressed as spikes per second, calculated in bins of 100 ms. Individual response traces for the individual trials are shown below the cumulative histogram. Each small vertical mark indicates an action potential (at high firing rates the vertical marks tend to blend). Individual trials show discrete episodes of increased activity, which were more likely to occur toward the end of each trial. The histogram only includes trials in which the monkey maintained fixation till the end of the trial. (C) Correlation between

increased neural activity in V2/V3 and perceptual filling-in (from De Weerd et al., 1995). Average activity in stimulus conditions with a gray square over or inside the RF (solid curve) and in conditions in which the square, and thus the RF were physically filled with texture (heavy dotted curve) in subsets of V2 and V3 neurons with significant activity increases. Fine dots show baseline activity recorded without a stimulus. Square size is shown at the top of the panels. The horizontal line on top of each abscissa indicates the 12-s stimulus presentation time, preceded and followed by a 1-s period in which activity was recorded in the absence of a stimulus. Human observers reported filling-in for the same stimuli as were used during physiological recordings in the monkey in a time range indicated by the shaded zones. Activity increases were statistically evaluated in 93 V2/V3 neurons that were recorded in all square size conditions, using paired *t*-tests (two-tailed, $p < 0.05$), in which firing rates in a 2.5-s interval starting 1.5 s after stimulus onset were compared with the rates in the last 2.5 s of stimulus presentation. For cells that initially responded similarly in the square and no-square conditions, there was less opportunity to show an activity increase. This was particularly true at square sizes of 3.2 degrees and smaller (which were also not as conspicuous to human subjects as the larger square), for which we found significant activity increases in only 12% of V2/V3 cells. For larger square sizes, significant activity increases were found for about one-third of V2 neurons and about half of V3 neurons. Thus different numbers of neurons and trials (up to 20 trials per condition per neuron) were included in the different histograms at different square sizes. The inhibition during presentation of the largest square in the early part of the response (1–4 s after stimulus onset) was predictive for the magnitude of response increases in the late part of the response for smaller square sizes. This suggests that adaptation of inhibition may be a permissive factor for the observed response increases in the recordings with RF over the square (De Weerd, 2006).

Surface spreading processes are controlled not only by boundary representations, but also by more global aspects of the stimulus. Data from Troxler paradigms suggest that factors that determine figure-ground assignment (Sakaguchi, 2001, 2006; De Weerd et al., 1998; Hamburger, Prior, Sarris, & Spillmann, 2006; Hsieh & Tse, 2006) and statistics of the textures themselves (Hindi Attar, Hamburger, Rosenholtz, Götzl, & Spillmann, 2007; Sagakuchi, 2006) play an important role in determining the outcome of the spread of visual surface features.

Overall, the data suggest that boundary representations control spreading activation, both by initiating and containing spread in normal vision and by permitting new spread when boundaries adapt during stabilized vision.

EMPIRICAL BASIS OF A COMPUTATIONAL MODEL OF SURFACE FILLING-IN According to our interpretation of the data, four principles of visual system organization can be used to guide the modeling of perceptual filling-in. First, surface representation is accomplished by separate but interacting boundary and surface mechanisms that are intertwined

in V1, V2, and V4. Second, spread of surface properties occurs via lateral connectivity in the surface representation system. Third, recurrent loops within hierarchically organized border and surface processing streams determine the perceptual outcome of spreading activation. Fourth, spread of surface feature is contained by inhibitory signal from the boundary system, and adaptation of inhibition is a permissive factor for new spreading activation across surface boundaries.

Rather than focusing on luminance and color stimuli (e.g., Grossberg, 2003a; Neumann, Pessoa, & Hanson, 2001), the present model aims to simulate texture filling-in in a Troxler paradigm, in which a figure is “invaded” by the background following figure boundary adaptation. We will not consider initial spreading events at stimulus onset. We aim to increase understanding of divergent results from fMRI and spiking data in filling-in studies, to study implications of anatomical intertwining of boundary and surface processing streams for the fMRI activity distribution, and to increase insight into the contribution of recurrent loops to surface perception.

A computational model for modal texture filling-in

STRUCTURAL ASSUMPTIONS AND ARCHITECTURE OF THE NEURAL NETWORK MODEL

Properties of elementary, single processing units A single processing unit in the neural network is not related to a single neuron but represents a whole cortical column (Goebel, 1993). Cortical columns can be considered the building blocks of neural coding within brain areas (e.g., Hubel & Wiesel, 1959, 1962). A single processing element in our network is called a *cortical column unit* (CCU). The dynamics of a single CCU is described by the following standard difference equations:

$$net_i(t) = \sum_{j=1}^n w_{ij}^a a_j$$

$$a_i(t) = (1-r)a_i(t-1) + \tau \sigma(net_i(t) + b_i)$$

where w_{ij} is the weight from unit j to unit i , $a_i(t)$ is the average spike output of unit i at time t , $net_i(t)$ is the net input (excitatory minus inhibitory input) for unit i at time t , b_i is a bias term, and $\sigma(x)$ is the logistic (sigmoidal) function. The value τ ($0 < \tau \leq 1$) determines how strongly the activation value (average spiking activity) at the last time point ($t-1$) is influencing the activity at the current time point t .

Global architecture of the neural network model Our large-scale recurrent neural network model (figure 30.3) incorporates *retinotopically organized*, rectangular sheets representing areas V1, V2, and V4. To distinguish simplified *Model* regions from related visual areas, the modeled regions are denoted as *Model*-<area> or *M*-<area>. At present, the network processes only luminance-defined input, and no distinction is made between parvocellular and magnocellular processing. The luminance input to the model retina (M-Retina) is encoded as a spatiotemporal pattern across a single rectangular input sheet. Although we demonstrate processing with a network of 80×80 M-Retina units, the network can be scaled programmatically to any desired size. Details of the model architecture and its operation are provided at <http://www.brainvoyager.com/n3d/finn/index.html>.

A CCU in M-V1 integrates activity from a small retinal patch forming classical (afferent) RFs. The sampling size of retinal patches increases from central to peripheral regions so that the overall connection pattern from M-Retina to M-V1 reproduces cortical magnification (e.g., Sereno et al., 1995). By further convergence, units in M-V2 and M-V4 *hierarchically* integrate responses from lower levels, creating larger RFs (figure 30.3). *Lateral connections* within M-V1, M-V2, and M-V4 as well as *top-down connections* from higher visual areas (M-V4 \rightarrow M-V2; M-V2 \rightarrow M-V1) implement contextual effects from outside the classical RF.

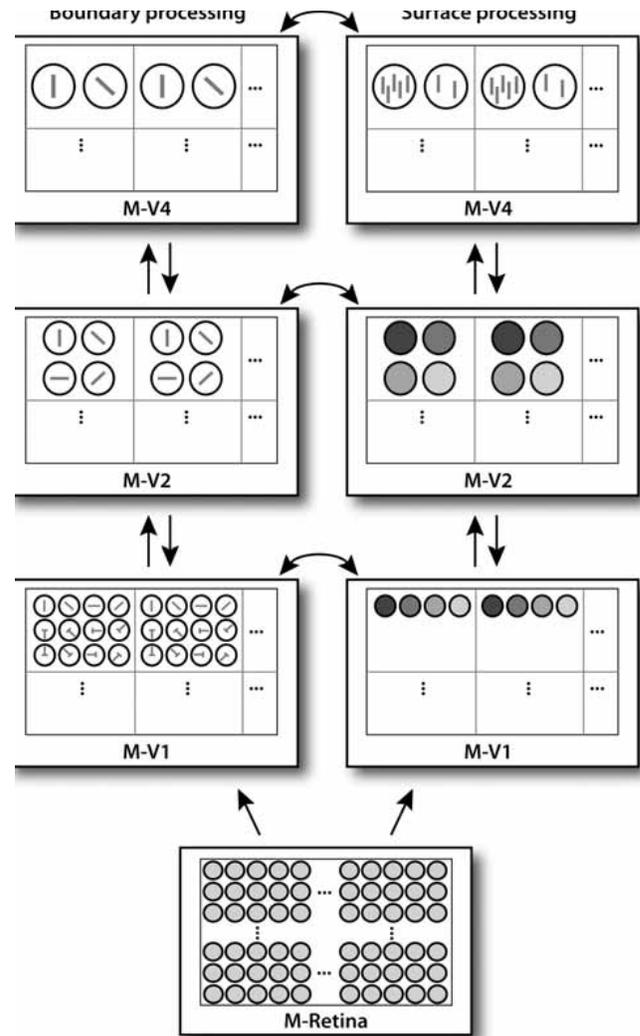

FIGURE 30.3 Architecture of the model. The model retina (M-Retina, 80×80 units) is the source of two streams specialized for boundary processing and surface processing, respectively, extending along three modeled areas, M-V1 (interblobs, blobs), M-V2 (interstripes, thin stripes), and M-V4. The connection pattern from M-Retina to M-V1 implements cortical magnification. Receptive field sizes of the retinotopically organized areas M-V1, M-V2, and M-V4 increases with increasing distance from M-Retina as indicated by the increasing size of the depicted units (circles). At each position, a number of different feature cells (hypercolumn) analyze a small, topologically corresponding, region at a lower level. As indicated by icons within the depicted units, the boundary-processing system detects oriented lines and end-stops, while the surface processing system contains units for luminance/brightness detection (M-V1/M-V2) and texture units (M-V4). Lateral and recurrent connections produce dynamic interactions within and between the boundary- and surface-processing systems. These connections include inhibitory synapses from each unit in the boundary-processing system to topologically corresponding units in the surface-processing system to prevent suprathreshold lateral spread in the surface system.

An important feature of the model is the definition of two parallel, interacting streams, a *boundary-processing system* and a *surface-processing system*, within each of the three relevant hierarchical levels. The boundary-processing subparts of M-V1 (interblob), M-V2 (interstripe), and M-V4 contain four orientation units at each position. The boundary processing subparts of M-V1 (interblobs), M-V2 (interstripes), and M-V4 also contain at each position 4×2 units with RFs detecting oriented line endings in two directions (bipolar “end-stop” units). For better visibility, units that code the same feature are shown as two-dimensional layers, separated from layers coding other features (see figures 30.3 and 30.6). A single feature map contains 30×30 units (see figure 30.6). For an anatomically more correct arrangement and to visualize modeled aggregate fMRI activity, different layers can also be stacked behind each other. A single set of feature detectors for the same small retinal position is referred to as a *hypercolumn*. The surface-processing subparts of M-V1 (blobs), M-V2 (thin stripes), and M-V4 contain units for the representation of surface features. In the case of homogeneous surface material, a unit in the surface-processing system represents luminance-related activity pooled from a small area of M-Retina. In the case of textured surfaces (e.g., a large field of small, randomly placed vertical lines), a M-V4 texture unit responds to a small surface patch if it contains a few elements at a preferred orientation. V4 contains texture units for a continuous range of orientations and texture element densities, but here we have included only layers in the model to demonstrate texture filling-in for vertically aligned texture elements. The model permits lateral spreading of different features at the same time in different M-areas (e.g., Ramachandran & Gregory, 1991). Further, *recurrent connections* produce dynamic interactions within and between the boundary-processing and surface-processing systems that determine the perceptual outcome of surface-related spreading processes.

The interaction between boundary and surface systems is modeled by the inhibitory connection of units in the contour processing system onto topologically corresponding units in the surface processing system. Boundary adaptation in the Troxler paradigm is modeled by a negative self-recurrent connection, causing activity in contour units to gradually decay over time. This decay reduces the inhibitory effect on the surface processing system eventually permitting *active* lateral spreading. These interactions occur simultaneously at multiple levels.

Network-brain links to visualize spiking and fMRI activity BOLD data reflect (suprathreshold) spiking activity, hemodynamic spread, and neural spread of subthreshold neural activity (Logothetis, Pauls, Augath, Trinath, & Oeltermann, 2001; Logothetis & Wandell, 2004; Oeltermann, Augath, & Logothetis, 2007; Maier et al., 2008). To investigate discrep-

ancies between spiking and BOLD data, spiking and the other components of BOLD must be modeled separately in an environment that permits a comparison with matching empirical data (Goebel & Horwitz, 2008). To compare modeled activity distributions with empirical data, modeled hypercolumns can be linked to topographically matching voxels obtained from structural brain scans and retinotopic mapping in human subjects, thereby establishing a common representational space for simulated and measured data. Thanks to these network-to-brain (NB) links, predicted data (e.g., fMRI signal) can be analyzed by using the same analysis tools as are used for the measured data (e.g., General Linear Model, Multi-Voxel Pattern Analysis). As an illustration, figure 30.4 shows NB links as established between M-V1 and topographically corresponding visual cortex of a subject.

To enable a direct comparison of modeled synaptic activity and spiking activity, the activity state of a unit is visualized in three ways using either the integrated synaptic activity net_i^{abs} , the average spike output level a_i , or the simulated fMRI data y_i . Note that net_i^{abs} is different from the standard “netto” input net , since it calculates the sum of the *absolute* activity arriving via excitatory and inhibitory synapses at unit i : $net_i^{abs} = |\Sigma \omega_j^{ex} a_j| + |\Sigma \omega_j^{inh} a_j|$. To create simulated proto-fMRI data in neuronal timing, the integrated synaptic input signal of a unit and the average spike output level is integrated as

$$a_i^{fMRI} = \lambda net_i^{abs} + (1 - \lambda) a_i$$

The weighting constant is set to a value of $\lambda = 0.8$, thereby biasing the fMRI signal to reflect the synaptic rather than the spiking activity. The ultimately predicted fMRI output value y_i is obtained by convolving a hemodynamic response function $HRF(x)$ with the predicted proto-fMRI data a_i^{fMRI} :

$$y_i = HRF(a_i^{fMRI})$$

For the HRF function, a single-gamma function (Boynton, Engel, Glover, & Heeger, 1996) or a two-gamma function (Friston et al., 1998) may be chosen in our model environment.

SIMULATION STUDIES

Mapping a gray figure in a dynamic noise texture background Prior to any fMRI investigation of perceptual filling-in of a figure by its surrounding background in a Troxler paradigm, it is essential to demonstrate that fMRI has the spatial resolution to distinguish the two surfaces. As is shown in figure 30.5, De Weerd, Karni, Kastner, Ungerleider, and Jezzard (1997) reported a failure in distinguishing fMRI activity obtained in V1 with a full-field dynamic texture from activity obtained with a texture containing a square figure, with figures as large as 6×6 at 7.2

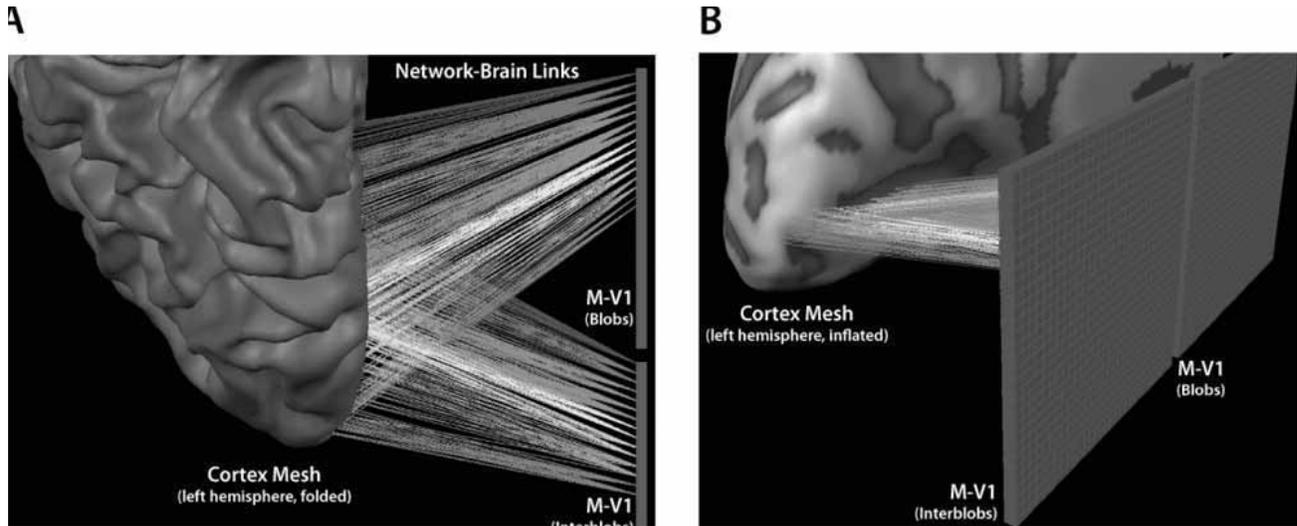

FIGURE 30.4 Selected network-brain (NB) links connecting cortical column units from one layer of the boundary processing system (interblobs) and one layer of the surface processing system (blobs) of M-V1 to a left hemisphere cortex mesh of a subject. Colored lines indicate NB links from foveal (red) to increasingly peripheral (orange, yellow, green, blue) locations within the model layers and corresponding regions within the calcarine sulcus of the subject's

cortex as identified by a fMRI retinotopic mapping experiment. (A) Top view depicting the cortex mesh in a folded state. (B) Lateral view depicting the cortex mesh in an inflated view. Note that NB links originating from the same retinotopic position of the boundary-processing M-V1 layer and surface-processing M-V1 layer are connected to the same position at the cortex mesh. (See color plate 43.)

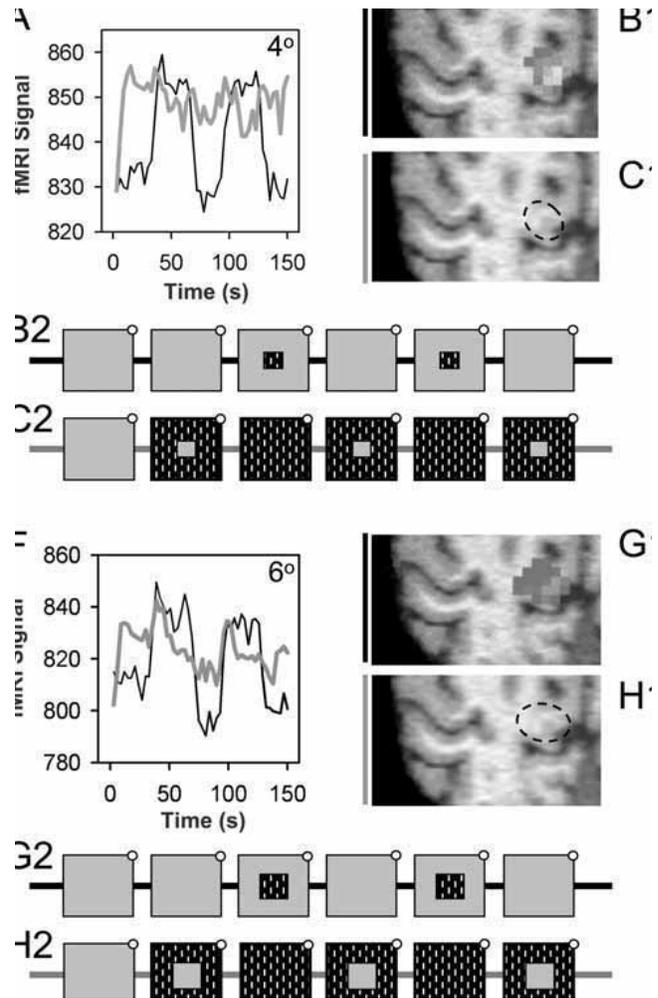

degrees of eccentricity (corresponding to about 10 mm in V1). This was surprising, because estimates of spatial resolution on the order of 2 mm had been reported around the same time (e.g., Engel et al., 1994; Engel, Glover, & Wandell, 1997). On the basis of our own findings, we have suggested that spatial resolution was much lower (Gaussian point spread of 7 mm at HWHM; De Weerd et al., 1997). The data from De Weerd and colleagues (1997) were obtained by using a 1.5T scanner and surface coil, but in recent years, we have confirmed their observations using a 3T scanner (unpublished data).

To investigate this phenomenon, we conducted a simple simulation study in which we presented either a rectangular figure made of dynamic texture on an “empty” background (Fig-On-Back-Off) or the inverse stimulus with an empty rectangular figure on a dynamic texture background (Fig-Off-Back-On). The figure was varied in size, and the resulting activity levels in the background and figure are shown in figure 30.6 (active voxels in white). Modeled fMRI signal is shown in M-V2, but it is reasonable to expect similar limitations in spatial resolution in other extrastriate areas. Modeled fMRI activity for a small empty figure on a texture background was as high in the figure as in the background representation (figure 30.6A). Only for a large empty square, the fMRI signal revealed a gradual fall-off of activity from the texture toward the center of the empty figure (figure 30.6B). Modeled spiking activity, however, was elevated only in the background representation and did not invade the representation of the empty figure (figures 30.6C and 30.6D).

The simulated, *passive spread of fMRI* may reveal the spread of *subthreshold synaptic activity* into modeled cortical regions where spiking activity is absent (for discussion, see the third part of the chapter). As expected, there was also significant spread of modeled fMRI signal from a stimulated figure representation into an empty background representation (Fig-On-Back-Off; figures 30.6E and 30.6F) beyond the activity distribution defined by spiking activity (figures 30.6G and 30.6H).

Perceptual filling-in of a gray figure by a dynamic noise texture background The lateral spreading described in the previous section does not lead to spiking activity in surface-processing units within the representation of a homogenous figure surrounded by texture. Hence the modeled fMRI spread is not a correlate of perceptual filling-in but rather a phenomenon that presents an obstacle to measure a fMRI correlate of perceptual filling-in. Here, we model filling-in of a figure by surrounding fine-grained dynamic noise. Prior to filling-in, inhibitory influences from the boundary-processing system are thought to contain spiking activity within surface boundaries. Figure 30.7A shows *spiking* activity during this state in boundary and surface systems in M-V1 and M-V2 (activity in white), during the presentation of a homogenous figure on a dynamic noise background to the M-Retina. Figure 30.7B shows fMRI activity for the same system state in boundary and surface systems of M-V2. The figure is sufficiently large to prevent the inflow of passive fMRI activity from the background to reach the middle of the figure rep-

FIGURE 30.5 Empirical data from a single subject illustrating limitations in fMRI resolution using 1.5 Tesla Signa Horizon Echospeed system. Similar data were obtained from a second subject, and data in both subjects were replicable across sessions. Functional scans were obtained with a gradient echo EPI sequence (BOLD images), using a 64×64 matrix, a FOV of 14–16 cm, coronal slices with $\text{Thk} = 4$ mm, $\text{TE} = 40$ ms, and $\text{TR} = 4$ s. Functional data were overlaid on high-resolution structural scans of the same person's brain. Structural scans were obtained by using 3D-SPGR, a $512 \times 384 \times 128$ matrix, with $\text{TE} = 5$ ms, $\text{TR} = 24$ ms, and a flip angle of 45 degrees. The testing of the effects of interest resulted in Wilkinson's maps, which were converted into z -maps. Single voxels were considered significant when the corresponding z -score exceeded 3.07. The coronal slice shown was positioned 16 mm anterior from the occipital pole. Dynamic texture stimuli (see figure 30.1A) were equiluminant with the background (24 cd/m^2). (A–C) fMRI signal as a function of time (A) during two block designs (B, C). In the first design (B2), two 30-s blocks of presentation of 4 degree square at 7.2 degrees eccentricity in lower left quadrant were interleaved with three 30-s periods of gray background. In the second design (C2), two 30-s blocks of presentation of a textured background were alternated with three 30-s periods of presentation of a gray 4-degree square at 7.2 degrees eccentricity. An initial period of baseline measurement without stimulus was discarded from analysis. Fixation spot (where subjects performed a demanding T/L discrimination task) is indicated at the top right of each stimulus panel. When the square was defined by dynamic texture on a gray background (B2), significant activity (black plot in A) was found in a large number of voxels in the upper bank of the calcarine sulcus (B1) using a regressor corresponding to the timing of the texture square in the block design in panel B2. When a full texture background was shown in blocks with or without a gray square (C2), there was no significant activity (C1) for the regressor corresponding to the physical filling-in of the gray square with texture (C2). The gray plot in panel A shows activity in the region of interest (ROI) defined by the response to the textured square (ROI is shown as a dashed oval in C1) during data from the block design shown in C2. For the design in C2, the data suggest spread of fMRI signal from the background texture into the gray figure. (F–H) Same conventions as in panels A–C, but the square size was 6 degrees. The gray plot in panel F shows a small, transient response to physical filling-in of the texture (design H2) that did not lead to significant activity in H1 (based on regressor corresponding to design H2). The fMRI signal in designs C2 and H2 inside the figure representation was not due to perceptual filling-in, as the signal was present from the beginning of stimulation (gray plot in panels A and F). Based on data in block designs showing a texture square on a gray background alternated with a gray background (as in B2 and C2), we found (averaged over subjects) activated regions of 158, 230, and 267 mm^2 for square sizes of 1, 4, and 6 degrees, respectively, while based on retinotopy (Serenio et al., 1995), activated regions of approximately 3, 45, and 110 mm^2 were expected. Averaged over subjects and conditions, a Gaussian filter of 7 mm (HWHM) was required to simulate the blurring of expected signal by fMRI. (See color plate 44.)

ensuing perceptual filling-in of the figure representation by activity from the background. Adaptation of the boundary units is implemented by self-recurring inhibitory connections. This causes an increase in net excitation of units within surface modules in the figure representation closest to the boundary. After some time, the units reach their threshold, producing spiking activity. Because of the excitatory lateral connections within the surface-processing system, units farther inward in the figure representation start to receive additional excitatory input from their spiking neighbors, which leads to spiking activity also in these units. Because of this evolving chain reaction, spiking activity quickly spreads inward until all units within the figure representation exhibit increased spiking activity. At this stage, the activity level of units within the former figure representation is comparable to the activity level that would have occurred had texture stimulus without a figure been presented. This activity state in the M2 surface-processing system is the modeled correlate of perceptual filling-in.

Perceptual filling-in of a homogenous figure by a dynamic, coarse texture background Many studies of perceptual filling-in use coarse

resentation and thus allows for the possibility to measure an fMRI signal related to perceptual filling-in exceeding fMRI signal related to passive spread. Figure 30.7C shows fMRI activity associated with adaptation of boundary units and

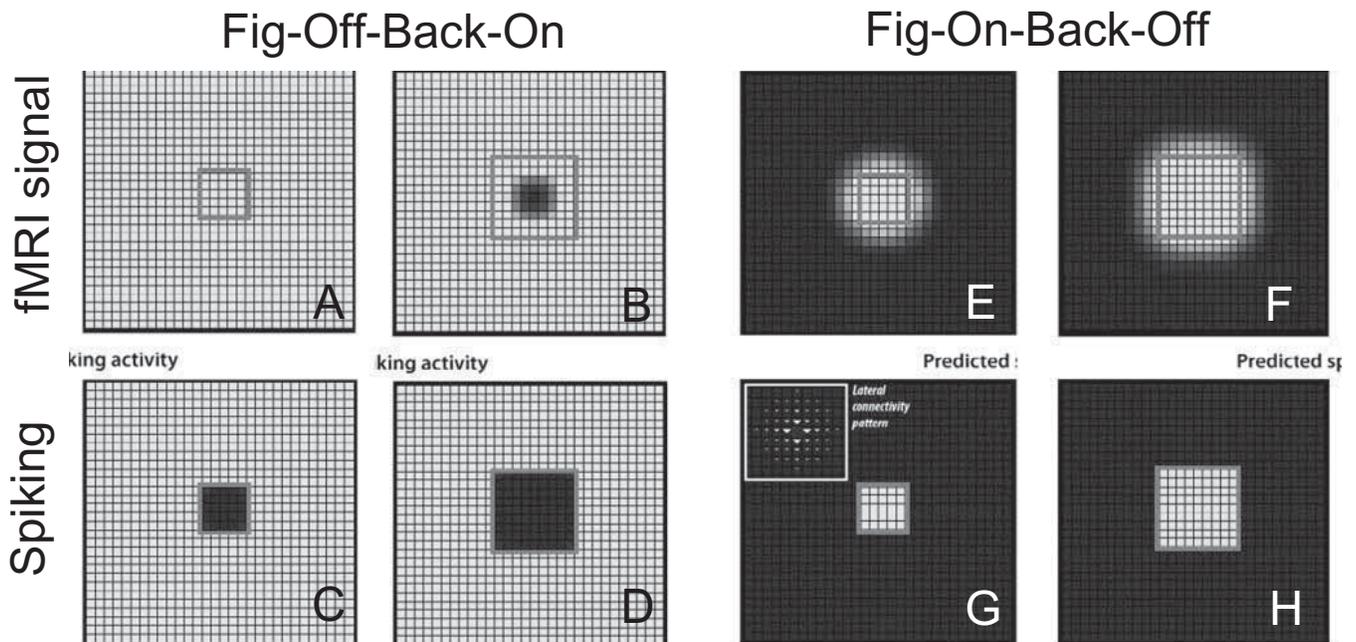

FIGURE 30.6 Simulation of spiking activity and fMRI signals when an “empty” square is surrounded by dynamic texture (Fig-Off-Back-On) or vice versa (Fig-On-Back-Off). As indicated by red outlines, stimuli were presented with a small square (5×5 rectangle; *A, C, E, G*) or a large square (9×9 rectangle; *B, D, F, H*). Each panel shows the activity state of the same layer from the surface-processing system of M-V2. The lateral connectivity pattern of each unit within this layer is shown in *G*. The activity state of a processing unit is indicated by a black-to-white color range corresponding to weak-to-strong activity. The predicted fMRI data in

the Fig-Off-Back-On condition show inflow from texture background into the figure representation (*A, B*), and only for the larger square (*B*) the interior is spared (shown in dark). Predicted spiking data (*C, D*) show a perfect representation of the square, without noticeable inflow from the background. The predicted fMRI data in the Fig-On-Back-Off condition show outflow of fMRI activity from the representation of the texture square into the empty background (*E, F*), while such outflow is unnoticeable for spiking data (*G, H*). (See color plate 45.)

texture backgrounds (e.g., De Weerd et al., 1998; Hindi Attar et al., 2007). For textures, especially when they are coarse, it can be asked what information is actually spreading during filling-in and how it is computed. In the first part of the chapter, we reviewed evidence suggesting that V4 neurons encode global statistics of texture patches, such as overall brightness, brightness, gradients, and texture density (Hanazawa & Komatsu, 2001; Tanabe et al., 2005). Similar statistical operations on multiple elements within a RF have been reported for V2 neurons (Anzai, Peng, & Van Essen, 2007), but unless textures consist of fine elements that are very densely packed, RFs of neurons in V2 might be too small to produce reliable estimates of texture statistics. Cortical areas at a level higher than V4 probably would produce statistical estimates that are insufficiently local to guide spreading processes in lower-order, retinotopic visual areas. Hence in our model, we assume that M-V4 has a special role in estimating global texture statistics and that these statistics are the kind of information that spreads during perceptual filling-in.

The computational processes that lead to spreading activation in figure representations in retinotopic maps

are the same as those described for fine-grained textures, but they now involve interactions between boundary- and surface-processing systems within both M-V4 and M-V2 (for details, see <http://www.brainvoyager.com/n3d/finn/index.html>). In addition, a recurrent loop involving the two M-areas is required to produce spreading activity in either area. Before active neuronal spreading has occurred, inhibition from units in the boundary-processing system of M-V4 is strong enough to prevent lateral spreading within the surface-processing system of M-V4, and the same holds in M-V2. After boundary adaptation, active spreading within M-V4 and M-V2 may occur, but the activity levels in units within the surface-processing systems of M-V4 and M-V2 are codependent. More specifically, lateral subthreshold inputs to units in the M-V4 surface module inside the representation of the homogenous figure must be supplemented with *feedforward* subthreshold input from units in M-V2 surface module at corresponding retinotopic locations. Similarly, lateral subthreshold inputs to units in the M-V2 surface module inside the representation of the homogenous figure must be supplemented by *feedback* subthreshold input from units in the M-V4 surface module at

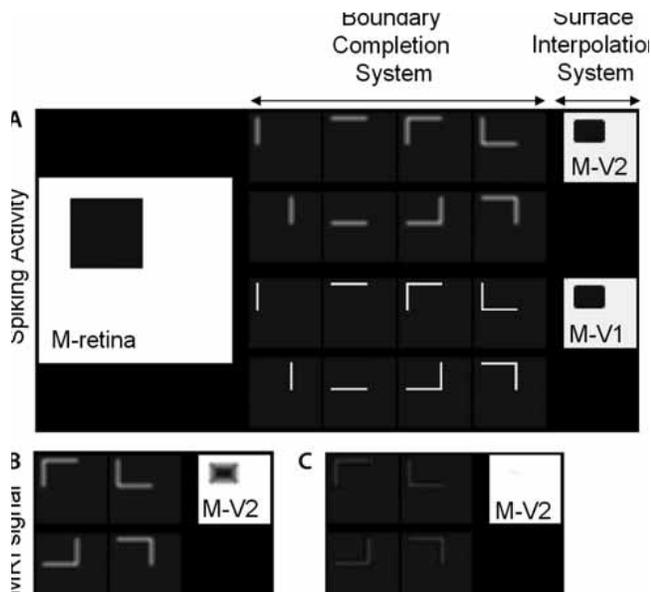

FIGURE 30.7 Filling-in simulation for an “empty” square surrounded by a fine noise texture. Average spiking or fMRI activity in relevant layers of the model is indicated on a dark-to-light scale (corresponding to low-to-high activity). (A) Initial spiking activity state after presenting the stimulus at M-Retina (left hand, large sheet). The boundary processing systems in M-V1 and M-V2 detect the borders separating the background from the central hole. The surface-processing system in M-V1 and M-V2 responds strongly to the texture background, revealing the empty square representation by an absence of activity. (B) fMRI activity in boundary and surface systems, with some spreading of fMRI signal into the figure representation in the surface system. (C) fMRI activity showing adaptation of boundary representations and ensuing active spreading in the surface system of M-V2. In panels B and C, only layers of M-V2 are shown, since the activity state in other layers do not change substantially.

corresponding retinotopic locations. This results in a recurrent loop, which leads to spreading of spiking activity from the texture surround into the figure within both M-V2 and M-V4.

By building appropriate structural assumptions into the recurrent M-V2/M-V4 loop, it could be possible to model effects of surface properties on perceptual filling-in during Troxler paradigms (e.g., see Hindi Attar et al., 2007). We focused on the contribution of recurrent loops to the interpolation of coarse texture, but such loops likely play a role in interpolation of other surface features. For particular features, such as brightness and color, recurrent loops that are relevant for surface interpolation might involve M-V1.

Insights, limitations, and future research directions

A SUMMARY OF ASSUMPTIONS AND INSIGHTS The main empirically based, structural assumptions that were built

into the model’s global architecture were (1) the presence of three levels of processing (M-V1, M-V2, and M-V4), (2) separate but interacting boundary- and surface-processing streams, (3) lateral connectivity within each module at each level, (4) recurrent connectivity between levels within modules, and (5) a specific strength of recurrent inhibition within the units of the boundary-processing system.

Below, we highlight three insights that follow from our modeling effort. First, we discuss consequences of the sensitivity of the fMRI signal to subthreshold neural activation for experiments on perceptual filling-in, for the notion of point spread, and for the comparability of fMRI and neuronal recording experiments. Second, we consider consequences of the inhomogeneity of cortex for the interpretation of fMRI data on perceptual filling-in. Third, we emphasize that the perceptual consequences of the recurrent loops in our model are in agreement with recent views on visual awareness and “conscious” perception.

INSIGHTS FROM MODELING THE SENSITIVITY OF fMRI TO SUBTHRESHOLD NEURAL ACTIVATION The explicit computation and visualization of average spiking activity and predicted fMRI data has proven valuable to understand the difficulty of mapping a homogenous figure surrounded by dynamic texture in retinotopic areas with fMRI. In the modeled data, we observed that a homogenous figure can easily be detected in the distribution of spiking activity while remaining undetectable in the distribution of fMRI activity. Our model thus reconciles the spiking results of De Weerd and colleagues (1995) with the fMRI data from De Weerd and colleagues (1997). Both studies investigated neural activity in the cortical representation of homogenous figures surrounded by texture. The former study found low spiking activity inside homogenous figures (prior to perceptual filling-in), whereas the latter study suggested that unless very large figures were used, the fMRI signal in the figure representation was high from stimulus onset on, irrespective of whether the figure was present or not. Our model might help to reconcile other, apparently conflicting results from fMRI studies and spike recording studies in animals that investigated the same phenomena across species (e.g., compare Kaas, Collins, & Chino, 2003, with Smirnakis et al., 2005; and see Tolias, Smirnakis, Augath, Trinath, & Logothetis, 2001; Maier et al., 2008). Note that while spiking data can be dissociated from fMRI signal, local field potentials (LFPs) are more robustly linked to the fMRI signal, as both LFPs and fMRI signal are thought to reflect predominantly (subthreshold) synaptic activity from large neuronal populations (Logothetis et al., 2001; Maier et al., 2008).

Our data also illustrate that estimates of fMRI spatial resolution, which have been reported to be as low as 1.8 mm

HWHM of Gaussian point spread (Engel et al., 1994, 1997), are often uninformative with respect to the prediction of fMRI activity distributions for stationary figures in a context of other stimuli. In fMRI studies that estimate spatial resolution, slowly moving dynamic checkerboard stimuli are used, presented isolated on a homogenous background. The isolated nature and the slow motion of these stimuli could limit the neural spread of subthreshold activity and reveal predominantly hemodynamic spread, thereby leading to the suggestion of excellent spatial resolution. However, complex stimuli composed of several parts that perceptually group together, or perceptually fill in, and involving prolonged stimulation at constant locations may increase the subthreshold inputs to neurons with RFs in between stimulus parts. This can lead to an *effective* fMRI spatial resolution (point-spread of spiking, hemodynamic, and subthreshold neural spread combined) that may be much lower than expected. Under these conditions, estimates have been reported on the order of 7 mm (De Weerd et al., 1997; Cornelissen et al., 2006). The sensitivity of fMRI signal to subthreshold neural activation makes fMRI point spread dependent on stimulus design and renders the notion of a generally applicable estimate of fMRI point spread obsolete.

INSIGHTS FROM MODELING SUBVOXEL SPECIALIZATION OF VISUAL CORTEX The subvoxel specialization among and within compartments of early visual cortex, combined with physical limits on temporal and spatial resolution, renders an fMRI correlate of surface-related spreading activity difficult to detect. At the neuronal level, spreading activity related to surface encoding (e.g., in V2) is present only in small subsets of neurons that are intertwined with other neurons that do not participate in the spreading or might be involved in other functions. Moreover, boundary-related effects that might intuitively be considered local might spread into the representation of the figure because of the sensitivity of fMRI to passive spread of subthreshold activity. Hence decreased responses to boundaries could contribute to the overall activity measured from the figure representation. If this signal decrease is relatively strong, it might outweigh any activity increases associated with surface-related spreading, and one might conclude incorrectly that surface interpolation is associated with a decrease in activation. Thus even in studying filling-in of large stimuli, the effective spatial resolution of fMRI might be insufficient to detect a weak correlate of filling-in and might instead reveal the stronger boundary adaptation effect that passively spreads into the figure representation (Mendola et al., 2006, Perna et al., 2005). The study from Weil and colleagues (2008) in which filling-in of a flickering target was associated with a decreased fMRI signal also suffered from these limitations: The 1.2×1.2 degree target at 8.75 degrees of eccentricity used in that study corresponds approximately to 1.3×1.3 mm of V1

cortex (Serenio et al., 1995), well below the 3×3 mm voxel size that is used for functional scanning. It cannot be excluded that reduced activation associated with adaptation to the (boundaries of) the flickering target dominated increased signal related to perceptual filling-in. In the work of Cornelissen and colleagues (2006), the failure to confirm a correlate of brightness induction might have been due to a combination of insufficient spatial and temporal resolution to resolve antiphase brightness modulations (1 Hz) in abutting cortical representations. On the basis of these considerations, we suggest that our model can be an important tool in the design of appropriate stimuli for fMRI experiments on perceptual filling-in. For example, on the basis of simulations, we know that to empirically demonstrate filling-in of a gray figure by surrounding dynamic texture with fMRI, an active interpolation signal must exceed the passive neural spread of fMRI activity from the texture into the cortical representation of the figure. Our model suggests that this problem may be avoided only when using very large figure sizes. Overlay of simulated fMRI activity distributions in sheets of units representing boundary- and surface-processing systems in a M-area that respects retinotopy and cortical magnification can be helpful to precisely assess the possibility of discerning activity specifically related to perceptual filling-in. In our model, coming to this assessment is facilitated by NB-links that can map simulated activity distributions onto a flat map of a human subject's cortex in which empirical data can later be collected.

INSIGHTS FROM MODELING RECURRENT CONNECTIONS BETWEEN M-V2 AND M-V4 The recurrent neural network model may offer a new account of modal and amodal completion/filling-in. First, the implementation of a recurrent loop between surface modules in M-V2 and M-V4 (see the second part of the chapter) is important for understanding what defines *modal* ("real") surface percepts. We suggest that modal completion or filling-in of a figure by its background requires spiking activity in figure representations in V2 and V4 comparable to the activity that would be observed in the absence of a figure on the background. Therefore only when active spreading occurs in V2 and V4 via spiking activity, the system has made a "decision" to consider the internally represented surface as "real." In this state, spiking neurons in V2 and spiking neurons in higher visual areas (e.g., V4) form functional circuits jointly representing the content of the filled-in percept. Although we only modeled spreading in the Troxler paradigm, we suggest that a "spreading" of the "real/visible" status of a surface also takes place during normal perception when there is a direct physical basis for the perceived surface, in which case recurrent processing might modulate bottom-up surface-related activity and the associated surface percept. Our discussion of modal completion/filling-in is in line with theories of conscious

visual experience that assign a crucial role to recurrent loops between lower- and higher-order visual areas (e.g., Lamme & Roelfsema, 2000; Tong, 2003). A successful recurrent loop might be signaled via synchronous activity between V2 and V4 neurons (Singer, 1999; Goebel, Muckli, & Kim, 2003). The strength of synchronous activity across the hierarchy would be determined by the amount of matching information that is exchanged between V2 and V4 neurons at corresponding topological regions.

Second, the implementation of a recurrent loop between surface modules in M-V2 and M-V4 (see the second part of the chapter) is also relevant for the interpretation of amodal completion. We suggest that the neural substrate of amodal completion is nothing else than the subthreshold activity related to parts of occluded surfaces that spreads within boundary and surface systems and thereby partially represents the invisible parts of the occluded surfaces. Because this “passive” spread of subthreshold activity is not driven by any physical input and because the spread within V2 can be expected to be more limited than that in V4, we suggest that there is insufficient coupling of topologically corresponding units in V2 and V4 to make the occluded surfaces “visible.” The presence of a subthreshold “trace” that amodally completes occluded shapes may, however, interact with higher levels in the visual system when high-level shape or object representations are activated. This could explain why performance in some cognitive tasks (e.g., search) can be strongly modulated by manipulations that permit or prevent amodal completion (for a review, see Davis & Driver, 2003).

LIMITATIONS AND FUTURE RESEARCH DIRECTIONS The model in its current state is sufficient to illustrate that computational modeling studies can provide important contributions to understanding the outcome of fMRI and neuronal recording experiments on the topic of perceptual filling-in and that they may help with the choice of appropriate stimuli and the invention of more sensitive experimental designs. However, an important limitation of the current model is that the connection weights in the model are fixed, and as a consequence, there is currently no modeling possible of attention or learning-induced plastic changes in connectivity. De Weerd and Pessoa (2003) have suggested that perceptual filling-in of a figure by a background may be comparable to the initial filling-in of a retinal scotoma and that it could form the beginning of a chain of plastic events leading to cortical remapping, as has been documented in visual and other sensory systems (e.g., Kaas et al., 2003). The implementation of learning rules might permit a simulation of these plastic effects.

ACKNOWLEDGMENTS We would like to thank David Janssen and Bert Jans for help in creating the network model as well as for many fruitful discussions.

31 Neural Transformation of Object Information by Ventral Pathway Visual Cortex

CHARLES E. CONNOR, ANITHA PASUPATHY, SCOTT BRINGAT, AND YUKAKO YAMANE

ABSTRACT Object perception is a critical aspect of cognition, and is essential to understanding the world we inhabit. It is also one of the brain's most remarkable computational abilities, considering the enormously complex, variable mapping between retinal images and physical objects. Retinal images are transformed into mental representations of objects by the ventral pathway of visual cortex. The vast dimensionality of the retinal image is compressed into a compact representation of object part configurations. This explicit representation of configural structure may serve as the basis for recognition, evaluation, and physical interaction with objects.

We live in a world of objects, and that world is familiar and comprehensible only because we are so good at recognizing and understanding those objects. Object perception is computationally difficult because of the high dimensionality of the retinal input (on the order of 10^6 channels) and the extreme variability in input patterns produced by any given object (depending on position, distance, orientation, lighting, etc.). The brain must transform this complex, variable retinal input into compact, stable representations of useful object information. This transformation is carried out by the ventral pathway of visual cortex (Ungerleider & Mishkin, 1982; Felleman & Van Essen, 1991), which splits off from the rest of the visual hierarchy at the connection between areas V2 and V4. Beyond V4, object information is processed through a posterior-to-anterior series of stages in inferior occipital and temporal cortex.

The first-order question about the ventral pathway transformation is how object information is encoded at each stage. This chapter describes the current understanding of object shape coding in area V4 and inferotemporal cortex (IT) based on neurophysiological studies in macaque

monkeys. The second-order and more difficult question is what computational mechanisms underlie the transformations between coding stages. Preliminary analyses of recurrent network mechanisms supporting the V4-to-IT transformation are described here.

Retinal signals must be transformed to support object vision

Two factors make the original retinal representation of objects unsuitable to support object perception. One factor is high dimensionality. The retinal representation is essentially a megapixel spatial map of local contrast that replicates the form of the optical image. A million-dimensional signal cannot be directly accessed by other brain regions to guide behavior and cannot be stored in memory. This high-dimensional pixel map must be transformed into a tractable, explicit code for useful object information. As will be described below, the ventral pathway achieves this by recoding large regions of the pixel map as object boundary fragments characterized by geometric derivatives. Entire objects are represented as spatial configurations of boundary fragments.

The other factor is variability. Any given object produces a potentially infinite range of retinal input patterns. This is due to the continually shifting relationship between the input spatial reference frame of the eye and the signal source reference frame of the object. The variable mapping between eye images and objects makes the retinal representation far too unstable for cognitive access and memory storage. As will be described below, the ventral pathway derives a more stable representation by transforming spatial information from eye coordinates into a reference frame that is at least partially defined by the object itself.

Object boundary fragments are summarized by geometric derivatives

The retinal response patterns produced by natural images are far from random. (Most random pixel patterns look like

television snow.) They are dominated by local correlations that are determined by the structure of objects in our world, which in turn reflect the constraints of physics, material properties, biological growth processes, and artifactual construction. Because of these constraints, object boundaries are relatively smooth and continuous on a local level, producing smooth, continuous contrast boundaries in the retinal image. This creates an opportunity for massive compression of the pixel map representation. The highly correlated pixel values along regions of smooth, continuous contrast can be re-described in terms of contrast boundary derivatives. For example, an image region that contains a long, vertical contrast edge comprises many pixel values but can be re-described with a single slope or orientation value. The visual system exploits this opportunity in primary visual cortex (V1) with neurons that are tuned for orientation (and spatial frequency) of local contrast regions (Hubel & Wiesel, 1959, 1965, 1968). These tuning functions provide a basis set for representing local orientation. Every point in visual space is represented by V1 neurons with a range of orientation-tuning peaks, and the local hill of activity among these neurons encodes local contrast orientation. Computational studies have demonstrated that this is an optimal scheme for compressing fragments of natural images (Olshausen & Field, 1996; Vinje & Gallant, 2000).

At successive processing stages in visual cortex, further compression is achieved by neurons with progressively larger receptive fields (RFs) that summarize larger image regions. In parafoveal V4, RFs encompass several degrees of visual angle (Gattas, Sousa, & Gross, 1988). On this larger scale, contrast boundaries more frequently undergo orientation changes within the RF and therefore can no longer be effectively summarized with a single first-order derivative. However, owing to the continuity and relative smoothness of natural objects, these larger boundary regions can be summarized with a combination of first- and second-order derivatives. Orientation often changes at a relatively constant rate that can be represented with a single second-order derivative: curvature. Convex or positive curvature (protrusion of the boundary away from the object interior) ranges from near zero (flat, infinite radius) to shallow to sharp. At the limit of sharpness, curvature becomes infinite (zero radius) and is perceived as a discontinuity in orientation (a point or angle). Concave curvature (indentation into the object interior) likewise ranges from shallow to infinite.

Visual cortex exploits this larger-scale structural regularity by explicitly representing curvature and orientation of contrast boundary fragments in area V4. Just as V1 encodes tiny boundary fragments with a basis set of orientation tuning functions, V4 encodes larger boundary fragments with a basis set of tuning functions in the curvature/orientation domain. The tuning domain has been sampled in V4 neural recording experiments with the kind of stimuli plotted in figure 31.1A

(Pasupathy & Connor, 1999). Average neural responses of three V4 neurons are plotted in figures 31.1B–31.1D. Darker backgrounds correspond to higher response rates (see gray-scale). The neurons in figures 31.1B and 31.1C exemplify tuning in the orientation/curvature domain. The figure 31.1B neuron responds to sharp convex curvature oriented (pointing) toward the left and upper left. The figure 31.1C neuron responds to shallow convex curvature oriented toward the right and lower right. Figure 31.1D exemplifies V4 neurons tuned for orientation at zero curvature, responding to all stimuli with a nearly flat component at the preferred orientation. Curvature/orientation tuning reflects a further compression of object boundary information. Larger boundary fragments that were originally represented by many component orientation signals in V1 can be summarized with a single hill of activity in the V4 curvature/orientation domain.

Objects are represented as spatial configurations of boundary fragments

The boundary fragments encoded by V4 neurons are large enough to constitute a basis set for structural or parts-based shape representation. According to structural shape-coding theories (Biederman, 1987; Marr & Nishihara, 1978; Milner, 1974; Selfridge, 1959; Sutherland, 1968), objects are represented as spatial configurations of common parts. Structural coding schemes have several advantages. First, they have a comparatively low dimensionality; an object that was originally represented by 10^4 – 10^6 pixels could be re-described as a configuration of parts numbering in the 10^1 – 10^2 range. Second, structural coding is highly generative, owing to the combinatorial explosion of part configurations, and therefore has the capacity for representing a virtual infinity of objects with a finite set of neural signals. Third, to the extent to which the spatial reference frame is defined by the object itself, structural representations can be stable across views. Fourth, explicit structural information could be used not only for recognition, but also for physical evaluation and guidance of physical interactions with objects. Structural coding also seems consistent with our linguistic tendency to describe objects as configurations of parts.

These theoretical considerations and the figure 31.1 neurophysiological result suggest that V4 instantiates a structural object representation based on boundary fragments. A critical prediction of this hypothesis is that neurons maintain parts-level selectivity across different global shape contexts. This prediction conflicts with the standard, intuitive notion that ventral pathway neurons are selective for a single range of stimulus shapes, centered on a “best stimulus” that evokes the strongest response and defines the information conveyed by that neuron. According to structural theories, the same neuron should respond strongly to an infinite variety of stimulus shapes as long as they contain the parts-level

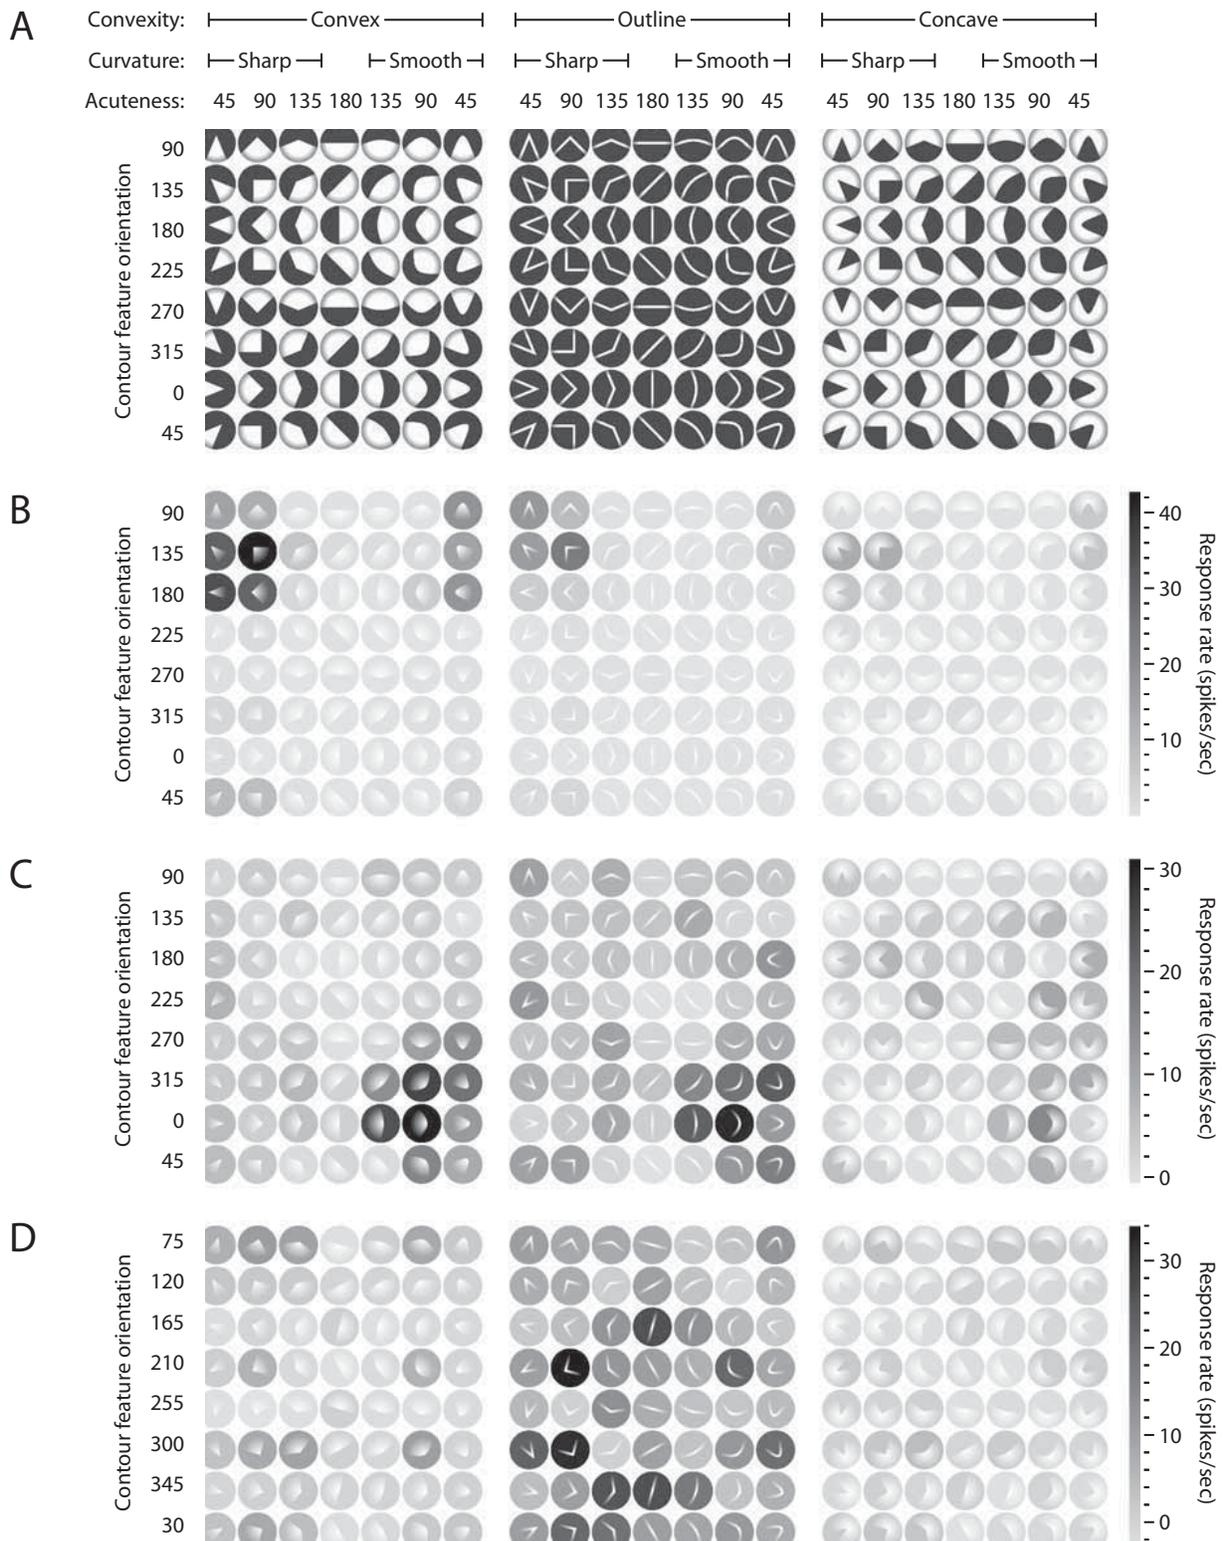

FIGURE 31.1 V4 neural tuning in the orientation/curvature domain. (A) Stimulus set comprising multiple levels of convex, outline, and concave boundary curvature at eight orientations. Spike activity of well-isolated individual neurons was recorded from lower visual field representations in V4 of rhesus macaque monkeys performing a fixation task to stabilize eye position. Stimuli were flashed in the neuron's RF for 500 ms each in random order. The stimulus was at full illumination within the RF perimeter and gradually faded to the background color outside the RF (only part of the fading is shown in these stimulus icons; the circular boundaries were not part of the stimuli). (B) Average response (across five

repetitions) of a V4 neuron to each stimulus is indicated by background color behind each stimulus (black corresponds to 40 spikes per second; see the scale bar at right). This neuron is tuned along both the curvature dimension (for sharp convexity) and the orientation dimension (around 135 degrees, which here means sharp convexities pointing toward the upper left). (C) Average responses of another V4 neuron tuned for shallow curvature oriented toward the right (0 degrees). (D) Average responses of another V4 neuron tuned for orientation and zero curvature, like most lower-level neurons. (From Pasupathy & Connor (1999). Used with permission from *Journal of Neurophysiology*.)

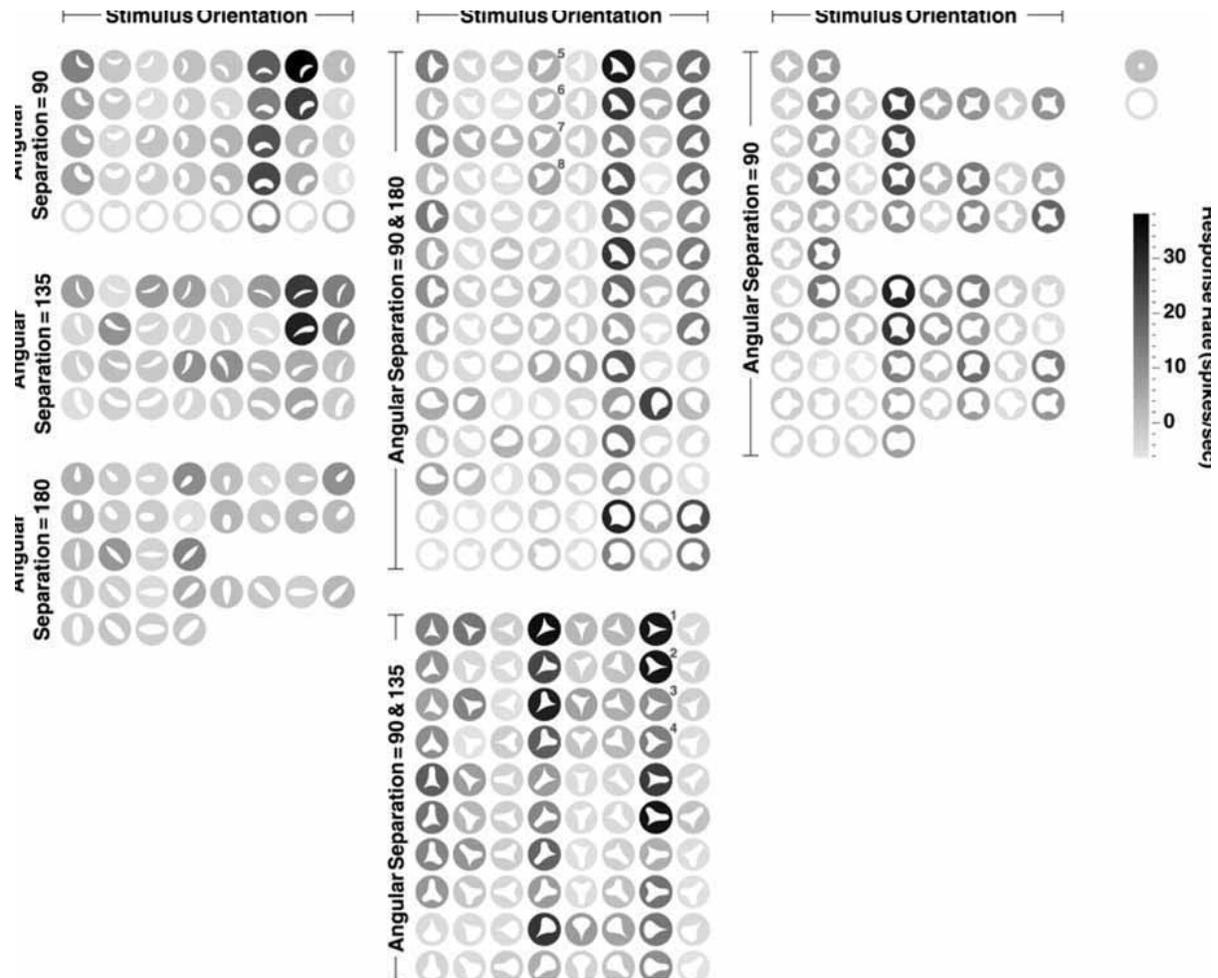

FIGURE 31.2 Responses of a V4 neuron to stimuli constructed by factorial combination of boundary fragments. Average responses across five repetitions are indicated by the background color for each stimulus. (The circular background was not part of the display.) This neuron was tuned for boundary fragments consisting of shallow

structure encoded by that neuron. This counterintuitive prediction has been confirmed in experiments exemplified by figure 31.2 (Pasupathy & Connor, 2001). For these experiments, a large set of stimuli was constructed by factorial combination of boundary fragments, so any given fragment appeared in a diverse set of global shapes. Each stimulus was presented entirely within the V4 neuron's RF, providing a strong test of consistency across global shape, since other parts of the shape could directly influence responses. This neuron responded to shapes that contained broad concave curvature facing downward adjacent to sharp convexities pointing to the lower left (see the stimuli labeled 1 and 2; either feature alone evoked weaker responses, as in stimuli 3–8). As can be seen in figure 31.2, this local structure evoked strong responses across wide variations in global stimulus shape. Thus V4 neurons encode parts-level, not global, shape. Analysis at the neural population level has demonstrated that these boundary fragment signals could

support complete structural shape representations (Pasupathy & Connor, 2002). support complete structural shape representations (Pasupathy & Connor, 2002). This tuning for local boundary structure remained consistent across wide variations in global stimulus shape. (From Pasupathy & Connor (2001). Used with permission from *Journal of Neurophysiology*.)

support complete structural shape representations (Pasupathy & Connor, 2002).

Configural coding of object structure becomes even more explicit at the next processing stage in posterior IT (PIT). Neurons in PIT are tuned for spatial configurations of multiple V4-like boundary fragments (Brincat & Connor, 2004). The stimulus responses of the figure 31.3 example neuron (figures 31.3A and 31.3B) reflect combined tuning for the boundary fragments diagrammed in the figure 31.3C tuning model. The best-fit model for this cell comprised tuning for two sharp concavities (labeled A and B) oriented toward the lower left and lower right, respectively, and positioned to the left of object center, combined with flat or shallow curvature facing to the right and positioned to the right of object center (labeled C). The model includes an inhibitory term corresponding to the concavity labeled D. Figure 31.3D illustrates how these boundary fragment sensitivities interact to determine neural responses.

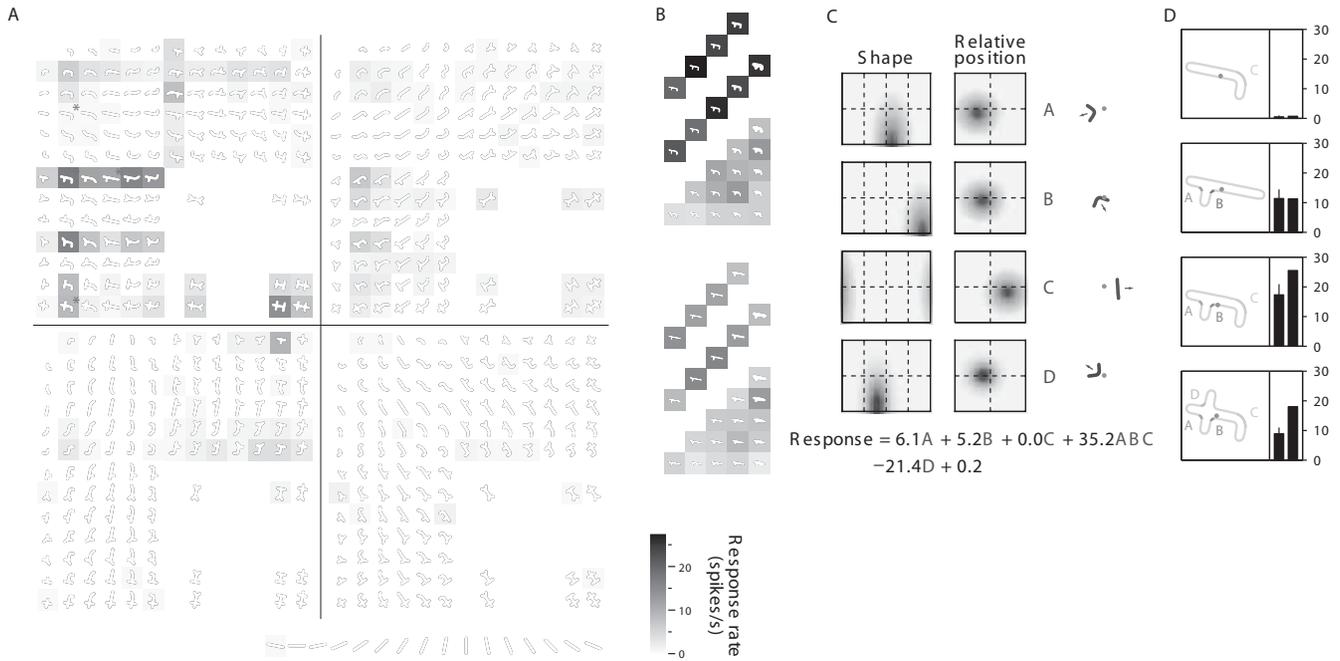

FIGURE 31.3 PIT neural tuning for boundary fragment configurations. (A) Average responses of a PIT neuron to stimuli constructed by factorial combination of boundary fragments. In this primary test, local curvature values were held constant. (B) Tuning for local curvature, tested with two representative shapes from the primary test. (C) Response model. The boundary fragment tuning dimensions for this model are orientation, curvature (mapped to a scale from -1.0 to 1.0), and XY position relative to stimulus center of mass. The best-fit model comprised three excitatory tuning regions

(A–C) and one inhibitory tuning region (D). The equation at the bottom shows that the strongest response factor was the combined presence of all three excitatory boundary fragments. (D) Example stimuli showing the interactive effects of boundary fragments near the tuning peaks. In each case, the left bar in the histogram indicates observed response \pm standard error, and the right bar indicates the response predicted by the model. (From Brincat & Connor (2004). Originally published in *Nature Neuroscience*.)

This kind of explicit single-neuron signal for configurations of disjoint parts is not envisioned in standard theories. One potential advantage of such signals is further compression of the object representation into a smaller number of more complex components. This would be particularly efficient if PIT neurons emphasize statistically common part configurations. At this scale, encompassing complete shapes, there is no simple geometric constraint on boundary structure, but common part configurations are bound to occur, owing to ecological factors. While this has not been investigated rigorously, it can be observed at an anecdotal level. The responses of the same example neuron to photographic stimuli (figure 31.4) illustrate how tuning for boundary fragment configurations might relate to common shape structures in natural object categories. In this case, the neuron responded to a leftward-facing quadruped (the polar bear), presumably owing to its combined sensitivity to opposed concavities on the left and broad curvature on the right. This is not to say that the neuron by itself signals the presence of quadrupeds. Rather, this neuron efficiently captures a common shape motif that would help to define quadrupeds as well as other object categories that have the same component structure. Other studies in more anterior parts of inferotemporal cortex suggest that responses to

natural objects could be explainable in terms of structural components (Fujita, Tanaka, Ito, & Cheng, 1992; Perrett, Rolls, & Caan, 1982; Sigala & Logothetis, 2002; Tanaka, Saito, Fukada, & Moriya, 1991; Tsunoda, Yamane, Nishizaki, & Tanifuji, 2001; Wang, Fujita, & Murayama, 2000).

Single-neuron configuration signals might also enhance the cognitive accessibility of configural structure, supporting our ability to evaluate the physical potential of objects and interact with them in an accurate and intelligent manner. Finally, configural shape signals might also provide a basis for further integration, leading to global shape sensitivity at higher processing stages. This might be especially true for highly familiar or behaviorally relevant object categories that require maximally efficient processing, at the cost of dedicated neurons with extremely narrow selectivity. For generic object representation, representation in terms of component part configurations could be the optimal compromise between flexibility and efficiency.

One critical result from these PIT studies is the demonstration of spatial tuning in an object-centered reference frame. This is a central prediction of structural shape-coding theories (Biederman, 1987; Marr & Nishihara, 1978). Transformation from retinotopic to object-centered coordinates

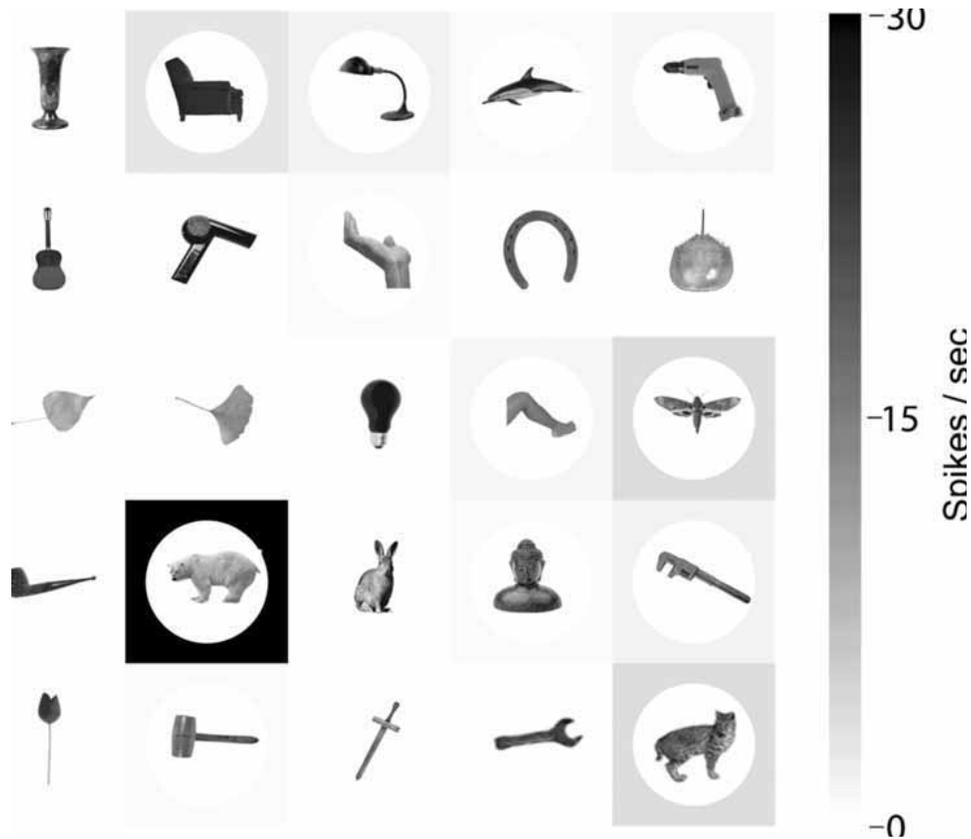

FIGURE 31.4 Responses of the same PIT neuron as in figure 31.3 to photographic stimuli. In each case, the average response to the photograph is indicated by the color of the background square (see scale bar at right).

achieves stability across changes in object position on the retina. Relative position signals in an object-centered reference frame provide the configural information that is required to distinguish different arrangements of the same parts. PIT neurons exhibit clear tuning for boundary fragment position with respect to object center. This is emphasized for the example neuron in figure 31.5, by showing the average response to stimuli containing the double-concavity configuration to the left of object center (top, strong responses) versus to the right (bottom, minimal responses). Figure 31.3A includes many stimuli with the same configuration in other object-centered positions (e.g., top or bottom) that likewise evoke little or no response. Control experiments (not shown) demonstrate that this tuning is consistent across retinotopic positions (within the PIT RF), so spatial tuning is much more acute in object-centered coordinates than in retinotopic coordinates.

Thus PIT neurons provide the kind of relative position information critical for parts-based structural coding. In addition to being centered on the object, the PIT reference frame probably scales with object size, given that PIT tuning functions (and tuning functions at higher stages in the ventral pathway; Ito, Tamura, Fujita, & Tanaka, 1995) exhibit remarkable consistency across size changes spanning multi-

ple octaves. However, the spatial reference frame does not appear to rotate with the object, since shape tuning is not consistent across rotated versions of the same stimulus. This is exemplified in figure 31.3A, in which substantially rotated versions of the high-response shapes evoke no response whatsoever. Thus the theoretical prediction of a stable reference frame completely defined by the object is only partially confirmed at this level in the ventral pathway. Generalization across object rotation could be achieved in some other way, possibly by learning associations between different object views (Vetter, Hurlbert, & Poggio, 1995; Edelman & Poggio, 1991).

Three-dimensional object shape is represented in terms of surface fragments

The results described above relate to two-dimensional object boundary shape. Objects produce two-dimensional contrast boundaries in the retinal image; therefore it would be reasonable if two-dimensional boundary representation were the primary mode for object vision. In physical reality, however, objects are three-dimensional, and classical theories (Biederman, 1987; Marr & Nishihara, 1978) posit explicit representation of three-dimensional

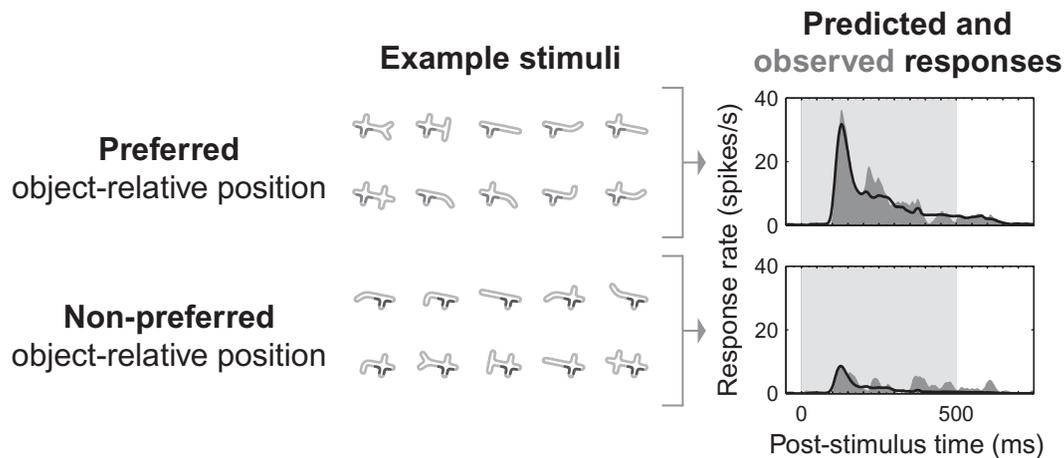

FIGURE 31.5 PIT tuning for object-centered position. Average responses of the same example neuron to two subsets of the stimuli in figure 31.3. In the top row, the opposed concavity configuration is positioned to the left of object center, and the average response

is high, as shown by the peristimulus-time response histogram at the right. In the bottom row, the double concavity configuration is positioned to the right of object center, and the average response is low.

object structure, based on three-dimensional spatial configurations of three-dimensional parts. This is a particularly strong prediction, given the computational difficulty of extracting three-dimensional structure from two-dimensional retinal images and the higher-dimensional neural coding that is required to represent three-dimensional structure. In contrast, current computational vision models favor direct processing of two-dimensional images with no explicit representation of three-dimensional object structure (Fei-Fei, Fergus, & Perona, 2006; Lowe, 2004; Moghaddam & Pentland, 1997; Murase & Nayar, 1995; Riesenhuber & Poggio, 1999; Turk & Pentland, 1991; Weber, Welling, & Perona, 2000).

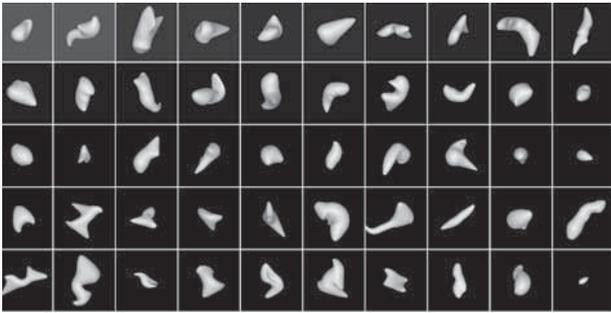

The three-dimensional structural coding hypothesis has not been directly tested, owing to the experimental difficulty of exploring the virtually infinite domain of three-dimensional object shape. In a recent attempt to overcome this obstacle, Yamane and colleagues (2008) used an evolutionary morphing strategy to sample three-dimensional object shape (figure 31.6). Neurons in central and anterior IT (CIT/AIT) were studied by first measuring their responses to an initial generation of 50 random three-dimensional shapes (figure 31.6, generation 1). The second stimulus generation included partially morphed descendants of higher-response stimuli from the first generation. This process was iterated across 8–10 generations, producing extensive sampling of stimuli in the high- and intermediate-response range of the cell. High-response stimuli were typically characterized by some shared local shape structure. In this case, the most noticeable shared structure is a ridge near the front of the shape facing out of the image plane.

When sampling was sufficiently complete, the response pattern could be used to constrain a quantitative model of

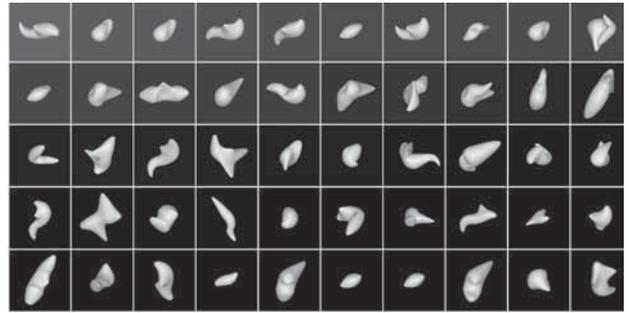

the three-dimensional shape information encoded by the neuron. The best-fit model for this cell (figure 31.7) captured both the forward-facing ridge near the front of the object and the shallow concave dorsal surface behind it that characterized high-response stimuli. The response model was highly nonlinear; predicted (and observed) responses were substantial only for stimuli with both surface fragments. The result shown here typifies three-dimensional shape tuning observed for a substantial fraction of CIT/AIT cells. These neurons were tuned for three-dimensional spatial configurations of multiple surface fragments defined by their surface curvatures and three-dimensional orientations. These observations support the classic hypothesis that three-dimensional shapes are represented as structural configurations of three-dimensional parts.

In contrast to these findings regarding biological object vision, recent computational systems for object recognition have been most successful with nonstructural processing of two-dimensional image information (Fei-Fei et al., 2006; Lowe, 2004; Moghaddam & Pentland, 1997; Murase & Nayar, 1995; Riesenhuber & Poggio, 1999; Turk & Pentland, 1991; Weber et al., 2000). This makes sense, given the computational expense of inferring and encoding three-dimensional structure. It may be that even in the brain, rapid object recognition depends on two-dimensional processing (Hung, Kreiman, Poggio, & DiCarlo, 2005; Serre, Oliva, & Poggio, 2007) and neural coding of three-dimensional structure instead supports other aspects of object vision requiring detailed structural knowledge. Comparing similar objects within a recognized class, evaluating the functionality and utility of unfamiliar objects, anticipating physical events, and guiding physical interactions with objects are all likely to require detailed knowledge of three-dimensional structure.

FIGURE 31.6 An evolutionary three-dimensional shape-morphing experiment. The first stimulus generation was created by randomly perturbing control points defining a topologically spherical spline mesh. Stimuli were rendered in three dimensions with shading cues (visible here) and corresponding stereoscopic (binocular disparity) cues. Stimuli were flashed at the center of gaze, and responses were recorded from a single neuron in AIT of a monkey performing a fixation task. For each stimulus, the background gray level denotes

the neuron's average response (see the scale bar, lower right). Subsequent stimulus generations included partially morphed descendants of stimuli from previous generations. Ancestor stimuli were drawn in equal proportions from higher, intermediate, and lower response-level ranges. The end result was extensive sampling around the peak, shoulders, and boundaries of the neuron's shape-tuning range. (From Yamane et al. (2008). Originally published in *Nature Neuroscience*.)

Boundary fragment configurations are derived by recurrent network processing

The results described above suggest that the ventral pathway encodes objects as spatial configurations of boundary fragments. If so, this begs the more difficult question of how such configural information is derived. A direct answer to this question would require comprehensive measurement of neural network activity across multiple processing stages, which is not currently possible. But one indirect approach to inferring underlying network mechanisms is fine-scale temporal analysis of neural responses. If shape information is derived by time-consuming network processes, the evolution of that information across time (following stimulus onset) may be observable in the neural responses. As will be detailed below, the evolution of configural shape signals in PIT is observable in this way.

The figure 31.3 PIT neuron exemplifies supralinear integration of information across boundary fragments. As the equation in figure 31.3C reflects, responses produced by individual fragments were low (factors A, B, and C have coefficients below 7 spikes per second), while responses to fragment combinations were high (factor ABC has a large coefficient of 35 spikes per second). This nonlinear

integration provides a selective, explicit signal for the overall configuration. In contrast, more linear summation of fragment information produces ambiguous signals associated with many different fragments or fragment combinations.

Fine-scale temporal analysis shows that PIT responses initially reflect linear summation, with nonlinear information emerging more gradually (Brincat & Connor, 2006). In many cases, this is observable in the responses of individual neurons. The PIT neuron represented in figure 31.8 was sensitive to concave boundary fragments oriented toward the upper left (135 degrees) and concave fragments oriented toward the lower right (315 degrees). The average temporal response profiles (solid gray histograms) for stimuli containing only the 315-degree concavity (top row) or only the 135-degree concavity (middle row) are phasic, confined to a window between 100 and 200 ms following stimulus onset. The response profile for stimuli containing both of these fragments (bottom row) includes an initial phasic spike in the 100- to 200-ms window that closely approximates the sum of the individual fragment responses (represented by the dark gray curve, which shows the predicted linear sum based on a temporal response model). For these stimuli, however, the response persists throughout the entire 500-ms stimulus

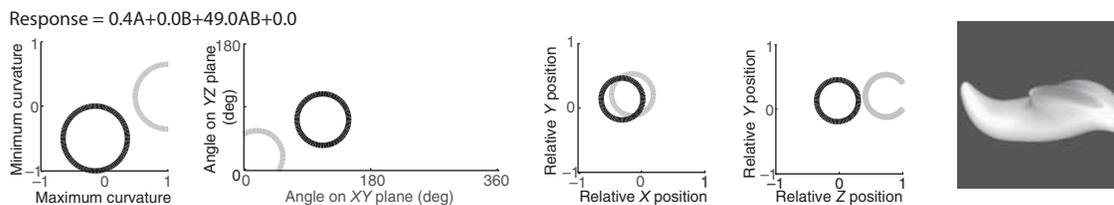

FIGURE 31.7 AIT neural tuning for three-dimensional surface fragment configuration. Each stimulus was defined in terms of its constituent surface fragments. Surface fragments were characterized in terms of their XYZ position relative to object center, three-dimensional orientation, and three-dimensional surface curvature (maximum and minimum cross-sectional curvature). Response patterns were fit with multiple Gaussian tuning functions in the position/orientation/curvature domain. The best-fit model for this cell was based on two Gaussian tuning regions (black and gray circles, describing 1.0 standard deviation boundaries). The gray tuning region defines surface fragments with sharp convex maximum curvature (near 1) and flat minimum curvature (near 0), that is, a ridge.

The surface normal orientation points toward the viewer (near 0 on the YZ -plane). The position is toward the front of the object (near 1 on the Z -axis). The surface region on a high response stimulus (at right) corresponding to this Gaussian function is tinted gray. The other Gaussian tuning region (black) defines shallow concave surfaces with normals pointing upward (near 90 degrees on the XY - and YZ -planes) positioned near object center. The response equation at the top indicates low responses to stimuli with only one surface fragment or the other (A or B) but high responses for the combination (AB). (From Yamane et al. (2008). Originally published in *Nature Neuroscience*.)

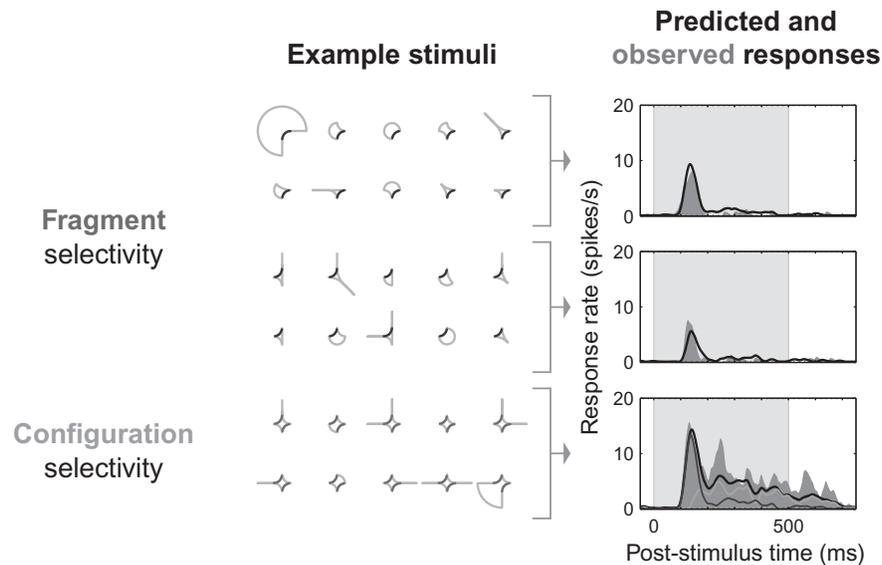

FIGURE 31.8 Time course of linear and nonlinear boundary fragment responses for a PIT neuron. *Top row*, Average response to stimuli containing a concavity oriented toward 315 degrees. The time course of observed response (gray histogram) and response predicted by a temporal model (black curve) are shown. The gray box indicates the stimulus presentation period. *Middle row*, Average response to stimuli containing a concavity oriented toward 135

degrees. *Bottom row*, Average response to stimuli containing both concavities. The total predicted response (black curve), predicted linear response due to individual fragment terms (dark gray curve), and predicted nonlinear response due to the fragment combination term (light gray curve) are shown. (Adapted from *Neuron* (Brincat & Connor, 2006) with permission from Elsevier.)

presentation. Thus beyond 200 ms following stimulus onset, this neuron exhibits highly nonlinear integration and conveys an explicit signal for the necklike configuration of two opposed concavities.

This example reflects a general trend in PIT for linear boundary fragment responses to evolve more quickly, peaking around 120 ms after stimulus onset (figure 31.9A; the black curve summarizes linear response strength across a sample of 89 PIT neurons). In contrast, nonlinear response strength evolved more gradually, peaking 180 ms after onset (figure 31.9A, gray curve). These trends were partly due to single-neuron tuning transitions as in figure 31.8 (figure 31.9B, thin curves) and partly due to differential response profiles of consistently linear neurons (figure 31.9B, thick black curve) versus consistently nonlinear neurons (figure 31.9B, thick gray curve). This overall pattern is consistent with a fairly simple neural network model in which neurons vary in the relative strength of V4-like boundary fragment inputs and recurrent inputs (recurrent excitatory inputs from cells with similar configuration tuning, recurrent inhibitory inputs from cells with dissimilar tuning) (Brincat & Connor, 2006; Salinas & Abbott, 1996). Neurons with stronger V4 inputs respond quickly and in a more linear fashion, while neurons with stronger recurrent connectivity respond more slowly and in a more nonlinear fashion. The 60-ms delay for part configuration signals in PIT is consistent with a remarkably similar delay for pattern motion signals in area MT (Movshon, Adelson, Gizzi, &

Newsome, 1985; Rodman & Albright, 1989; Pack, Berezovskii, & Born, 2001; Smith, Majaj, & Movshon, 2005). In both cases, it could be that some kind of recurrent network processing is required to generate unambiguous signals based on integration across multiple stimulus components. There are, however, alternative interpretations that cannot be ruled out at this point. For example, selectivity for combined inputs might be produced by a static threshold nonlinearity and could be temporarily masked by transient onset responses.

Summary: Configural representation of object structure

The findings reviewed above suggest at least a partial explanation of how the ventral visual pathway achieves compact, stable representation of useful object information. In area V4, object boundary fragments are summarized in terms of their first- and second-order derivatives (orientation and curvature), greatly reducing the dimensionality of the retinal response pattern. At the next processing stage in PIT, configurations of multiple fragments are represented (further reducing dimensionality) in an object-centered reference frame (producing stability across changes in retinal position). Recent results in more anterior regions of inferotemporal cortex suggest that this configural coding scheme generalizes to three-dimensional shape representation in terms of object surface fragments. Considering the processing time that is required to perfect these configural representations (on the

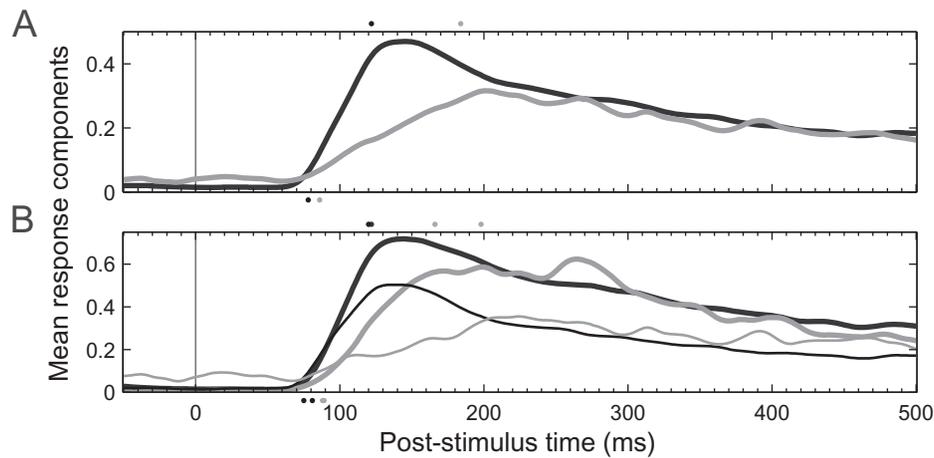

FIGURE 31.9 The average time course of linear and nonlinear response components in PIT. (B) The same linear and nonlinear response strength averages are partitioned

order of 200 ms), they might not explain the most rapid human recognition speeds (Thorpe, Fize, & Marlot, 1996). However, these rapid reaction times could be limited to coarse categorization (Rousselet, Mace, & Fabre-Thorpe, 2003), based on nonconfigural parts-level information available after about 100 ms (figure 31.9A, black curve). Finer discrimination based on larger-scale shape configurations rather than diagnostic parts requires longer processing times (Arguin & Saumier, 2000; Wolfe & Bennett, 1997; Ringach & Shapley, 1996), consistent with the delayed emergence of explicit configural signals (figure 31.9A, gray curve). Aside from recognition and discrimination, configural representations could support other important aspects of object vision, including cognitive evaluation of object structure and function as well as guidance of precise physical interactions with complex objects.

32 The Cognitive and Neural Development of Face Recognition in Humans

ELINOR MCKONE, KATE CROOKES, AND NANCY KANWISHER

ABSTRACT Conventional wisdom has long held that face recognition develops very slowly throughout infancy, childhood, and adolescence, with perceptual experience as the primary engine of this development. However, striking new findings from just the last few years have overturned much of this traditional view by demonstrating genetic influences on the face recognition system as well as impressive face discrimination abilities that are present in newborns and in monkeys that were reared without ever seeing a face. Nevertheless, experience does play a role, for example, in narrowing the range of facial subtypes for which discrimination is possible and perhaps in increasing discrimination abilities within that range. Here we first describe the cognitive and neural characteristics of the adult system for face recognition, and then we chart the development of this system over infancy and childhood. This review identifies a fascinating new puzzle to be targeted in future research: All qualitative aspects of adult face recognition measured behaviorally are present very early in development (by 4 years of age; all that have been tested are also present in infancy), yet functional magnetic resonance imaging and event-related potential evidence shows very late maturity of face-selective neural responses (with the fusiform face area increasing substantially in volume between age 7 years and adulthood).

Introduction

One of the most impressive skills of the human visual system is our ability to identify a specific individual from a brief glance at their face, thus distinguishing that individual from hundreds of other people we know, despite the wide variations in the appearance of each face as it changes in viewpoint, lighting, emotional expression, and hairstyle. Though many mysteries remain, important insights have been gleaned over the last two decades about the cognitive and neural mechanisms that enable humans to recognize faces. Here, we address an even more difficult and fundamental question: How does the machinery of face

recognition get wired up during development in the first place?

Our review of the available evidence supports a view of the development of face recognition that is dramatically different from the one suggested by the first studies in the field. Twenty years ago, the standard theory was that core aspects of the ability to discriminate faces were not present until 10 years of age, and their emergence and eventual maturity were determined primarily by experience (Carey & Diamond, 1977; Carey, Diamond, & Woods, 1980). This position has been overturned by recent findings that demonstrate striking abilities even in neonates and by mounting evidence of genetic contributions.

We organize our review by age group. Throughout, we ask how the available data address the following fundamental theoretical questions:

1. What are the inherited genetic contributions to the specification of the adult system for processing facial identity information?
2. What is derived from experience?
3. How exactly do genes and/or experience work separately or together across the course of development to produce the adult system?

The perception of face identity in adulthood

We begin with a characterization of the end state of development: the cognitive and neural basis of the perception of facial identity in adults. Note that this is a major topic in its own right, with much internal theoretical debate. However, to facilitate our present interest in the *developmental* course of face recognition, we focus on empirical phenomena, especially those that are well established in adults and have subsequently been tested in development.

CORE BEHAVIORAL PROPERTIES OF FACE IDENTITY PERCEPTION IN ADULT HUMANS Basic properties of face identification in adults are as follows. Identification is more accurate when faces are upright than when they are inverted (i.e., upside

ELINOR MCKONE and KATE CROOKES Department of Psychology, Australian National University, Canberra, Australia
NANCY KANWISHER McGovern Institute for Brain Research and Department of Brain and Cognitive Science, Massachusetts Institute of Technology, Cambridge, Massachusetts

down) on both memory and perceptual tasks, and the inversion decrement is substantially larger for faces than for nonface objects (the *disproportionate inversion effect*; Yin, 1969; see also Robbins & McKone, 2007). Generalization from a single image of a novel face in one viewpoint to an image in another is relatively poor, albeit better from the three-quarter view to front or profile views than between the more distinct profile and front views (the *three-quarter view advantage*; Logie, Baddeley, & Woodhead, 1987). For familiar faces, performance on memory tasks relies more strongly on inner face regions than on external regions that include hair; for unfamiliar faces, the pattern is reversed (*inner versus outer features effects*; Ellis, Sheperd, & Davies, 1979). Finally, identification of own-race faces is better than identification of other-race faces (the *other-race effect*; Meissner & Brigham, 2001). Note that the first two properties (i.e., the disproportionate inversion effect and the three-quarter view advantage) derive directly from perceptual processing, but the last two are known to derive at least partly from deliberate task strategies (e.g., reliance on hair for novel faces if distinctive hair is present; Duchaine & Weidenfeld, 2003) or social and attentional factors (other-race effect; Bernstein, Young, & Hugenberg, 2007).

Additional experimental findings can be grouped under the heading of phenomena that have motivated the concept of *holistic/configural* processing. Holistic/configural processing is defined (e.g., Tanaka & Farah, 1993; Maurer, Lewis, & Mondloch, 2005) as (1) a strong integration at the perceptual level of information from all regions of the face (so that altering one region leads to changes in the percept of other regions), which (2) codes the exact spacing between face features (and, more controversially, exact feature shape as well; Yovel & Duchaine, 2006), and (3) is strongly sensitive to face inversion. Relevant phenomena are as follows. Subjects find it harder to identify one half of a combination face (e.g., the top half of George Bush's face with the bottom half of Tony Blair's face) if the inconsistent other half-face is aligned with the target half rather than misaligned (the *composite effect*; Young, Hellawell, & Hay, 1987). Subjects are also better able to distinguish which of two face parts (e.g., two noses) appeared in a previously shown face when these are presented in the context of the whole face than when they are presented in isolation (the *part-whole effect*; Tanaka & Farah, 1993). Part choice is also better in the original whole than in a version of the whole face with an alteration in spacing between nontarget features (the *part-in-spacing-altered-whole effect*; Tanaka & Sengco, 1997), a finding that is consistent with other evidence of strong *sensitivity to spacing changes* (e.g., distance between eyes) in upright faces (e.g., Rhodes, Brake, & Atkinson, 1993; McKone, Aitkin, & Edwards, 2005). When an upright and an inverted version of a face are superimposed in transparency, the upright face is perceived more strongly (*perceptual bias to upright*; Martini,

McKone, & Nakayama, 2006). All these holistic effects are specific to upright faces; they are not found for inverted or scrambled faces (Young et al., 1987; Tanaka & Sengco, 1997; Robbins & McKone, 2003; Martini et al., 2006) and are weak or absent for objects, including objects of expertise (for reviews, see McKone, Kanwisher, & Duchaine, 2007; Robbins & McKone, 2007).

Finally, other behavioral phenomena have been taken to indicate coding within a perceptual "face-space," defined as a multidimensional space in which each individual face is coded as a point by its value on underlying dimensions describing different aspects of facial structure and for which the "average" face lies at the center of the space (Valentine, 1991). These phenomena include *distinctiveness effects*, in which performance is better for distinctive faces than for typical faces on old-new recognition tasks but the pattern is reversed on face versus nonface classification tasks (Valentine & Bruce, 1986), and *adaptation aftereffects*, in which, for example, adaptation to expanded faces make a physically normal face appear contracted (Webster & MacLin, 1999) and adaptation to "anti-Bill" (the physical opposite of Bill in face space) makes the average face appear like Bill (Leopold, O'Toole, Vetter, & Blanz, 2001).

NEUROPHYSIOLOGY AND FUNCTIONAL MAGNETIC RESONANCE IMAGING IN ADULT MONKEYS Adult monkeys show cortical mechanisms specialized for face perception. Strongly face-selective responses from single neurons ("face cells") are well established in the temporal lobes of macaques (Desimone, Albright, Gross, & Bruce, 1984; Foldiak, Xiao, Keyser, Edwards, & Perrett, 2004), and face-selective cortical regions have been reported in macaques using functional magnetic resonance imaging (fMRI) (Tsao, Freiwald, Knutsen, Mandeville, & Tootell, 2003; Pinsk, DeSimone, Moore, Gross, & Kastner, 2005). Tsao, Freiwald, Tootell, and Livingstone (2006) demonstrated direct correspondence between face-selective fMRI patches and face selectivity of single cells within those patches. Note that the role of "face cells" in supporting the behavioral phenomena described in the previous section is mostly unexplored, with the exceptions that a preponderance of face-selective cells are tuned to upright (Perrett et al., 1988) and that their tuning to facial distortions from the "average face" is consistent with a face space coding of facial identity (Leopold, Bondar, & Giese, 2006). In development, only basic face selectivity has been studied.

FUNCTIONAL MAGNETIC RESONANCE IMAGING: CORTICAL LOCI OF FACE IDENTITY PROCESSING IN ADULT HUMANS Brain imaging in humans reveals three face-selective cortical regions (figure 32.1), of which the fusiform face area (FFA) (Kanwisher, McDermott, & Chun, 1997), is the main one that is investigated in children. This region, which can be

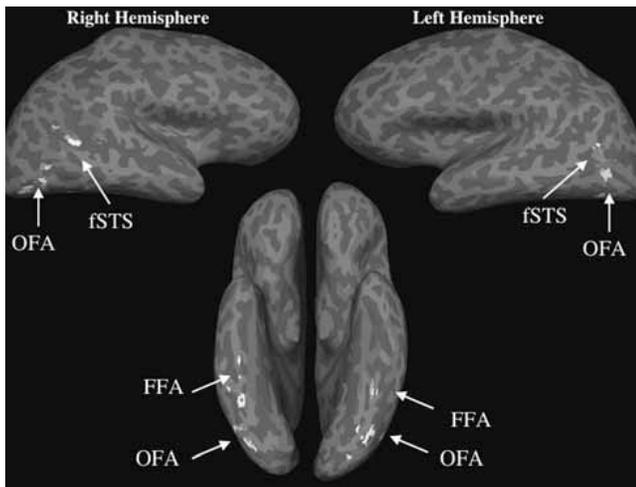

FIGURE 32.1 Face-selective activation (faces > objects, $p < 0.0001$) on an inflated brain of one adult subject, shown from lateral and ventral views of the right and left hemispheres. Three face-selective regions are shown: the FFA in the fusiform gyrus along the ventral part of the brain, the OFA in the lateral occipital area, and the fSTS in the posterior region of the superior temporal sulcus. For studies of face identification (rather than expression, etc.), the FFA and OFA are of greatest interest. (See color plate 46.)

found in essentially every normal adult in a short “localizer” scan (Saxe, Brett, & Kanwisher, 2006), responds more strongly to faces than to letter strings and textures (Puce, Allison, Asgari, Gore, & McCarthy, 1996), flowers (McCarthy, Luby, Gore, & Goldman-Rakic, 1997), and indeed all other nonface stimuli that have been tested to date, including mixed everyday objects, houses, hands (Kanwisher et al., 1997), and objects of expertise (Kanwisher & Yovel, in press).

fMRI adaptation studies show that neural populations in the FFA can discriminate face identity (Rotshtein, Henson, Treves, Driver, & Dolan, 2005) but not facial expression (Winston, Vuilleumier, & Dolan, 2003). The FFA is involved in individual discrimination of upright but not inverted faces (Yovel & Kanwisher, 2005; Mazard, Schiltz, & Rossion, 2006), and its inversion effect (i.e., higher response to upright than inverted faces) correlates with the behavioral inversion effect (Yovel & Kanwisher, 2005). The FFA also demonstrates holistic processing, specifically a composite effect (Schiltz & Rossion, 2006).

ELECTROPHYSIOLOGICAL SIGNATURES IN HUMAN ADULTS A negative-going event-related potential (ERP) response peaking about 170 ms after stimulus onset over posterior temporal sites (N170) has been widely replicated to be face-selective (Halgren, Raij, Marinkovic, Jousmaki, & Hari, 2000; Liu, Harris, & Kanwisher, 2002). This peak is delayed by 10 ms, and is larger in amplitude for inverted faces than for upright faces (Bentin, Allison, Puce, Perez, & McCarthy, 1996). The N170 also shows identity discrimination (a lower

response for repeated compared to unrepeated faces) when the faces are upright but not inverted (Jacques & Rossion, 2006; Jacques, D’arripe, & Rossion, 2007). An important point that is relevant to the interpretation of developmental studies is that the neural source of the N170 is unknown even in adults, and the sources of suggested equivalent components in children and infants could possibly be different still.

Data from adult subjects relevant to the roles of experience and genetics

Before considering what developmental studies tell us about the roles of experience and genetics in face recognition, we describe several findings from adults that also bear directly upon these issues.

Clearly, *experience in isolation* can influence face perception. Adults continue to learn new faces throughout life, and this improves perceptual discrimination of these faces: Matching the correct face photograph to a degraded security camera video image is more accurate if the face is familiar than if it is unfamiliar (Burton, Wilson, Cowan, & Bruce, 1999; also see Bruce, Henderson, Newson & Burton, 2001). Temporary aftereffects from adaptation to distorted faces (e.g., Webster & MacLin, 1999) also indicate purely experience-based changes in the tuning of perceptual representations of faces. Training effects on the ability to discriminate trained and novel faces have also been demonstrated in an adult prosopagnosic (DeGutis, Bentin, Robertson, & D’Esposito, 2007). Interestingly, however, there is no evidence that experience alone produces any fundamental *qualitative* change in face processing either neurally or cognitively; for example, holistic processing, “face space” effects, and FFA activation all occur strongly for both familiar faces and unfamiliar faces (Young et al., 1987; Kanwisher et al., 1997; Webster & MacLin, 1999; Le Grand, Mondloch, Maurer, & Brent, 2004; Carbon et al., 2007).

Studies of human adults provide two sources of evidence for genetic contributions. Inability to recognize faces in the absence of any known brain injury (developmental prosopagnosia) often runs in families (Duchaine, Germine, & Nakayama, 2007; Grueter et al., 2007; Kennerknecht, Pluempe, & Welling, 2008). Also, in normal adults, fMRI shows greater similarity in the pattern of activation across the ventral visual stream for monozygotic compared to dizygotic twins, but only for stimulus classes for which an evolutionary origin of the observed selective cortical regions could reasonably be proposed: faces and places but not written words or chairs (Polk, Park, Smith, & Park, 2007).

In summary, results from adults tell us that experience can fine-tune face recognition without changing its qualitative properties and that genes explain some of the variation behaviorally and neurally. Importantly, adult studies do not tell us at what developmental stage genes have their

influence. In particular, they do not necessarily demonstrate that a face system is present at birth. Some genetically predetermined processes are present at birth (e.g., the sucking reflex), but others affect maturational processes later in childhood or adolescence (e.g., puberty).

Development: Infancy

In exploring genetic and experience-based contributions to face recognition via infancy studies, several interrelated questions are relevant. First, which abilities, if any, are present at birth? Visual abilities that are present in neonates (or in monkeys that have been deprived of all face input) cannot be derived from experience and therefore provide the only method of revealing genetic influences in isolation from any visual learning. Second, if babies are born with a face representation, is its purpose merely to draw attention to faces (cf. CONSPEC in Morton & Johnson, 1991) or to support individuation? Third, how broadly tuned is any such representation: broad enough to cover any primate face, specific to own-species faces, or perhaps even to own-race faces? Finally, which, if any, of the types of effects of experience in early infancy that are found in other perceptual and cognitive domains occur for faces: Improvements with increasing experience? Perceptual narrowing (i.e., destruction of earlier ability)? Critical periods? Studies of these topics published within the last few years have dramatically altered our understanding of infant face recognition.

In a classic result, newborns (median age: 9 minutes) track an upright “paddle face” (figure 32.2*A*) further than versions in which the position of the internal blobs is scrambled or inverted (Goren, Sarty, & Wu, 1975; Johnson, Dziurawiec, Ellis, & Morton, 1991). Although it has been suggested that this preference could arise from general visual biases (e.g., for stimuli with more elements in the upper visual field; Simion, Macchi Cassia, Turati, & Valenza, 2003), preference only for the normal contrast polarity of a (Caucasian) face (Farroni et al., 2005) argues for a level of specificity to facelike structure. Thus humans are born with some type of innate preference that, at the very least, attracts infants’ attention to faces. Note that the innate representation supporting face preference could be different from that supporting face individuation in adults (Johnson, 2005); indeed, a finding that neonates track faces in the temporal but not nasal visual field (Simion, Valenza, Umlita, & Dalla Barba, 1998) suggests a subcortical rather than cortical origin.

Our concern in this chapter is primarily with the development of face individuation ability. This can be measured in infants by looking time measures that assess preference and dishabituation-to-perceived-novelty. A classic finding is that neonates less than 4 days old can discriminate their mother from similar-looking women (Pascalis, de Schonen, Morton, Deruelle, & Fabre-Grenet, 1995; Bushnell, 2001), although

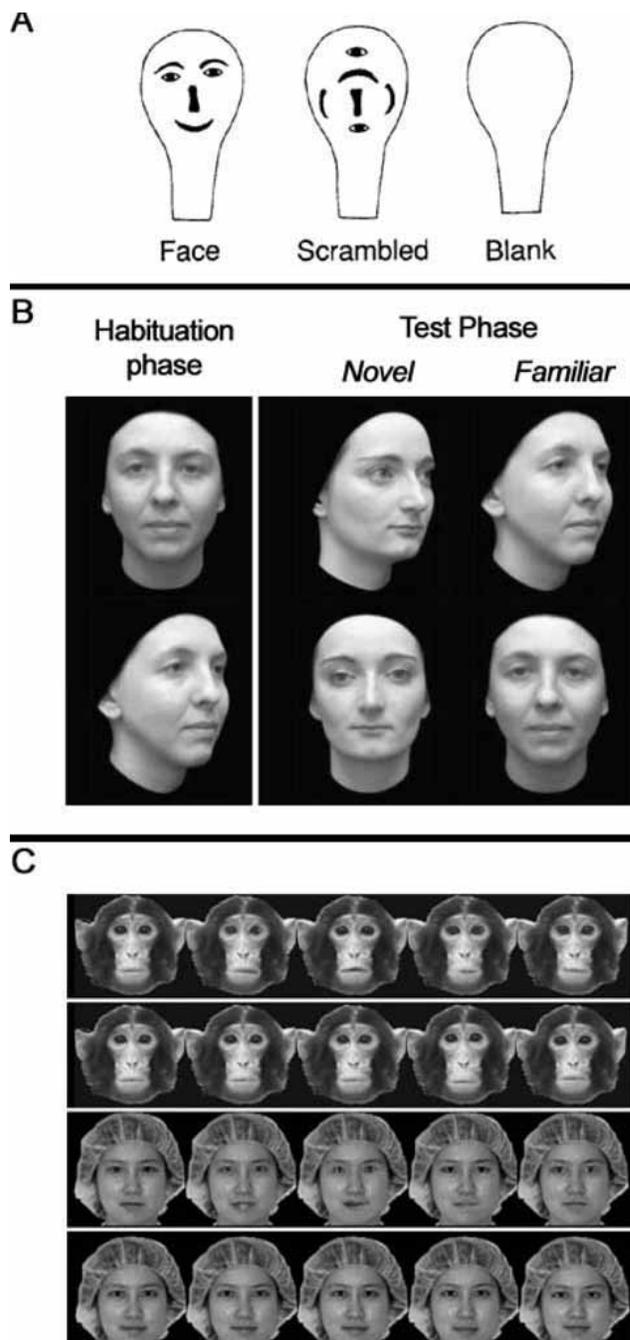

FIGURE 32.2 Face perception without experience. (*A*) Newborn humans (<1 hour old) track the “paddle face” on the left further than the scrambled version (Morton & Johnson, 1991). (*B*) Newborn humans (<3 days) look longer at the novel than habituated face, indicating recognition of face identity even across view change (Turati et al., 2008). (*C*) Japanese macaques raised with no exposure to faces can, on first testing, discriminate very subtle differences between individual monkey faces (including differences both in shape and in spacing of internal features) and can also do this for human faces (Sugita, 2008).

mother recognition in the first 24 hours may be partially dependent on prenatal familiarity with her voice (Sai, 2005). More recent data demonstrate even more striking abilities. Three-month-olds can recognize the identity of *novel* individuals, with *similar-looking* faces (same sex, age, race), *without hair*, and *across view changes* (Pascalis, De Haan, Nelson, & de Schonen, 1998; Kelly et al., 2007). Indeed, it has very recently been discovered that newborns (<3 days) can perform this task (Turati, Bulf, & Simion, 2008; see figure 32.2B). Moreover, the newborns discriminated only front to three-quarter view changes and not three-quarter to profile, in a pattern somewhat (although not precisely) similar to the three-quarter view advantage that is seen in adults. Finally, newborns demonstrate an inversion effect on discrimination, with babies 1–3 days old discriminating same-view faces without hair upright but not inverted (Turati, Macchi Cassia, Simion, & Leo, 2006).

The newborn discrimination findings strongly suggest that a face representation, tuned to upright and able to support individual-level representation, is present at birth. It seems unlikely that 3 “days” of experience with faces—in fact, a maximum of perhaps 12 hours of visual experience of any kind (newborns sleep 16 hours per day and have their eyes shut during breastfeeding and crying)—would be sufficient for a purely learning-based system to support the level of fine discrimination ability that is observed.

Even more compelling, however, is a recent behavioral study in monkeys (Sugita, 2008). Japanese macaques were raised by human caregivers wearing masks, giving the monkeys no exposure to faces but otherwise normal visual experience in a complex environment. On their *very first* experience with faces (aged 6–24 months), the monkeys showed a preference to look at static photographs of faces over photographs of objects that were equally novel in their visual environment (e.g., cars, houses) and discriminated very subtle differences between individual faces (figure 32.2C) in a habituation paradigm.

A variety of other infant findings also either directly argue that a representational capacity for differentiating individual face structures is present at birth or at least do not reject this conclusion. Newborns (<1 week) prefer faces rated by adults as attractive over unattractive faces when the faces are upright but not inverted (Slater, Quinn, Hayes, & Brown, 2000). Regarding holistic processing, Sugita’s (2008) monkeys discriminated spacing changes (figure 32.2C) with almost no prior experience of faces (they had been exposed to faces only during the short face preference task), and five-month-old humans discriminate spacing changes small enough to fall within the normal physical range, upright but not inverted (Hayden, Bhatt, Reed, Corbly, & Joseph, 2007); also babies 6–8 months old show a composite-like effect in which the combination of the inner features of one old face with the outer features of another old face is treated as a new

individual, upright but not inverted (Cohen & Cashon, 2001). At 3 months (although not at 1 month), human infants falsely recognize the average of four studied faces as “old,” a phenomenon that is also shown by adults (de Haan, Johnson, Maurer, & Perrett, 2001). Importantly, there are no major behavioral properties of face recognition present in adults that are known *not* to be present in infants; where we have not mentioned properties (e.g., adaptation aftereffects), this is because no relevant data exist, not because infants have been tested and failed to show effects.

Findings of *perceptual narrowing* indicate that (1) a representational capacity for faces that is present at birth can initially be applied to a wide range of faces but that (2) this range gets restricted during the first several months of life to include only the kinds of faces (i.e., species or race) that have been seen in this period. Perceptual narrowing is best known from the domain of language (e.g., Kuhl, Tsao, & Liu, 2003). Infants are born with the ability to discriminate phoneme boundaries from all possible languages in the world (e.g., English and Japanese), but over the first 6–12 months of life, they lose the ability to discriminate phonemes from nonexperienced languages (e.g., Japanese for a child from a monolingual English-speaking family), and even extensive exposure as an adult is usually insufficient to regain native-speaker levels of discrimination and reproduction. For faces, five studies have reported and explored properties of perceptual narrowing. In humans, Pascalis, de Haan, and Nelson (2002) showed that 6-month-old infants could discriminate both human and monkey faces, while 9-month-olds and adults could discriminate only human faces. Kelly and colleagues (2007) reported that Caucasian babies from the north of England, with high exposure to Caucasians but essentially no exposure to African or Asian faces, could recognize individuals (across view change) from all three races at 3 months of age. At 6 months, Caucasian babies could no longer individuate African faces; at 9 months, they had additionally lost the ability to individuate Asians. The Sugita (2008) study described earlier reported that on first exposure to faces, the monkeys not only could discriminate individual monkey faces (other macaques), but also could make extremely fine discriminations among human faces (figure 32.2C). Following 1 month of exposure to a single face type (either human or monkey, involving live interaction for least 2 hours per day), Sugita’s monkeys lost the ability to discriminate individuals of the nonexperienced species. Relearning was also difficult; monkeys that were initially exposed only to humans failed to discriminate monkey faces even after subsequently sharing a cage with 10 other monkeys for 11 months. (Note, however, that there is some evidence of flexibility in humans into middle childhood: Korean children adopted to Caucasian Francophone countries at age 3–9 years showed, as adults, better recognition memory for Caucasian faces than for Korean faces; Sangrigoli, Pallier,

Argenti, Ventureyra, & de Schonen, 2005). During human infancy, perceptual narrowing can be avoided by deliberate exposure to face types that the infant would not naturally see; regular exposure to monkey faces beginning at 6 months leads to retained ability to discriminate monkey faces at 9 months (Pascalis et al., 2005). Perceptual narrowing for faces also has an interesting possible link with narrowing for language. Lewkowicz and Ghazanfar (2006) reported that human infants could make cross-modality matches of a monkey vocalization to a picture of a monkey face making that particular sound at 4 and 6 months but that this ability was lost at 8 and 10 months.

Importantly, the perceptual narrowing effects for faces described above indicate only a destructive effect of experience across infancy (i.e., loss of initial ability with other species and other races). In the domain of language, loss of phonetic discrimination ability within nonexperienced languages has been shown to co-occur with an improvement of phonetic discriminability within the experienced language (Kuhl et al., 2006). Thus perceptual narrowing for faces might similarly include enhanced ability to discriminate experienced face subtypes; that is, discrimination for own-species own-race faces might start crude and *improve* with practice. Potentially consistent with this prediction, Humphreys and Johnson (2007) showed that the physical difference between faces that was required to produce novelty preference was smaller in 7-month-olds than in 4-month-olds, indicating that the older babies could either make finer perceptual discriminations or keep these in memory longer across the 1–5 item test delay. Neural systems that are present at birth are often associated with a *critical* (or *sensitive*) *period* (Sengpiel, 2007), requiring environmental input of the appropriate stimulus type within a specified period after birth to avoid being taken over for other purposes. In a classic example, cats are born with cells tuned to all line orientations, but if raised in an environment containing only vertical lines, they lose horizontal-responsive cells and demonstrate a corresponding lack of behavioral sensitivity to horizontal lines. For faces, Le Grand and colleagues report evidence consistent with a critical period for one important aspect of face perception: holistic processing. Congenital cataract patients, specifically people born with dense cataracts disrupting all pattern vision who had the cataracts removed at 2–28 months of age, were tested at ages ranging between 9 years and adulthood. Despite their many years of postcataract exposure to faces, patients who had had early bilateral cataracts showed no composite effect for faces (Le Grand et al., 2004). Also, patients who had had right-eye-only or bilateral cataracts, which produce a deficit of input to the right hemisphere due to the wiring of the infant visual system, showed a later deficit in processing spacing information in faces, while patients who had had left-

eye-only cataracts did not (Le Grand, Mondloch, Maurer, & Brent, 2003), a pattern that is consistent with the normal role of the right hemisphere in holistic processing (Rossion et al., 2000). Interestingly, there does not appear to be a critical period for the ability to discriminate faces *per se*. Anecdotally, the Canadian cataract patients are not functionally prosopagnosic (Daphne Maurer, personal communication); for example, they report even being able to recognize other-race students when teaching English in Korea (Rachel Robbins, personal communication). Formal testing shows good ability to match novel faces (without view change) both in these patients (Geldart, Mondloch, Maurer, de Schonen, & Brent, 2002) and in an Indian woman whose congenital cataracts were not removed until 12 years of age (Ostrovsky, Andalman, & Sinha, 2006). Also, lack of visual experience with faces for the first 6–24 months in Sugita's (2008) monkeys did not destroy discrimination ability. The reason why a requirement for early visual input exists for holistic processing but not face discrimination remains to be resolved. One possibly relevant observation is that holistic processing could perhaps have a particular role in cross-view recognition (McKone, 2008), and the Canadian cataract patients have a specific problem with recognition of once-seen faces across view changes (Geldart et al., 2002). (Note that the Indian patient and Sugita's monkeys were tested on same-view faces only.)

The behavioral findings reviewed above, demonstrating abilities present at birth, perceptual narrowing and critical periods, are all consistent with a genetically determined “innate” contribution to infant face recognition. In particular, they argue for an innate contribution to face individuation.

Neurally, face individuation in adults is associated with cortical rather than subcortical function. What is the evidence regarding cortical face-processing function in infants? There are few available studies and none in neonates. Results do, however, demonstrate face selectivity and inversion effects. In infant macaques, Rodman, Scalaidhe, and Gross (1993) found that the response magnitude of single units in inferotemporal cortex was lower overall than in adults, but selectivity for form, including face selectivity, was present at the youngest ages that were tested, within 2 months of birth. In humans, a PET study of 2.5-month-olds is somewhat suggestive of face-selective activation in the fusiform gyrus (and other cortical regions), although the infants were not neurologically normal, the statistical threshold was extremely lenient ($p < 0.05$ uncorrected), and the contrast (faces versus blinking diodes) confounds selectivity for faces with responses to visual shape information (Tzourio-Mazoyer et al., 2002). With the use of ERPs, human 3-month-olds exhibit an “N290” component that has larger amplitude for human faces than for monkey faces in the right hemisphere only

(Halit, de Haan, & Johnson, 2003), although adult N170 shows the opposite pattern. At 12 months of age, this N290 was higher in amplitude for inverted faces than for upright faces only for human faces, not monkey faces (like the adult N170). Although the same study reported that this sensitivity to inversion was not found in 3-month-olds, another analysis of the same data using a different method (Johnson et al., 2005) did claim to find such inversion sensitivity. Further, other ERP components (the P400 and the P1) do show inversion effects at 3 months, the youngest age tested (Halit et al., 2003). Similarly, near-infrared spectroscopy (NIRs) responses in 5- to 8-month-old infants are stronger for upright faces than for inverted faces over the right hemisphere only (Otsuka et al., 2007; note the cortical source of this effect was most likely the STS). Overall, the available neural evidence from infants is consistent with the existence of cortical machinery for processing faces within a few months after birth, and there is no evidence to suggest that this is not present earlier.

Taking all findings together, we conclude that infants are born with a rich capacity to represent the structure of upright faces that supports face discrimination rather than merely drawing attention to faces. Results further show that this representation interacts with experience during infancy in particular ways. A probable critical period suggests that holistic processing is “experience-expectant” (i.e., early environmental input is required for its maintenance). Perceptual narrowing shows that early experience restricts the range of faces that can be accommodated; that is, an initial representation of faces is sufficiently broadly tuned to support individuation of all face types including those of other primates, and experience with one subtype of face (own-species, own-race) removes this initial ability with other face types (other-species, other-races) at the same time that it possibly improves perceptual tuning for faces of the experienced subtype. Regarding neural origin of face discrimination in infants, there is evidence of relevant cortical representation by midinfancy, but no data are available regarding whether the discrimination ability that is present at birth is supported by cortical as opposed to subcortical representations.

Development: Four-year-olds to adults

In understanding the interaction of genetic inheritance and learning, investigation of the developmental trajectory of face processing in childhood through adulthood can be informative. When no change is found in a given behavioral or neural measure of face perception in this period, that argues against extended maturation or learning as being necessary for the construction of the adult system. If instead protracted development is observed, this could reflect learning (as often assumed), though crucially it could also reflect

biological maturation (Carey et al., 1980) or an interaction of genetic and experiential factors.

BEHAVIORAL MEASURES OF FACE IDENTITY PERCEPTION For children 4–5 years and older, it is possible, with care, to adapt adult behavioral paradigms directly and thus to compare child performance with adult performance on exactly the same tasks. For each phenomenon that is established in adults, two empirical questions are of interest. First, is there some age below which children simply do not show that phenomenon at all (i.e., is there *qualitative* change with age)? Second, regarding any phenomena that are observed, when are full maturity levels reached (i.e., is there *quantitative* change with age)?

We consider qualitative change first. Early behavioral research appeared to suggest that core perceptual processes involved in face identification did not emerge at all until quite late in development (e.g., 10 years for holistic processing; Carey & Diamond, 1977; Carey et al., 1980). Unfortunately, researchers in the face neuroscience literature (e.g., Gathers, Bhatt, Corbly, Farley, & Joseph, 2004; Aylward et al., 2005; Golarai et al., 2007; Scherf, Behrmann, Humphrey, & Luna, 2007) commonly emphasize only these few early findings, which give an inaccurate representation of the current state of knowledge. In fact, research in the last 15 years has clearly established that all standard adult face recognition effects are present in young children. (Indeed, we showed earlier in the chapter that all phenomena that were tested, including inversion effects, were present in infancy.)

In child-age studies using adult tasks, every key adult property of face recognition that has been investigated has been obtained at the youngest age tested. With respect to holistic processing, these results include the inversion effect on short- and long-term recognition memory (3 years old: Sangrigoli & de Schonen, 2004; 4 years old: Carey, 1981; 5–6 years old: Brace et al., 2001; 7 years old: Flin, 1985), the composite effect (4 years old: De Heering, Houthuys, & Rossion, 2007; 6 years old: Carey & Diamond, 1994; 6 years old: Mondloch, Pathman, Maurer, Le Grand, & de Schonen, 2007), the part-whole effect for upright but not inverted faces (4 years old: Pellicano & Rhodes, 2003; 6 years old: Tanaka, Kay, Grinnell, Stansfield, & Szechter, 1998), the part-in-spacing-changed-whole effect for upright but not inverted faces (4 years old: Pellicano, Rhodes, & Peters, 2006) sensitivity to exact spacing between facial features (4 years old: McKone & Boyer, 2006; Pellicano et al., 2006), the perceptual bias to upright in superimposed faces (8 years old: Donnelly, Hadwin, Cave, & Stevenage, 2003), and the internal-over-external features advantage for familiar face identification (5–6 years old: Wilson, Blades, & Pascalis, 2007). Regarding face-space coding, results include

distinctiveness effects on perception at 4 years (McKone & Boyer, 2006) and on memory at 6–7 years (Gilchrist & McKone, 2003), an other-race disadvantage on recognition memory at 3 years (Sangrigoli & de Schonen, 2004) and a recent conference report of adaptation aftereffects in 4–5-year-olds (Jeffrey & Rhodes, 2008). Where early studies did not show effects, this has generally been established to have arisen from methodological problems, the most common one being floor effects on the task in young children (e.g., see Carey et al., 1980, versus Carey, 1981; or Johnston & Ellis, 1995, versus Gilchrist & McKone, 2003). Another case of note is the early suggestion that children could not perform face identification at all in the presence of distracting paraphernalia (Carey & Diamond, 1977); this finding was overturned (Lundy, Jackson, & Haaf, 2001) by simply making the faces larger. (Also note that even adults are sometimes strongly distracted by paraphernalia; Simons & Levin, 1998.) In summary, it is clear that there is no qualitative change in face perception beyond 4–5 years of age; quite possibly, there is none beyond infancy.

The question of whether quantitative change occurs is more difficult to answer. Certainly, performance on just about any experimental task involving faces improves very substantially across childhood and well into adolescence (see figures 32.3A and 32.3B). The crucial issue is how much of this development reflects development in face perception (e.g., in holistic processing or in the fine tuning of face-space) and how much reflects development in other general cognitive factors that are known to improve substantially across this age range and would affect task performance whatever the stimuli (e.g., explicit memory ability, ability to concentrate on the task to instruction). A common bias of face researchers is to assume, given data showing increasing memory for faces with age (e.g., figure 32.3A), that it is face perception that is changing, and that the task type—explicit memory—is irrelevant; yet an implicit memory researcher looking at the same set of data would likely conclude that “explicit memory” is developing and presume that the particular stimulus type—faces—is irrelevant.

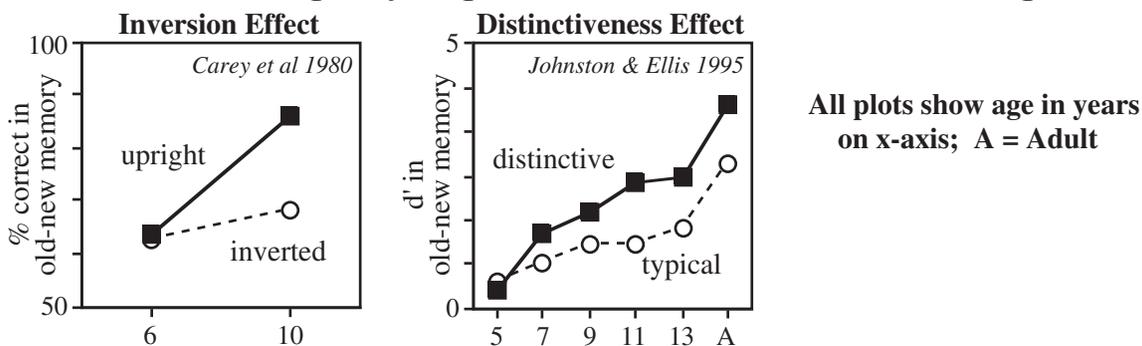

Various attempts have been made to overcome the limitations of simply tracking age-related improvement in raw performance. To our minds, none of these are methodologically satisfactory, and none produce a clear conclusion regarding whether face perception per se does, or does not, improve between early childhood and adulthood. One approach is to compare two conditions across development, for example, asking whether the size of the difference between upright and inverted (or typical and distinctive, etc.) changes with age (e.g., Carey et al., 1980; Johnston & Ellis, 1995). The results of almost all such studies, however, are confounded with overall “baseline” changes across age groups, such that (1) when room to show effects is potentially compressed by approaching floor in young children but is not

restricted (i.e., no ceiling effect) in adults, results seem to suggest quantitative *increases* in the effect of interest with age (figure 32.3A), but (2) when room to show effects is restricted by approaching ceiling in adults but is not restricted in young children (i.e., no floor effects on accuracy or, alternatively, use of a reaction time measure), results seem to show quantitative *decreases* with age (figure 32.3B). Taking seriously the results of the first type of study as showing quantitative development in face perception (as is commonly done) requires also taking seriously the results of the second type of study—apparently leading to the conclusion that face perception gets consistently *worse* between early childhood and adulthood! A further requirement for valid comparison of rates of development for two stimulus types is that performance be equated for the two types in one or other endpoint age group. This is commonly not done. As one example, Mondloch, Le Grand, & Maurer’s (2002) finding that sensitivity to feature changes reaches adult levels earlier than spacing changes can be attributed (McKone & Boyer, 2006) simply to the fact that the features changes were easier in adults (that is, performance on an easier stimulus set reaches adult levels before performance on a more difficult stimulus set does). Another general issue in studies comparing faces versus objects, for example, in rate of development (Golarai et al., 2007) or size of inversion effects (Carey & Diamond, 1977; Teunisse & de Gelder, 2003; Aylward et al., 2005), is that in addition to producing very mixed results, the object classes that have been tested to date (houses, scenes, sculptures, shoes) have not been well matched to faces on basic parameters, such as not sharing a first-order configuration (houses, scenes) or not being natural objects (sculptures, shoes).

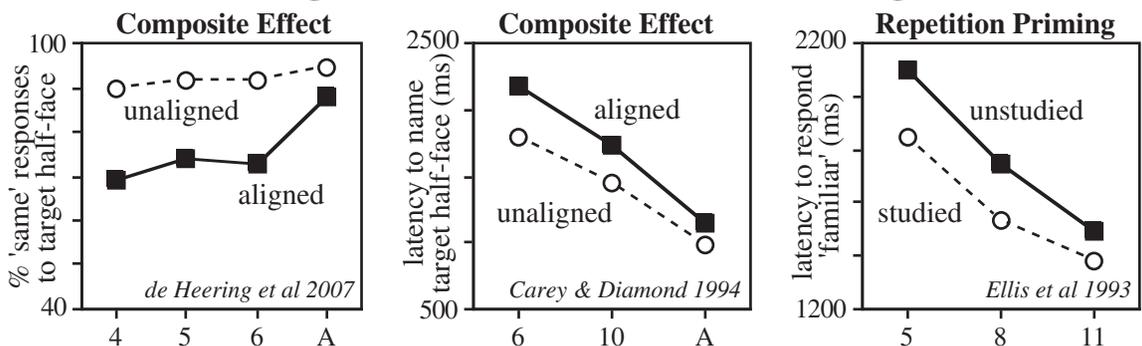

Overall, we conclude that current behavioral evidence demonstrates qualitatively adultlike processing of faces in young children but does not resolve whether processing is quantitatively mature. We note, however, that at least some evidence suggests a conclusion that is likely to be surprising to many readers, namely, that even quantitative maturity might be reached by early childhood. The three studies that appear to have the most suitable methodology, in which baselines were matched across age groups (Carey, 1981; Gilchrist & McKone, 2003) or restriction of range problems was otherwise avoided (Mondloch et al., 2007), all indicate no change in holistic processing (inversion effect: Carey, 1981; composite effect: Mondloch et al., 2007; spacing sensitivity: Gilchrist & McKone, 2003; or distinctiveness effects: Gilchrist & McKone, 2003) between early childhood (4–6 years) and adulthood (figure 32.3C).

NEURAL MEASURES OF FACE IDENTITY PROCESSING (FFA AND N170) As with behavioral studies, we discuss results of neuroimaging and ERP studies in children with respect to two issues: qualitative development and quantitative development.

A. Restriction of range in young children: face effects *increase* with age

B. Restriction of range in adults: face effects *decrease* with age

C. No range restrictions: face effects are *stable* with age

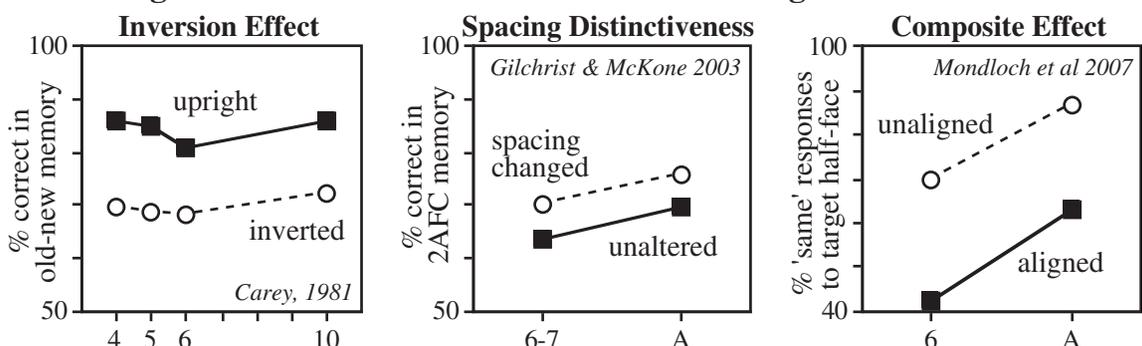

FIGURE 32.3 Behavioral face recognition effects in the preschooler to adult age range. A basic finding is of overall improvement with age: higher accuracy or lower reaction time. Note that in part C, the left and middle plots show studies in which the researchers deliberately removed this trend by using smaller learning set sizes

in younger children. Our major point is that apparent developmental trends in the strength of core effects (size of inversion effect, size of composite effect, ability to represent recently seen faces in implicit memory, etc.) depend on whether and how room to show effects is potentially restricted.

Three studies have used fMRI to scan children age 5 years to adult on face and object tasks, enabling these studies to track the existence and size of face-selective regions of cortex (figure 32.4). (A fourth study will not be discussed here because it used such liberal criteria to define “FFAs” that the regions that were so identified were clearly not face-selective even in adults; see figure 1d–f in that study, Gathers et al., 2004.) Considering qualitative effects, evidence of a face-selective FFA has been found in most children at the youngest ages tested. Although no FFA was revealed in young

children by group analyses (in which all subjects are aligned in a common space; 5- to 8-years old: Scherf et al., 2007; 8–10 years old: Aylward et al., 2005), in the two studies reporting individual-subject analyses, Scherf and colleagues found an FFA in 80% of the children in 5- to 8-year-olds (albeit at a very liberal statistical threshold), and Golarai and colleagues (2007) found an FFA in 85% of children in their 7- to 11-year-old group (using a more standard statistical threshold). One study (Passarotti, Smith, DeLano, & Huang, 2007) also reported an inversion effect (a higher response to inverted

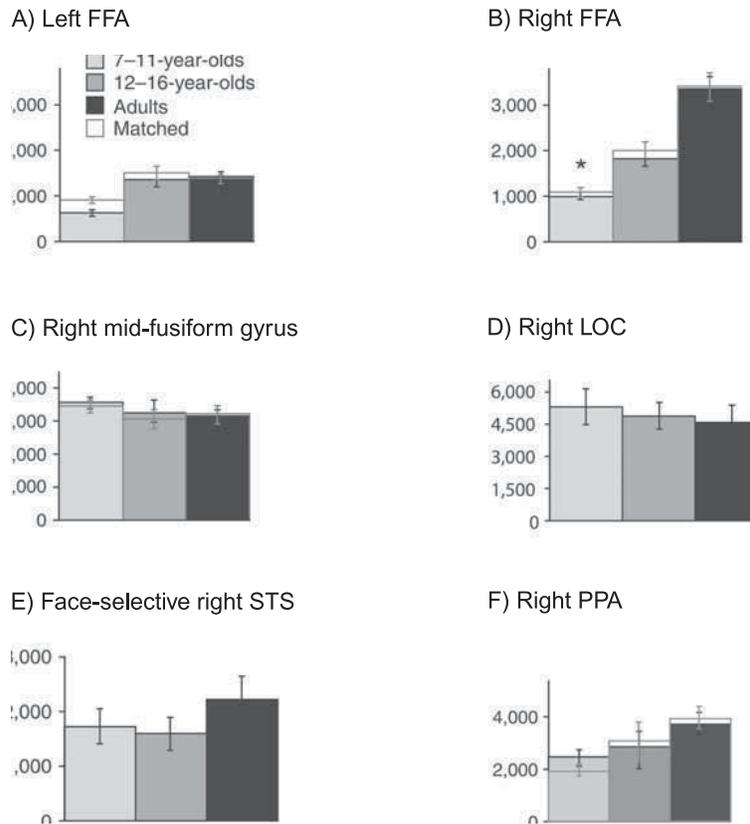

FIGURE 32.4 Mean volume across subjects in each age group of individually defined (A) left and (B) right FFA, (C) anatomically defined right mid-fusiform gyrus, (D) functionally defined right LOC, and functionally defined (E) face-selective right STS and (F)

right place-selective PPA. Red bars indicated values in subsets of subjects matched for BOLD-related confounds. (From Golarai et al., 2007.) (See color plate 47.)

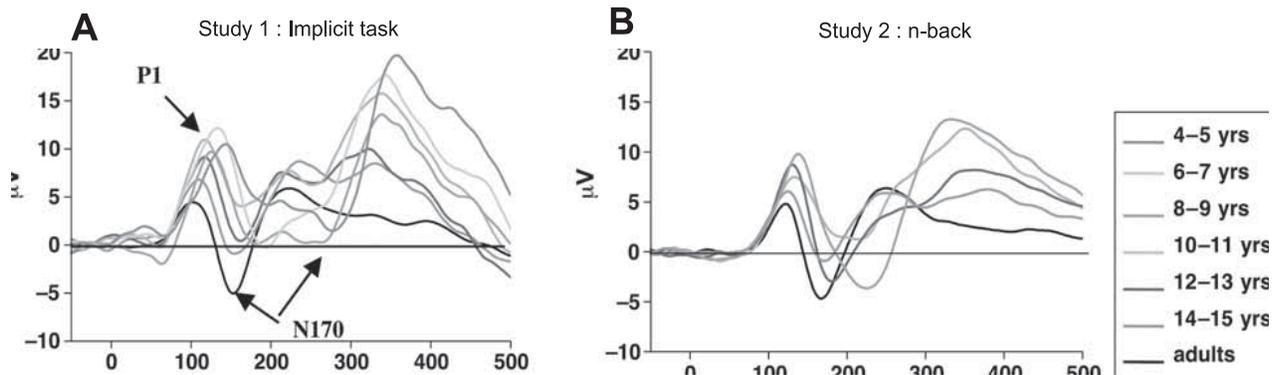

FIGURE 32.5 ERPs from right posterior temporal scalp locations in response to face stimuli, separately for each age group. (From Taylor et al., 2004.) (See color plate 48.)

faces than to upright faces) in the region of the right (but not the left) FFA in children 8–11 years of age (and an effect in the opposite direction in adults). Regarding ERPs, young children (like infants) show both face-selective responses and inversion effects upon these (see figures 32.5 and 32.6; Taylor, Batty, & Itier, 2004). These fMRI and ERP findings in children add to the infant data to confirm that at least some form of face-specific neural machinery is established early.

Quantitatively, the neural machinery that is involved in face perception demonstrates substantial changes in face-selective neural responses continuing late into development. In all three fMRI studies, the FFA increases markedly in volume between childhood and adulthood (Aylward et al., 2005; Golarai et al., 2007; Scherf et al., 2007), even though total brain volume does not change substantially after age 5 years. These studies clearly show that the rFFA is still chang-

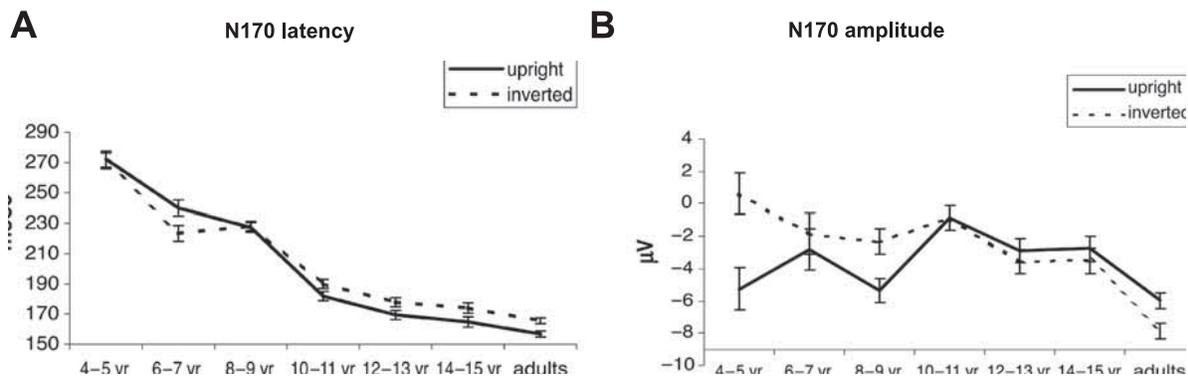

FIGURE 32.6 Mean N170 latency (left) and amplitude (right) for upright and inverted faces as a function of age. (From Taylor et al., 2004.)

ing late in life—certainly after age 7 and in some studies much later.

Comparing fMRI data across children and adults is fraught with potential pitfalls. Children move more in the scanner and are less able to maintain attention on a task. These or other differences between children and adults could in principle explain the change in volume of the rFFA. However, notably, control areas that are identified in the same scanning sessions do not change with age. For example, object-responsive regions and the scene-selective “parahippocampal place area” in the right hemisphere or rPPA (Epstein & Kanwisher, 1998) did not change in volume from childhood to adulthood (Golarai et al., 2007; Scherf et al., 2007), although somewhat surprisingly, Golarai and colleagues found that the IPPA did increase in volume with age. These findings reassure us that the changes in the rFFA with age are not due to across-the-board changes in the ability to extract good functional data from young children.

Golarai and colleagues (2007) asked how changes in the rFFA relate to changes in behavioral face recognition over development. Right FFA size was correlated (separately in children and adolescents but not in adults) with face recognition memory but not with place or object memory. Conversely, IPPA size was correlated (in all age groups independently) with place memory but not with object or face memory. This double dissociation of behavioral correlations clearly associates the rFFA with changes in face recognition measured behaviorally.

ERP findings are consistent with the evidence from fMRI that the cortical regions that are involved in face recognition continue to change well into the teenage years. Face-related ERPs show gradual changes in scalp distribution, latency, and amplitude into the mid-teen years (figures 32.5 and 32.6). Both the early P1 component and the later N170 component show gradual decreases in latency from age 4 to adulthood. Regarding neural inversion effects, late developmental changes are found with both fMRI and ERP

(see figure 32.5), including a reversal of the direction of the inversion effect between children and adults in both methods (Taylor et al., 2004; Passarotti et al., 2007). Future research might best approach this question not just by measuring mean responses to upright versus inverted faces, but also by using identity-specific adaptation to ask when the better discrimination of upright than inverted faces seen in adulthood emerges (Yovel & Kanwisher, 2005; Mazard et al., 2006).

COMPARING DEVELOPMENT FOR BEHAVIORAL AND NEURAL MEASURES Taking the findings from the 4-to-adult range together with the infant literature, we can draw the following conclusions. First, the results regarding qualitatively adultlike face processing appear to agree well across behavioral and neural measures; that is, just as all behavioral face recognition effects have been obtained in the youngest age groups tested, face-selective neural machinery as revealed by fMRI, ERPs, NIRs, and single-cell recording has also been found in the youngest children and infants tested. Nonetheless, fMRI data are not available for children younger than 5–8 (pooled together), and the ERP studies in infants and children often go in opposite directions from those in adults. For example, the inversion effect on the N170 switches polarity between childhood and adulthood, as shown in figure 32.6, despite maintaining the same polarity in behavior.

Second, the evidence for quantitative development is less clear. It might be that the improvements with age on behavioral tasks do reflect ongoing development of face perception itself; if so, this could agree neatly with the increasing size of the FFA. As we have noted, however, findings such as those shown in figures 32.3B and 32.3C suggest that behavioral face perception could be fully mature early and that ongoing behavioral improvements with age reflect changes in other, more general, cognitive factors. This view would produce an apparent discrepancy—behavioral maturity arising well before maturity of relevant cortical regions—that would need to be resolved. If this is the case, two ideas

FIGURE 32.7 For each property of face processing, we indicate for each age group whether that property is *qualitatively* present (☺), debatable (?), not present (X), or not yet tested (gray). Deprived = monkeys deprived of face input from birth. Note: All references can

be found in text except inversion effect on spacing sensitivity aged 6 years to adult is from Mondloch et al. (2002) and adaptation aftereffect aged 9 years to adult is from Pellicano, Jeffery, Burr, & Rhodes (2007).

might be worth exploring. It might be that the measured size of the FFA in children is affected by top-down strategic processing that (for some unknown reason) affects faces and not objects. Another possibility is that the FFA might play some role in the long-term storage of individual faces (e.g., it shows repetition priming; Pourtois, Schwartz, Seghier,

Lazeyras, & Vuilleumier, 2005; Williams, Berberovic, & Mattingley, 2007) and that the increased size of the FFA could arise simply because people continue to learn faces across life; this idea would have to propose that the number of new faces learned is much greater than the number of new objects.

Conclusion

For decades, conventional wisdom has held that face recognition arises very slowly in development and that experience is the primary engine of this development. The new evidence that we have reviewed here refutes this hypothesis. Impressive face recognition abilities are present within a few days of birth and are present in monkeys who have never seen faces before. Some form of inherited genetic influence is also indicated by Polk and colleagues' imaging study of twins and by the fact that developmental prosopagnosia can run in families. Qualitatively, behavioral findings indicate establishment of all adultlike face recognition effects by 4 years at the latest and in infancy wherever tested; the striking breadth of this evidence is summarized in figure 32.7. The available evidence also indicates early initial establishment of face-selective neural machinery at the cortical level (again see figure 32.7). It is not, however, that experience plays no role in development. Perceptual narrowing of the range of facial subtypes for which discrimination is possible reveals a destructive role for experience. Further, there is a requirement for early-infancy input (consistent with a critical period) for the development of holistic face processing but (mysteriously) not face discrimination.

Three major questions remain for future research. First, it will be critical to determine whether face perception performance improves quantitatively after age 4 years or whether instead improvement in performance after this age reflects improvement in domain-general mechanisms. Second, if face perception itself does improve quantitatively after age 4, what role does experience play in this improvement? A final critical challenge will be to understand the relationship between cognitive and neural development, especially the substantial increase in the size of the FFA.

ACKNOWLEDGMENTS We thank Mark Johnson for useful comments and Bettiann McKay for help with the manuscript. Preparation of this chapter was supported by NEI grant 13455 and a grant from the Ellison Foundation to N.K. and by grant DP0450636 from the Australian Research Council to E.M.

33 Roles of Visual Area MT in Depth Perception

GREGORY C. DEANGELIS

ABSTRACT One of the most impressive capacities of the visual system is the ability to infer the three-dimensional structure of the environment from images formed on the two retinas. Although several areas of visual cortex are involved in computing depth, the precise roles of different areas in three-dimensional vision remain unclear. It is important to establish how neural representations of depth in different brain regions are specialized to perform different tasks. This chapter summarizes studies that establish such links between representation and function in visual area MT. The nature of the representation of binocular disparity in MT is first considered, along with the functional roles of MT in coarse and fine depth discrimination. The recently discovered role of area MT in computing depth from motion parallax is then examined. These findings are compared with those from other visual areas to consider possible functional streams of analysis in three-dimensional vision.

We carry out our daily activities in a three-dimensional (3D) environment. Therefore a fundamental task for the visual system is to construct a 3D representation of our surroundings. This is difficult because the image formed on the retina of each eye is a two-dimensional projection of 3D space—hence there is no direct quantitative information about depth in a single retinal image. Rather, the depth structure of the scene must be reconstructed by the brain.

The visual system makes use of a wide variety of cues to estimate depth relationships (Howard & Rogers, 1995, 2002). Broadly speaking, these cues can be placed into two categories that I shall label *pictorial cues* and *geometric cues*. Pictorial cues to depth are those that are present in a single snapshot of the scene, including occlusion, perspective, shading, relative size, texture gradients, and blur. Together, these cues can be potent, as is evidenced by the fact that we can infer depth relationships in photographs. However, they generally provide only ordinal depth information or require prior knowledge to provide metric depth information. For example, the size of an object in the retinal image can be used to estimate the distance to that object if one knows the true physical size of the object.

Geometric depth cues are those that arise when a scene is viewed from multiple vantage points. For species with frontally located eyes, the horizontal separation between the two eyes generates systematic differences—known as binocular disparities—between the images projected onto the two retinas (figure 33.1A). Thus images from two simultaneous vantage points are available. Binocular disparity (hereafter referred to as *disparity*) is known to be sufficient to provide precise depth discrimination in the absence of other depth cues, as demonstrated with random-dot stereograms (Howard & Rogers, 1995; Julesz, 1971; Parker, 2007). Combined with an estimate of viewing distance (the distance from the eye to the point of fixation), disparity can provide quantitative estimates of the location of objects in depth. Another geometric cue, motion parallax, arises because of the translation of the observer, as illustrated in figure 33.1B. As the observer's head moves from left to right, for example, the vantage point of the left eye changes over time. If the observer's head moves through one interocular distance, then the image that is projected onto the retina of the left eye will vary over time, the endpoint being the same view that would be seen by the right eye at the beginning of the movement (figure 33.1B). Thus there is a formal geometric similarity between disparity and motion parallax cues, at least when the latter arise because of lateral head movements. This means that motion parallax can provide metric depth information when a subject views the scene with one eye, as long as the eye moves relative to the scene. Not surprisingly, then, humans can make judgments of depth from motion parallax that are similar in precision to judgments based on disparity (Rogers & Graham, 1979, 1982). As we shall see later, the similar geometry of these two cues suggests that they might be processed using the same neural mechanisms.

Where and how are depth cues processed in the brain? For the pictorial depth cues, very little is known about the neural mechanisms that lead to depth percepts; therefore I shall not consider pictorial cues further here. Until recently, very little was also known about the neural basis of depth from motion parallax, and we shall consider the available physiological information in the last section of this chapter. By comparison, a great deal is known about the neural circuits that process disparity cues for depth perception, as has

GREGORY C. DEANGELIS Department of Brain and Cognitive Sciences, Center for Visual Science, University of Rochester, Rochester, New York

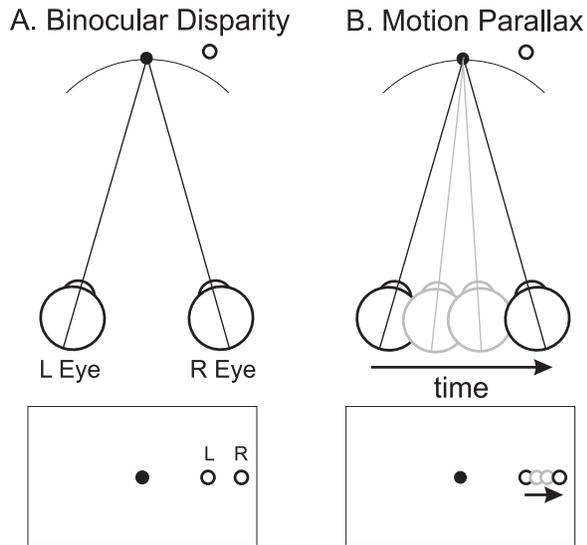

FIGURE 33.1 Binocular disparity and motion parallax as depth cues. (A) Points falling along the geometric horopter, or Vieth-Muller circle (curved line), have zero binocular disparity. A far object (open symbol) projects to disparate points in the two retinal images (bottom). (B) If the head translates rightward, the image of the far object moves on the retina. If the eye moves through one interocular distance, the position change on the retina due to motion parallax is equivalent to the binocular disparity. Hence depth from motion parallax is often expressed in units of equivalent disparity.

also been reviewed elsewhere (Cumming & DeAngelis, 2001; DeAngelis, 2000; Gonzalez & Perez, 1998; Parker, 2007). I shall focus mainly on work that has been performed using macaque monkeys as experimental subjects. However, it should be noted that many important contributions have also been made in other species, particularly cats (for reviews, see Freeman, 2004; Freeman & Ohzawa, 1990; Ohzawa, DeAngelis, & Freeman, 1997).

The primary visual cortex (V1) was the major focal point of most early physiological studies of disparity processing (Barlow, Blakemore, & Pettigrews, 1967; Poggio & Fischer, 1977). Neurons in V1 provide the initial encoding of disparity signals (Cumming & DeAngelis, 2001), and the representation of disparities in V1 likely limits the precision of a number of aspects of stereopsis (Nienborg, Bridge, Parker, & Cumming, 2004, 2005; Prince, Pointon, Cumming, & Parker, 2000). However, a series of elegant experiments over the past decade has demonstrated that the representation of disparity in V1 is not sufficient to account for various aspects of our perceptual experience of depth (Cumming & Parker, 1999, 2000, 1997; Nienborg & Cumming, 2006). Therefore it seems clear that disparity processing beyond V1 is critical to account for behavior. During this same period, we have learned that disparity signals are represented in a variety of visual cortical areas that were not previously known to contain disparity-selective neurons, including area V4 (Hegde & Van Essen, 2005; Hinkle & Connor, 2005; Tanabe,

Doi, Umeda, & Fujita, 2005), inferotemporal (IT) cortex (Janssen, Vogels, Liu, & Orban, 2003; Janssen, Vogels, & Orban, 1999, 2000b; Uka, Tanaka, Yoshiyama, Kato, & Fujita, 2000), and lateral area MST (Eifuku & Wurtz, 1999). Disparity selective-neurons have also been documented in areas not conventionally considered to be predominantly visual, such as the frontal eye fields (Ferraina, Pare, & Wurtz, 2000) and the lateral (Genovesio & Ferraina, 2004; Gnadt & Mays, 1995) and caudal (Taira, Tsutsui, Jiang, Yara, & Sakata, 2000; Tsutsui, Jiang, Yara, Sakata, & Taira, 2001; Tsutsui, Sakata, Naganuma, & Tanaka, 2002) portions of the intraparietal sulcus. Combined with earlier studies showing the presence of disparity-tuned neurons in areas V1, V2, V3, V3A, MT, and dorsal MST (reviewed in Cumming & DeAngelis, 2001), these studies suggest that disparity signals are much more widely distributed in the primate brain than was suspected a decade ago.

The proliferation of disparity signals in visual cortex raises fundamental questions regarding the roles of different cortical areas: How are the representations of disparity specialized in these different areas, and what are the specific roles that particular areas play in 3D vision? These are not simple questions to answer because they require both a detailed understanding of the responses of single neurons to a variety of stimulus configurations and causal tests in which neural activity is manipulated and the consequences on behavior are observed. Over the past several years, considerable progress has been made on these fronts, and there is cause to be optimistic that these experimental approaches will lead to a functional taxonomy that describes how different visual areas contribute to the various perceptual capacities of depth perception.

My goal in this chapter is to summarize what we know about how disparity and motion parallax cues are processed in the middle temporal (MT) area of visual cortex and to review experiments that suggest a specialized functional role for area MT in depth perception. Along the way, I shall try to place the findings from area MT into the context of what is known from related studies performed in other parts of primate visual cortex.

Binocular disparity processing in area MT

Area MT is a relatively small ($\sim 60 \text{ mm}^2$) visual area located along the posterior bank of the superior temporal sulcus in macaque monkeys. It receives much of its visual input from areas V1, V2, and V3, and it projects extensively to other occipitoparietal areas, including MST, FST, VIP, and LIP (reviewed in Born & Bradley, 2005). Area MT is well known for its role in processing visual motion, and an extensive body of literature implicates area MT both in the perception of motion and in guiding smooth eye movements that are driven by visual image motion (Born & Bradley, 2005).

BASIC ASPECTS OF DISPARITY PROCESSING IN MT Despite heavy emphasis on the role of MT in motion processing, it has been known for quite some time that MT is rich in neurons that are selective for binocular disparities (Maunsell & Van Essen, 1983b). A more recent quantitative study, using random-dot stereograms (figure 33.2*A*), reported that 93% of single neurons in MT have statistically significant selectivity for disparity (DeAngelis & Uka, 2003). The strength of disparity selectivity in MT is, on average, stronger than that seen in areas V1 (Prince, Pointon, Cumming, & Parker, 2002) and V4 (Tanabe et al., 2005). As shown in figure 33.2*B*, disparity tuning curves in MT take on a variety of shapes and have continuously varying preferences over a wide range of disparities (note that zero disparity represents a surface containing the point of ocular fixation). Most frequently, however, MT neurons tend to have tuning that is roughly odd-symmetric around zero disparity, with a well-defined peak response that is either near (e.g., cells 2 and 3 in figure 33.2*B*) or far (cells 5 and 6) in figure 33.2*B* or far (cells 5 and 6). In this regard, MT differs notably from area V1, where disparity tuning curves are much more frequently even-symmetric and tend to peak at disparities closer to zero (Cumming & DeAngelis, 2001). As one ascends the dorsal visual pathway in the macaque, disparity tuning curves progress from largely even-symmetric

in V1 to having an odd-symmetric bias in MT to being strongly odd-symmetric in area MST (see Cumming & DeAngelis, 2001, for comparison; Roy, Komatsu, & Wurtz, 1992; Takemura, Inoue, Kawano, Quaia, & Miles, 2001).

Nearly all neurons in area MT show directionally selective responses to visual motion (DeAngelis & Uka, 2003; Maunsell & Van Essen, 1983a; Zeki, 1974), and nearly all neurons are selective for speed of motion as well (Maunsell & Van Essen, 1983a; Nover, Anderson, & DeAngelis, 2005; Rodman & Albright, 1987). Thus most MT neurons respond substantially more strongly to a moving stimulus than a stationary one. Importantly, however, the majority of MT neurons do produce sustained visual responses to stationary flashed stimuli, and the disparity tuning of these responses is nearly identical to those elicited by moving stimuli (Palanca & DeAngelis, 2003). Thus MT provides reliable disparity signals to the rest of the brain when we look around a stationary scene.

Disparity-selective neurons in area MT are organized into a topographic map according to their disparity preferences (DeAngelis & Newsome, 1999), and this disparity map coexists with the well-known map for direction of motion in MT (Albright, Desimone, & Gross, 1984). In contrast to the clear columnar organization for disparity in MT, there is no clear

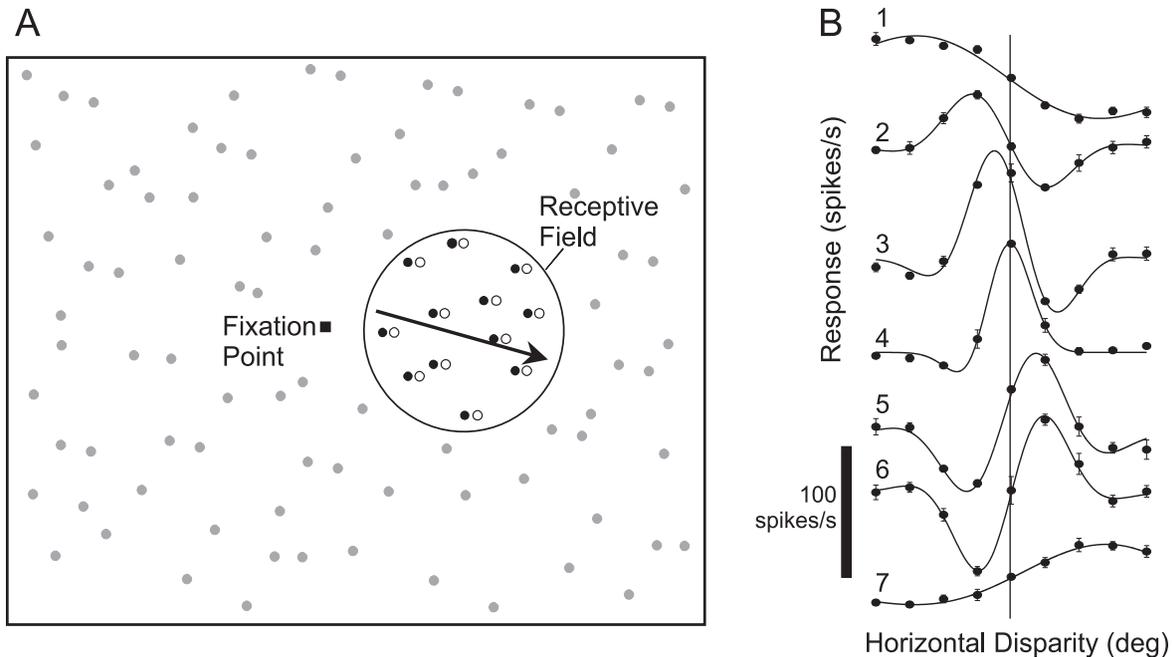

FIGURE 33.2 Schematic illustration of random-dot stereogram stimulus and example disparity tuning curves measured with this stimulus. (*A*) A circular patch of moving dots having variable disparity was presented over the receptive field (circle, not present in the actual display) of an MT neuron. Solid and open dots within the receptive field denote the images seen by the left and right eyes; the separation between each pair of open and solid dots is the binocular disparity. The remainder of the screen was filled with stationary dots presented with zero disparity (gray dots). The monkey

was required to maintain fixation on the fixation point during each trial. (*B*) Disparity tuning curves for seven representative MT neurons. Solid symbols and error bars show the mean response to each disparity \pm standard error. The smooth curve through each data set is the best-fitting Gabor function. Neurons are presented (from top to bottom) in order of their preferred disparities, from large Near to large Far. The vertical scale bar corresponds to 100 spikes per second. (Adapted from DeAngelis & Uka, 2003.)

evidence for such a map in area V1 of monkeys (Chen, Lu, & Roe, 2008; Prince et al., 2002). However, there is clear evidence for a map of disparity in both areas V2 (Chen et al., 2008; Nienborg & Cumming, 2006) and V3 (Adams & Zeki, 2001), and it is possible that the map of disparity in MT is at least partially inherited from one or both of these sources.

ABSOLUTE AND RELATIVE DISPARITY SELECTIVITY Over the past several years, an important distinction to emerge in the cortical processing of binocular disparity involves the difference between absolute and relative disparity coding. Absolute disparity refers to the interocular difference in the angle subtended by a point in space relative to the projection of the fixation point, which lands on the fovea in each eye (figure 33.3A). Thus absolute disparities are defined relative to the point of ocular fixation. In contrast, the relative disparity between two points in space refers to the difference in their absolute disparities (figure 33.3B). This distinction becomes especially important when one considers changes in the fixation distance of a subject and hence the vergence angle of the eyes. When we converge or diverge our eyes to focus on a near or far object, respectively, all of the absolute disparities change. On the other hand, the relative disparity between two points in space is unaffected by changes in vergence angle. This means that uncontrolled errors and

variations (i.e., noise) in vergence state will affect absolute disparities much more than relative disparities.

For this reason, it has been hypothesized that the visual system might need to contain a neural representation of relative disparities to allow precise discrimination of small differences in disparity (Neri, 2005; Neri, Bridge, & Heeger, 2004; Parker, 2007; Prince et al., 2000; Thomas, Cumming, & Parker, 2002). This hypothesis is supported by behavioral evidence. Both humans and monkeys are able to discriminate much smaller differences in the disparity of a target when that target is located close to a reference disparity (Prince et al., 2000; Westheimer, 1979), suggesting that neurons somewhere in the visual system locally compute relative disparities.

To determine whether cortical neurons represent absolute or relative disparities, Thomas and colleagues (2002) devised a test in which two patches of random-dot stereogram are presented in a concentric (center-surround) arrangement and the disparity of both the center and surround are varied in a fully crossed design (figure 33.4A). For a neuron that responds solely to the relative disparity between center and surround, the disparity tuning curve in response to the center disparity should shift with the disparity of the surround (figure 33.4B). In contrast, no such shift would be observed for a neuron tuned to absolute disparity (figure 33.4C). In their ground-breaking study, Thomas and colleagues (2002) found that neurons in area V1 signal absolute disparity, confirming a previous report (Cumming & Parker, 1999), whereas a subset of neurons in area V2 signal relative disparity.

More recently, we have performed similar tests in area MT and have found that MT neurons generally signal absolute disparities, similar to neurons in V1 (Uka & DeAngelis, 2006). This is seen as a distribution of shift ratios (figure 33.4D) that cluster around zero, whereas neurons that are tuned for relative disparity would have a shift ratio near one. Fujita and colleagues have recently performed the same test in area V4 and have reported that the majority of V4 neurons have shift ratios greater than zero, with some neurons representing purely relative disparity while many others show an intermediate representation (shift ratios near 0.5) (Umeda, Tanabe, & Fujita, 2007). These comparative results across areas are summarized in figure 33.4E (modified from Umeda et al., 2007).

The finding of relative disparity tuning in area V4 but not MT suggests that the ventral processing stream may emphasize relative disparities, whereas the dorsal stream emphasizes absolute disparities. These results are consistent with the results of a functional magnetic resonance imaging (fMRI) study in humans that used an adaptation paradigm to test for sensitivity of different cortical areas to absolute and relative disparities (Neri et al., 2004). This study found that ventral stream areas adapt to both absolute and relative

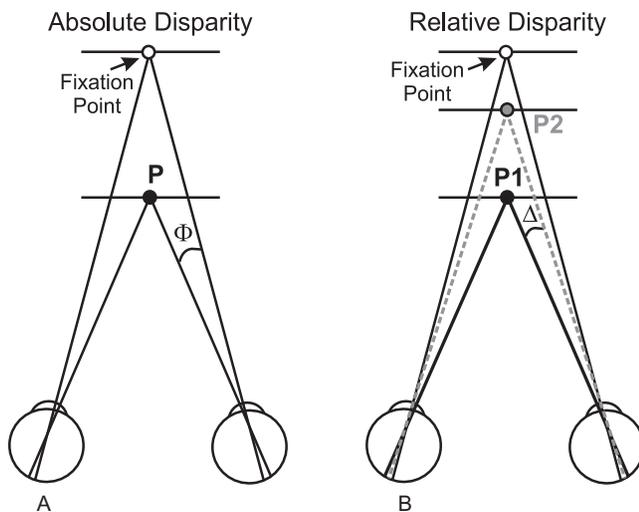

FIGURE 33.3 Geometric definitions of absolute disparity (Φ , left) and relative disparity (Δ , right). Each panel shows a top-down view in which the eyes are converged on a fixation point (open symbol) directly in front of the subject. (A) The absolute disparity of point P refers to the angle, Φ , subtended by this point relative to the point of fixation. Thus when the subject converges or diverges their eyes to focus at a different distance, the absolute disparity of point P will change. (B) The relative disparity of point P1 with respect to point P2 is given by the angle, Δ , which is the difference between the absolute disparities of these two points. If the eyes converge at a different distance, the relative disparity between P1 and P2 will be unchanged.

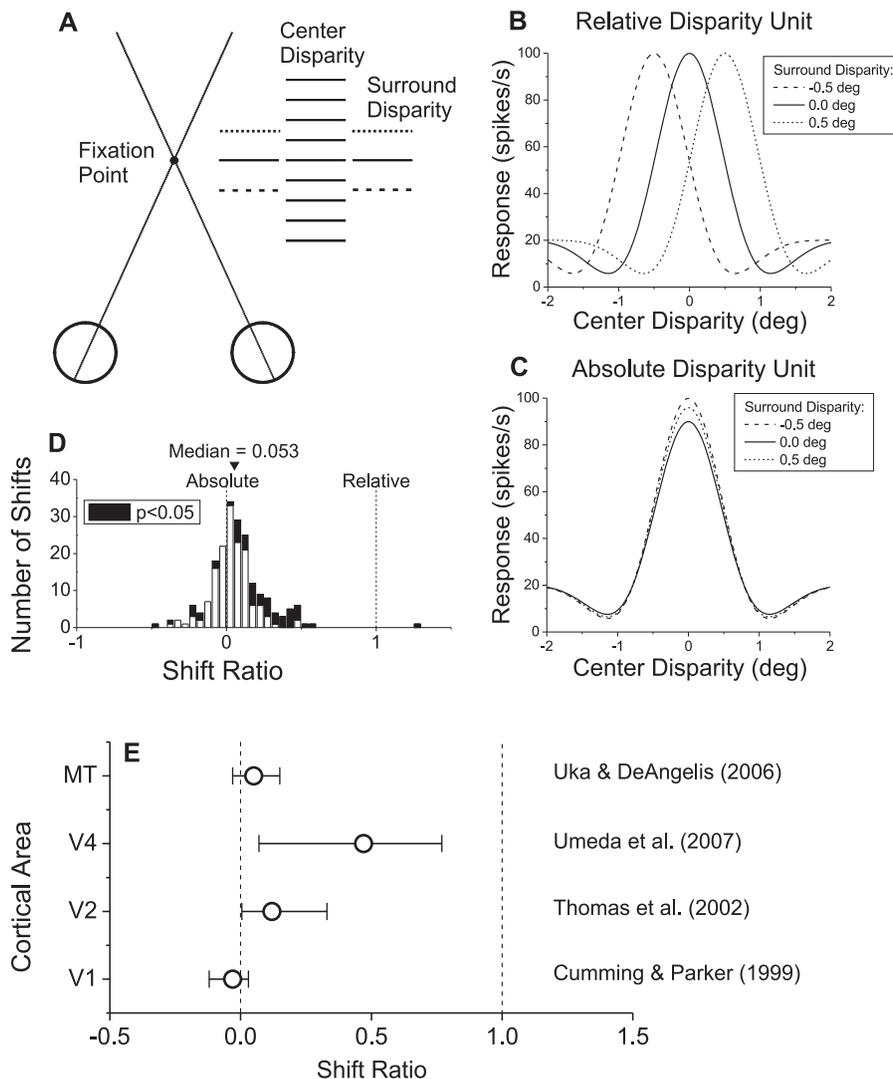

FIGURE 33.4 Stimuli, predicted outcomes, and results of tests for absolute versus relative disparity tuning. (A) Top-down view of the stimulus configuration, consisting of a center patch of dots and a surrounding annulus. All combinations of nine center disparities and three to five surround disparities were presented in randomly interleaved trials. (B) If a neuron signals relative disparity, the disparity tuning in response to the center patch should shift horizontally by an amount equal to the change in surround disparity. (C) If a neuron signals absolute disparity, no shifts should be seen, although some amplitude variations may occur. (D) Distribution of shift ratios for 201 pairings of surround disparities from 45 MT neurons. The shift ratio is computed as the horizontal shift of the tuning curve divided by the difference between the two surround disparities. Thus an idealized relative disparity neuron will have a shift ratio of 1, and an idealized absolute disparity neuron will have

a shift ratio of 0. Note that shift ratios from area MT are distributed around zero, with a slight but significant bias toward positive values (sign test, $p < 0.0001$). Solid bars denote shift ratios that were significantly different from zero (sequential F -test, $p < 0.05$; 52/201 shifts). (Panels A–D were adapted from Uka & DeAngelis, 2006.) (E) Summary of results of the relative disparity test across studies of four different visual areas, adapted from Umeda and colleagues (2007). For each area, the open symbol indicates the median shift ratio, and the error bars represent the range from the 25th percentile to the 75th percentile. Data were compiled by Umeda and colleagues (2007) across four studies, as indicated. Note that relative disparity selectivity increases from V1 to V2 to V4 (presumably reflecting ascension of the ventral stream), whereas neurons in area MT show absolute disparity tuning.

disparities, whereas dorsal stream areas adapt only to absolute disparities. Together, these findings from monkeys and humans are consistent with the hypothesis that the ventral stream carries out sophisticated disparity computations to represent the 3D shape of objects, whereas the dorsal stream carries out somewhat simpler computations that are aimed at computing the location of objects in 3D space and also perhaps at representing the coarse layout of surfaces in the scene (see also Neri, 2005; Parker, 2007). Along these lines, we might expect area MT to contribute to coarse judgments of depth based on absolute disparities but not to fine judgments of depth based on relative disparities. We shall return to this prediction later.

CODING OF THREE-DIMENSIONAL SURFACE ORIENTATION Most physiological studies of disparity processing in visual cortex have examined responses to frontoparallel planar surfaces that vary in distance from the observer. In natural scenes, however, binocular disparity varies smoothly across surfaces that can have many possible 3D orientations relative to the observer. Spatial gradients of disparity thus provide powerful cues to 3D object shape and 3D surface orientation (Howard & Rogers, 1995, 2002). The simplest form of spatial variation involves monotonic gradients of disparity across space that specify the 3D orientation of planar surfaces. As illustrated in figure 33.5A, the 3D orientation of planar surfaces can be parameterized in terms of *tilt* and *slant*.

Whereas human perception of tilt and slant defined by gradients of disparity has been studied considerably (Howard & Rogers, 2002; Sedgwick, 1986), only recently have physiologists examined how cortical neurons represent 3D orientation. In area MT, we have tested neurons with random-dot stereograms containing linear gradients of disparity, and we have found that more than half of MT neurons show significant tuning for the tilt of planar surfaces (Nguyenkim & DeAngelis, 2003). This property is shown for an example neuron in figure 33.5C. The neuron shows broad but robust tuning for the tilt of the surface, and this tuning is maintained across variations in the mean disparity of the stimulus. This insensitivity to variations in mean disparity around the peak of the cell's disparity-tuning curve (figure 33.5B) indicates that tilt selectivity cannot be simply explained by miscentering the gradient stimulus on the receptive field or by receptive field inhomogeneities (Nguyenkim & DeAngelis, 2003).

Interestingly, this finding of invariant tilt tuning suggests that MT neurons possess some form of relative disparity selectivity when tested with disparity gradients, whereas they do not show this property when tested with concentric edges (figure 33.4D). Although the mechanisms underlying this difference remain unclear, this comparison highlights the important point that there is no single unique test for relative

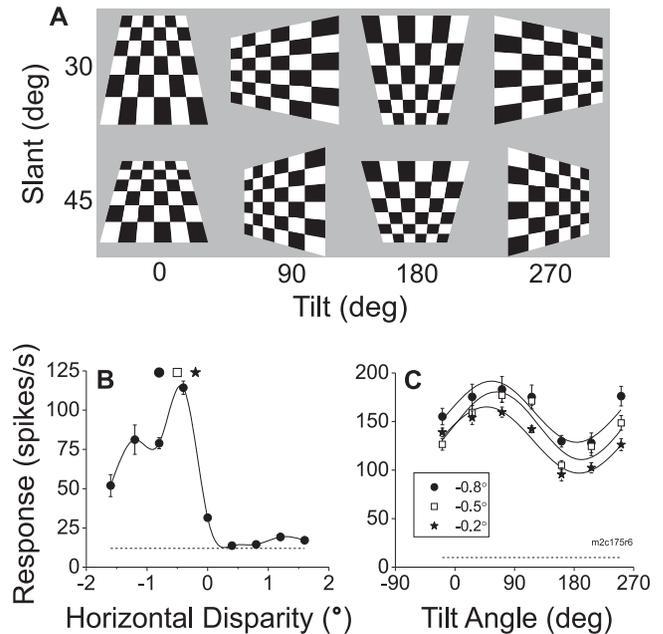

FIGURE 33.5 Schematic illustration of the 3D orientation of planar surfaces, parameterized by tilt and slant, as well as data from a tilt-selective MT neuron. (A) *Tilt* refers to the axis around which the plane is rotated away from frontoparallel, and *slant* defines the amount by which the plane is rotated. Zero slant corresponds to a frontoparallel surface for which the tilt is undefined. In this illustration, tilt and slant are defined by perspective and texture gradient cues. In the MT experiments, surface orientation was defined solely by the direction and magnitude of a linear gradient of horizontal disparity in a random-dot stereogram. (B) A conventional disparity-tuning curve for an MT neuron measured using random-dot stereograms (slant was zero, and different uniform horizontal disparities were applied). Mean responses \pm standard error are shown for each stimulus disparity, along with a spline fit. Symbols at the top indicate the three mean disparities used for testing tilt selectivity with disparity gradients. (C) Tilt-tuning curves for the same MT neuron are shown at three different mean disparities (coded by symbol shape). Smooth curves indicate the best fits of the modified sinusoid function. Note that the neuron shows clear tuning for the tilt of a planar random-dot surface and that this tilt tuning is robust to changes in the mean disparity of the stimulus. (Adapted from Nguyenkim & DeAngelis, 2003.)

disparity selectivity, and it might depend greatly on stimulus geometry. In MT, tilt tuning is seen only for stimuli that are presented at large slants (generally >45 degrees) (Nguyenkim & DeAngelis, 2003), suggesting that 3D orientation coding in MT involves a rather coarse mechanism that is more likely to be involved in providing the basic layout of surfaces in the scene rather than in analyzing the details of 3D shape (see also Parker, 2007), though this remains to be tested further.

Selectivity for 3D surface orientation has also been observed in other cortical areas. In the caudal intraparietal area (CIP), Sakata and colleagues have described neurons that signal the tilt of surfaces defined by disparity gradients

(Taira et al., 2000; Tsutsui et al., 2001, 2002). Hinkle and Connor (2002) have also described neurons in area V4 that are selective for the 3D orientation of bar stimuli, although this selectivity could be driven more by orientation differences between the eyes because the same neurons did not generally show tuning for tilt and slant in disparity-defined random-dot surfaces. In the inferotemporal (IT) cortex, Janssen, Orban, and colleagues have conducted an impressive series of studies showing that IT neurons have selectivity for 3D shape defined by gradients of disparity as well as boundary cues (Janssen, Vogels, Liu, & Orban, 2001; Janssen et al., 1999, 2000a, 2000b). Thus it is clear that neurons at the upper levels of both the dorsal and ventral processing streams make use of spatial gradients of disparity to extract information about both 3D shape and object/surface orientation. However, much remains to be learned, and the respective roles of these areas in perception of 3D structure are still not well understood.

In addition to disparity gradients, the 3D orientation of surfaces may be specified by gradients of texture, velocity, or luminance (shading) (Sedgwick, 1986). Neurons that are closely involved in perception of 3D orientation may thus be expected to signal tilt and slant based on multiple cues. In area CIP, Sakata's group has shown that neurons signal tilt by gradients in both disparity and texture (presented separately), and that their tilt preferences for the two cues are often well matched (Tsutsui et al., 2002). However, no published study has examined how neurons respond to multiple cues to 3D orientation presented simultaneously. In area MT, neurons have previously been shown to exhibit selectivity for tilt defined by velocity gradients (Treue & Andersen, 1996; Xiao, Marcar, Raiguel, & Orban, 1997). We have presented preliminary evidence that individual MT neurons are tuned for tilt defined by both disparity and velocity gradients (Nguyenkim & DeAngelis, 2004). Some neurons have matched tilt tuning for the two cues, whereas others do not. Responses to both cues together appear to be well predicted by weighted linear summation of the individual cue responses (unpublished). It is currently unclear whether MT plays a role in perceptual cue integration for 3D orientation perception or whether it may simply be an early stage at which disparity and velocity gradients begin to interact. A recent fMRI study, performed by using behaving macaques, suggests that there is considerable additional processing of 3D surface orientation and shape in regions of the intraparietal sulcus that receive inputs from area MT (Durand et al., 2007).

Linking neural representation to function: Roles of area MT in coarse and fine depth discrimination

As was discussed above, binocular disparity information is now known to be represented across a broad range of visual

cortical areas in primates. There seem to be two main possibilities for why this might occur: (1) Disparity processing is highly distributed such that most aspects of depth perception depend on simultaneous activation of many regions of cortex, or (2) different cortical areas have specialized representations of binocular disparity that are well suited to some tasks but not others. In the latter scenario, depth perception in a specific context could depend on only a small subset of visual areas or perhaps only on a subset of neurons within a single visual area.

Thus far, we have already discussed evidence that favors the notion of specialized representations, namely, that ventral stream areas appear to represent the precise relative disparity information that is thought to be needed for fine depth discrimination and 3D shape perception, whereas the dorsal stream appears to emphasize absolute disparities (Thomas et al., 2002; Uka & DeAngelis, 2006; Umeda et al., 2007). Moreover, it is likely that we know about only a small fraction of the differences between areas and between visual streams at this time. If different cortical areas are specialized to perform different tasks, then it should be possible to identify experimentally the areas and/or neurons that contribute to performance of a particular task. In recent years, my laboratory has attempted to clarify the functional roles of area MT in stereo vision by performing a series of experiments with monkeys that were trained to perform tasks that were chosen to reveal differences in function that may be linked to absolute versus relative disparity representations.

COARSE AND FINE DEPTH DISCRIMINATION TASKS To probe depth perception based on coarse absolute disparity information, we trained monkeys to perform the Coarse task illustrated in figure 33.6A. In this task, dots in a stereogram are divided into two groups with adjustable percentages: "signal" dots are all presented at the same disparity in each trial, which is near or far relative to the plane of fixation; "noise" dots are given random disparities in each trial such that they form a 3D cloud. The monkey's task is to judge whether the net depth of the stimulus is near or far and to make a saccadic eye movement to signal its choice (Uka & DeAngelis, 2003). Across trials, the relative proportion of signal and noise dots, indexed by a variable called *binocular correlation*, is varied to manipulate task difficulty. Figure 33.7A (open symbols) shows a psychometric function for one monkey in a typical session. Note that in this task, the monkeys always discriminated between two signal disparities (e.g., -0.4° and $+0.4^\circ$) that were on opposite sides of zero disparity and were well above stereoacuity thresholds.

To assay the contribution of neurons to depth perception based on fine relative disparities, we also trained monkeys to perform the Fine task depicted in figure 33.6B. In this task, a bipartite center-surround random-dot stereogram is presented, and the monkey is required to report whether

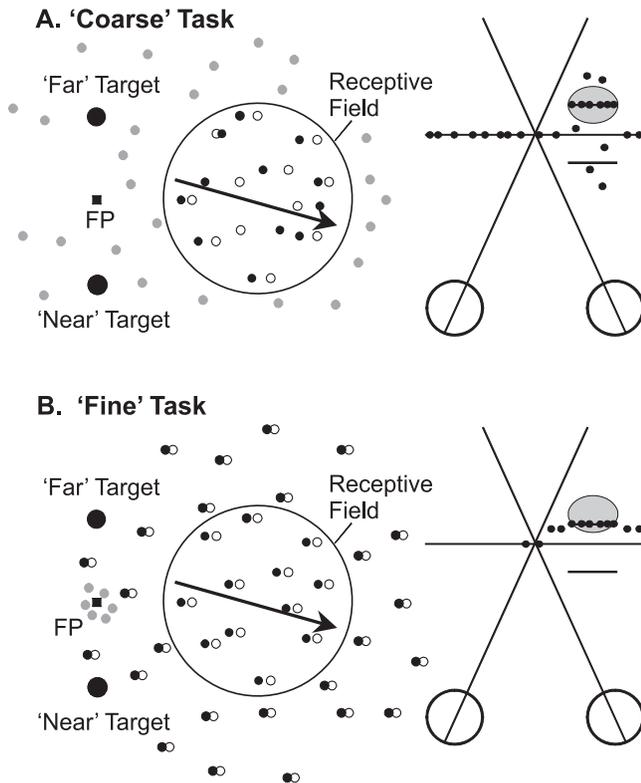

FIGURE 33.6 Schematic illustration of two depth discrimination tasks used to study functional contributions of area MT. (A) The Coarse task. A random-dot stereogram was presented over the receptive field (RF), and dots moved at the neuron's preferred velocity (arrow). Solid and open dots represent left and right half-images, respectively. The background was covered with dynamic zero-disparity dots (gray). Saccade targets were located 5° above and below the fixation point, corresponding to far and near choices, respectively. The strength of the depth signal was adjusted by varying binocular correlation. At 50% binocular correlation (right), half of the dots within the receptive field were presented at either the neuron's preferred disparity (horizontal line inside gray oval) or the disparity that elicited a minimal response (null disparity). The remaining dots had random disparities. (B) The Fine task. A bipartite (center-surround) random-dot stereogram was presented. The center patch covered the RF and contained dots moving at the preferred velocity (arrow). The surrounding annulus contained stationary dots presented (in most cases) at a nonzero disparity. A small patch of zero-disparity dots (gray) surrounded the fixation point to help anchor vergence. The monkey reported whether the center patch was in front of or behind the surround patch, and task difficulty was manipulated by finely varying the center disparity around the surround disparity. (Adapted from Uka & DeAngelis, 2006.)

the center patch of dots appears near or far relative to the surround (Uka & DeAngelis, 2006). Both center and surround are presented without noise (100% binocular correlation), and the relative disparity between center and surround is varied in fine steps to measure psychophysical threshold (e.g., figure 33.7B). Importantly, the absolute disparities of

the center and surround could be both far or both near, such that monkeys are required to judge relative depth to achieve high performance on this task.

Given that neurons in area MT have fairly broad disparity tuning and do not represent relative disparities in a center-surround configuration (figure 33.4D), we hypothesized that MT would play a significant role in the Coarse task but not the Fine task. This was assessed by using a variety of approaches, as described below (see also Parker & Newsome, 1998).

NEURONAL VERSUS BEHAVIORAL SENSITIVITY From the distributions of firing rates measured during performance of the tasks, we used ROC analysis to compute the ability of an ideal observer to discriminate depth on the basis of the responses of each single MT neuron (Uka & DeAngelis, 2003, 2006). Example neurometric functions for representative MT neurons are shown in figure 33.7A for the Coarse task and figure 33.7B for the Fine task (solid symbols). These neurometric functions describe how the performance of the ideal observer increases as the differences between near and far stimuli become more salient. From each such data set, we computed psychophysical and neuronal thresholds as the stimulus values at which performance reaches 82% correct. Thus each experiment yielded both a psychophysical and a neuronal threshold that could be compared quantitatively.

Figure 33.7C shows the distribution of the ratio of neuronal-to-psychophysical thresholds for 104 MT neurons studied during the Coarse task (Uka & DeAngelis, 2003). While threshold ratios span a wide range, the average ratio (geometric mean = 0.98) was close to unity, indicating that the average MT neuron could discriminate coarse disparities in noise with sensitivity comparable to that of the animal. This result is very similar to that found by Newsome and colleagues for direction discrimination in MT (Britten, Newsome, Shadlen, Celebrini, & Movshon, 1992). Thus neuronal sensitivity suggests that area MT could account for coarse depth discrimination.

Figure 33.7D shows the analogous distribution of threshold ratios for 98 neurons that were tested during the Fine task. In this case, the average threshold ratio (1.76) is closer to 2, indicating that MT neurons are not as sensitive as the animal is. However, the best neurons could be sufficiently sensitive to account for behavior.

CHOICE PROBABILITIES In a psychophysical task performed around threshold, the same (weak) stimulus gives rise to different perceptual reports, as well as different neural responses, across repeated trials. By testing for a correlation between the trial-to-trial fluctuations in perceptual reports and neural responses (choice probability, or CP), it may be possible to identify neurons that are functionally coupled to perceptual decisions (Britten et al., 1996; Krug, 2004). An advantage of this approach is that it affords single-cell

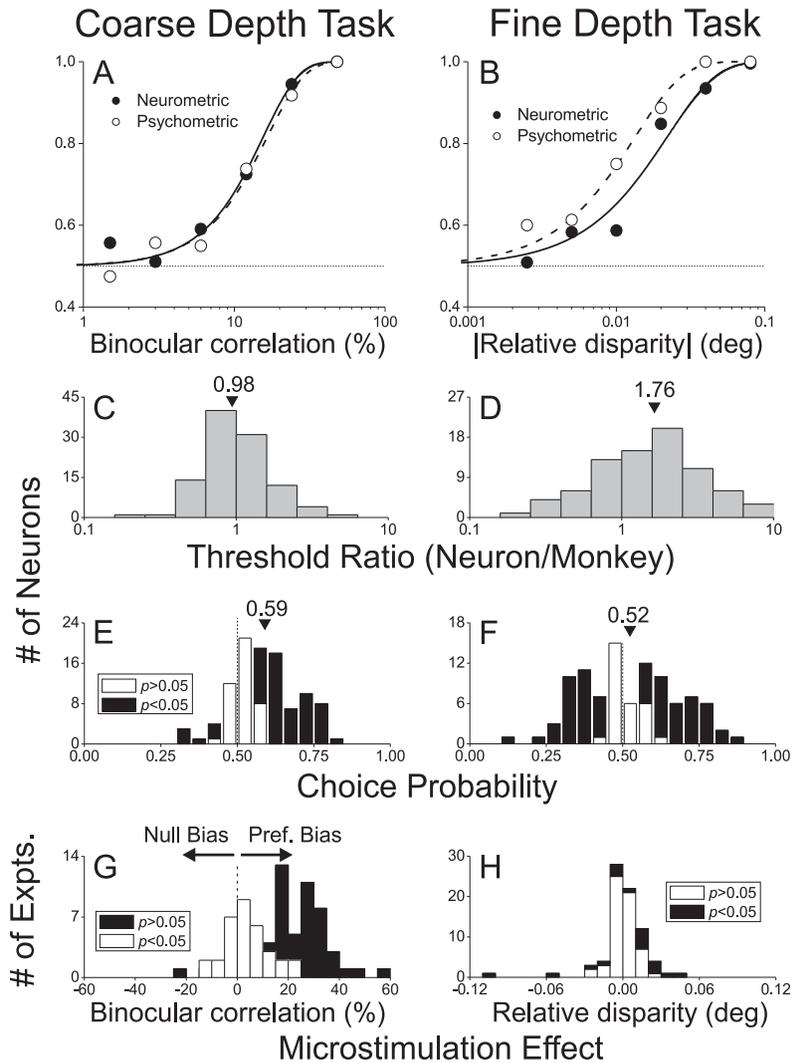

FIGURE 33.7 Summary of single-unit and microstimulation experiments performed in area MT using both the Coarse (left column) and Fine (right column) depth tasks. (A) Example data from a typical experiment using the Coarse task. The psychometric function (open symbols) shows the monkey's percentage of correct responses as a function of binocular correlation. The neurometric function (solid symbols) shows the predicted performance of an ideal observer based on the responses of a single MT neuron. In this example, the neuron has sensitivity nearly identical to that of the animal. (B) Example psychometric and neurometric functions for a typical experiment using the Fine task. In this case, performance is plotted as a function of the (unsigned) relative disparity between center and surround stimuli. In this experiment, the neuron is about half as sensitive as the monkey. (C) Distribution of the ratio of neuronal/psychophysical threshold ratios across 104 recording sessions involving the Coarse task. The geometric mean ratio was 0.98 (arrowhead). (D) Distribution of neuronal/psychophysical threshold ratios for the Fine task ($N = 98$). The

geometric mean was 1.76. (E) Distribution of choice probabilities for the Coarse task ($N = 104$). CP values significantly different from 0.5 are indicated by solid bars. Note that most CP values are greater than 0.5. (F) Distribution of choice probabilities for the Fine task ($N = 98$). (G) Distribution of microstimulation effects for the Coarse task ($N = 78$). Solid bars denote individually significant effects. Positive values indicate biases toward the preferred disparity of the stimulated neurons, as measured in units of percent binocular correlation for the Coarse task. Most experiments produced a significant preferred bias. (H) Distribution of microstimulation effects for the Fine task ($N = 46$). Shifts are now measured in degrees of relative disparity. Most experiments produced no effect, and the median shift was not significantly different from zero. (Panels A and C were adapted from Uka & DeAngelis, 2003; panel E was adapted from Uka & DeAngelis, 2004; panel G was adapted from DeAngelis et al., 1998, including additional data; panels D and H were adapted from Uka & DeAngelis, 2006. Data in panel F are previously unpublished.)

resolution and allows one to relate the tuning properties of neurons to behavior. Although CPs simply reflect a correlation between neurons and perceptual decisions, there is evidence to suggest that significant CPs reflect a functional contribution of neurons. For example, CPs in area MT and V2 have been shown to vary according to the tuning properties of neurons in a manner that appears to reflect the animal's (suboptimal) strategy for solving the task (Nienborg & Cumming, 2007; Uka & DeAngelis, 2004).

We have used CPs as another means to evaluate the role of area MT in the Coarse and Fine depth tasks. As is shown in figure 33.7E, most MT neurons have CPs greater than 0.5 in the Coarse task, which indicates that the neurons tend to fire more strongly when the monkey reports that an ambiguous (e.g., 0% binocular correlation) stimulus matches the preferred depth of the neuron (Uka & DeAngelis, 2004). The average CP is 0.59, which is significantly greater than 0.5 ($p \ll 0.001$). This means that an ideal observer could predict the choices of a monkey with 59% correct accuracy by monitoring the activity of an average MT neuron. This finding is consistent with the notion that area MT makes an important contribution to the Coarse depth task.

Recently, Nienborg and Cumming (2006, 2007) have examined responses of neurons in area V1 and V2 during performance of a task that is nearly identical to our Coarse task. Interestingly, neurons in V2 show CPs comparable to those we have seen in MT, whereas neurons in V1 do not. Thus trial-to-trial variability in the representation of disparities in V1 does not seem to be linked to depth percepts, whereas similar variability in V2 and MT does correlate with percepts. It is currently unclear whether neurons in V2 with significant CPs in the Coarse task reside in the portions of V2 (the thick stripes) that project heavily to area MT. However, a recent study shows that inactivating areas V2 and V3 by cooling substantially reduces disparity selectivity in MT (Ponce, Lomber, & Born, 2008), consistent with the idea that MT may inherit at least some of its disparity selectivity from V2.

It is also interesting to note that CPs for the Coarse task have thus far been seen in areas (V2, MT) that contain a topographic representation of disparity (Chen et al., 2008; DeAngelis & Newsome, 1999) but not in area V1, which lacks such a map for disparity (Chen et al., 2008; Prince et al., 2002). It will be fascinating to see whether a correlation between functional architecture and CPs emerges as similar data are collected from additional tasks in additional areas.

Figure 33.7F shows analogous CP data from area MT during performance of the Fine task (unpublished data). In this case, the mean CP is 0.52, which is not significantly different from 0.5 ($p > 0.05$). This may be taken as evidence that area MT does not contribute to performance of the Fine task. Note, however, that many more neurons than expected

by chance have CPs significantly different from 0.5 (solid bars). These neurons are significantly correlated with perceptual decisions about fine relative disparities, but there is no consistent relationship between firing rates and choices across the population. Thus, on average, one cannot reliably predict a monkey's choices by measuring the response of MT neurons in the Fine task. However, this pattern of results remains somewhat puzzling, as it is not clear why MT neurons should show significant CPs that are both lower and higher than 0.5. If one speculates that CPs arise through a top-down signal from decision circuitry to MT, then it might be that these top-down signals cannot correctly target MT neurons because MT does not contain a topographically organized representation of relative disparities.

CAUSAL MANIPULATIONS Choice probabilities establish a correlation between neural responses and perceptual decisions (independent of the physical stimulus) but do not establish a causal contribution of those neurons to perception. To further link a particular visual area with specific functions in 3D vision, we need to directly manipulate neural activity during performance of relevant tasks. One approach involves electrical microstimulation (Cohen & Newsome, 2004; Salzman, Murasugi, Britten, & Newsome, 1992; Tehovnik, 1996), in which weak biphasic current is passed through a recording electrode to activate a cluster of neurons near the tip of the electrode whose tuning properties are known. By placing an electrode into the midst of one of the disparity columns in area MT (DeAngelis & Newsome, 1999), we have used microstimulation to probe the causal contribution of area MT to the Coarse and Fine tasks.

In the Coarse task, microstimulation systematically biases monkeys' judgments of depth, as summarized in figure 33.7G (see also DeAngelis, Cumming, & Newsome, 1998; Uka & DeAngelis, 2006). A positive effect of microstimulation means, for example, that electrical stimulation of a cluster of near-tuned neurons causes the monkey to report stimuli as "near" significantly more often than occurs when microstimulation is withheld. Note that microstimulation frequently produced statistically significant effects in the Coarse task (solid bars in figure 33.7G) and that the vast majority of these effects were positive. Only one experiment produced a microstimulation effect in the "wrong" direction, such that stimulation of a cluster of far-preferring neurons produced a bias in favor of perceiving near. This finding, coupled with the sensitivity and CP analyses described above, establishes that area MT contributes to coarse depth perception based on absolute disparities.

Figure 33.7H shows comparable microstimulation results for the Fine task. In this case, the median effect of microstimulation is not significantly different from zero ($p = 0.88$). Moreover, when microstimulation did produce a significant

effect (solid bars) it was frequently in the wrong direction (Uka & DeAngelis, 2006). Thus we found no clear evidence that area MT contributes to performance of the Fine task, consistent with the hypothesis that MT's role in this task is limited because it does not carry a representation of fine relative disparities.

Together, these findings establish a satisfying connection between the neural representation of disparities in area MT (absolute, not relative) and the functional contributions of area MT to depth perception. These findings are consistent with the idea that different visual areas contain specialized representations of binocular disparity signals, and specifically support the notion that the dorsal stream (including MT) mainly processes absolute disparity information to localize objects in 3D space, whereas the ventral stream emphasizes computations of relative disparity for the purpose of 3D shape perception (Neri, 2005; Parker, 2007). Our findings spur hope that similar studies, employing a variety of tasks in a variety of areas, will be capable of revealing a functional taxonomy of visual cortical areas with respect to their roles in 3D vision. This remains to be seen, but there is reason to be optimistic that we can understand the selective contributions of individual areas to this overall process.

A weakness of the comparisons that we have made between the Coarse and Fine tasks is that several aspects of the stimuli differ between the two tasks, including absolute versus relative disparities, the range of disparities, inclusion of noise, and presence of segmentation boundaries. Going forward, it will be important to design stimuli that allow us to test perception of depth versus 3D shape while eliminating or minimizing differences in other stimulus variables.

Selectivity for depth from motion parallax in area MT

As is illustrated in figure 33.1B, self-movement (e.g., moving one's head from side to side) generally causes the image of an object to move on the retina, and both the direction and speed of image motion depend on the location of the object in depth. This depth-dependent image motion is called *motion parallax*. Motion parallax can also arise because of the movement of objects that have depth structure, but here I shall focus on motion parallax resulting from observer movement.

In a ground-breaking series of psychophysical studies, Rogers and Graham placed subjects in an apparatus with a sliding chin rest and asked them to move their heads back and forth while fixating a point on a video display with one eye (Graham & Rogers, 1982; Rogers & Graham, 1979, 1982; Rogers, 1993; Rogers & Rogers, 1992). As the subjects moved their heads (and correspondingly their eyes), the experimenters updated the positions of dots in the display such that their motion was consistent with the presence of a

corrugated surface in depth. Despite the lack of disparity or any pictorial depth cues, this arrangement produces a compelling sensation of depth. Studies have shown that depth perception from motion parallax is almost as precise as from disparity (Rogers & Graham, 1982). Moreover, psychophysical studies suggest that disparity and motion parallax processing may share a common neural substrate. Depth percepts from disparity and motion parallax can cross-adapt each other, and combining the cues together can yield substantial improvements in sensitivity over either cue alone (Bradshaw & Rogers, 1996).

Whereas perception of depth from motion parallax has been well studied (Nawrot & Joyce, 2006), the neural basis for this behavior has remained unknown. Surely, a neural substrate for depth from motion parallax requires neurons that are selective for the direction and speed of visual motion, and such neurons can be found in many visual areas in primates beginning with V1. It has also been suggested that neurons with relative motion selectivity (Cao & Schiller, 2003; Li, Lei, & Yao, 1999) might provide important inputs to such a depth mechanism. However, the presence of visual motion selectivity alone, even relative motion selectivity, does not establish that neurons can provide depth information based on motion parallax.

How, then, can we identify neurons that participate in computing depth from motion parallax? Our approach has been to exploit the fact that visual image motion itself can be depth-sign ambiguous, as illustrated in figures 33.8A and 33.8B. In the absence of pictorial depth cues such as occlusion and size, the retinal image motion generated by near and far objects (having equivalent disparities) is identical except for the phase of the motion relative to movement of the subject's head (or eyes). Objects that are nearer than the point of fixation will move in the direction opposite to head motion, whereas far objects will move in the same direction as the head. Thus in the absence of pictorial cues, neurons must combine retinal image motion with extraretinal signals related to head and/or eye movement to determine the sign of depth from motion parallax. We designed random-dot stimuli that were depth-sign ambiguous by removing all pictorial cues to depth (stimulus size, dot size and density, occlusion, etc.) (Nadler, Angelaki, & DeAngelis, 2008). If neurons simply respond to visual image motion, then they cannot differentiate between our near and far stimuli. On the other hand, if neurons receive extraretinal inputs that specify the phase of visual image motion relative to head or eye motion, then they may become selective for depth sign.

Figures 33.8C and 33.8D illustrate responses from a neuron recorded from area MT under monocular viewing conditions (ipsilateral eye occluded). In the Retinal Motion condition (figure 33.8C), the visual stimulus simulated a

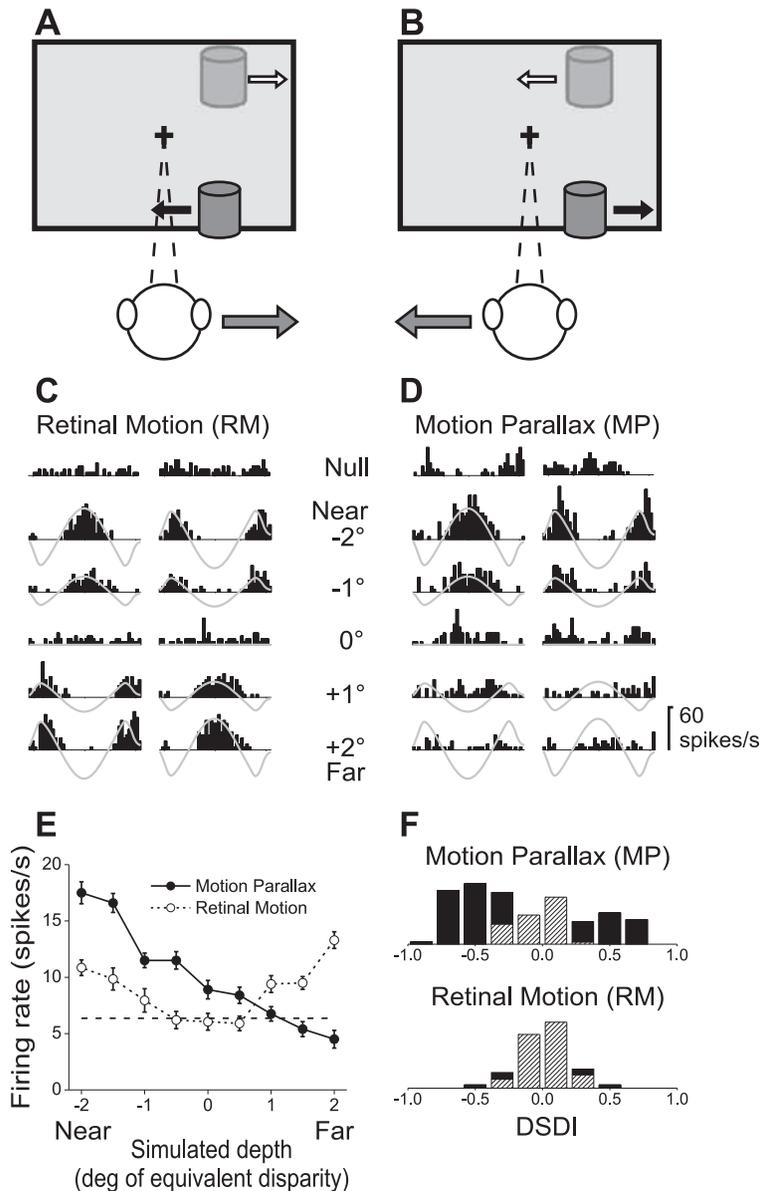

FIGURE 33.8 Motion parallax, depth-sign ambiguity, and a potential solution in area MT. (*A*, *B*) Schematic illustration of how head translation generates motion parallax. As the head moves to the right (*A*), the image of a near object (bottom cylinder) moves to the left while the image of a far object (top cylinder) moves to the right. The opposite occurs during head movement to the left (*B*). If pictorial cues to depth, such as size and occlusion, are not present, the only difference between the near and far objects is how the phase of their visual motion relates to that of the observer's motion. Thus an extraretinal signal related to head movement or eye movement is needed to determine depth sign from motion parallax. (*C*, *D*) Responses of an example neuron showing selectivity for depth from motion parallax. Panel *C* shows PSTHs in response five simulated depths during the Retinal Motion (RM) condition, in which the monkey remains stationary while visual motion simulates depth. One column of poststimulus time histograms (PSTHs) is shown for each starting phase of simulated observer motion. Traces of the retinal velocity of the stimulus within the receptive field are superimposed in gray, with peaks representing image motion in the preferred direction and troughs indicating motion in the anti-

preferred direction. The depth-sign ambiguity in the retinal motion stimulus is reflected in the responses of this MT neuron, which are symmetric in strength about 0° in the RM condition. PSTHs labeled "Null" represent responses obtained when no random dots were presented in the receptive field. (*D*) Responses of the same neuron in the Motion Parallax (MP) condition. Note that responses to near stimuli are accentuated, while responses to far stimuli are suppressed relative to the RM condition. A modest modulation can be seen in the "Null" condition, reflecting a response associated with head/eye movement. (*E*) Depth-tuning curves for the same neuron are shown for the RM (open symbols) and MP (solid symbols) conditions. This neuron prefers near stimuli in the MP condition. DSDI values are -0.73 and 0.15 in the MP and RM conditions, respectively. Error bars are standard errors. The dashed horizontal line represents spontaneous activity. (*F*) Distributions of the depth sign discrimination index (DSDI) are shown for 144 MT neurons tested during the MP (top) and RM (bottom) conditions. DSDI values significantly different from zero are indicated by solid bars. (Adapted from Nadler et al., 2008.)

surface placed at different distances from the animal, but the monkey's head and eyes remained still such that the stimulus was depth-sign ambiguous. In this case, the neuron responds more strongly as stimuli lie farther away from the plane of fixation (which has an equivalent disparity of 0°), but the response is very similar for stimuli of opposite depth signs (e.g., -1° versus $+1^\circ$). This can be seen further when the data are plotted as a tuning curve (figure 33.8E, open symbols). The tuning curve for the Retinal Motion condition is symmetric around 0° , indicating that the neuron does not distinguish the sign of depth. In the Motion Parallax condition (figure 33.8D), the trained animal is translated side-to-side by a motion platform while maintaining ocular fixation on a world-fixed target. Thus as the animal is translated rightward, it makes a smooth leftward eye movement to keep focused on the fixation target. The retinal image motion in this condition is the same as that generated (artificially) in the Retinal Motion condition, but now the monkey's movement provides extraretinal signals. Under this condition, the same neuron now responds more strongly to near stimuli and more weakly to far stimuli (figure 33.8D). Plotted as a tuning curve (figure 33.8E, filled symbols), the responses show a clear preference for near stimuli over far stimuli in the Motion Parallax condition. Since retinal image motion was the same in these two stimulus conditions (see Nadler et al., 2008, for details), this difference in tuning must arise from the interaction between extraretinal signals and visual motion information.

Figure 33.8F summarizes results from a population of 144 MT neurons, as quantified by a depth sign discrimination index (DSDI), which takes on values near -1 for strong near tuning, values near 0 for no depth-sign tuning, and values near $+1$ for strong far tuning. In the Motion Parallax condition, DSDI values take on a broad range of values (figure 33.8F, top), and $\sim 70\%$ of MT neurons show significant selectivity for depth sign based on motion parallax (filled bars). In the Retinal Motion condition, the distribution of DSDI is more tightly centered around zero with few cells passing the test for significance (figure 33.8F, bottom). Thus a majority of neurons in area MT are able to combine visual image motion with extraretinal signals to compute the sign of depth based on motion parallax.

These findings provide the first clear evidence for a population of neurons that represent depth from motion parallax and establish a second major neural mechanism of depth perception in the brain. These results also raise many questions for additional research:

1. Is selectivity for depth-sign created de novo in area MT, or does it occur at earlier stages in the visual pathways? This can be tested by performing similar experiments in areas that provide substantial inputs to MT, namely, V1, V2, and V3.

2. Are the depth-sign signals in area MT actually used by monkeys to judge depth from motion parallax? Alternatively, these findings could be a by-product of interactions between visual and extraretinal signals for some other purpose. This can be tested by training monkeys to discriminate depth sign from motion parallax and by applying electrical microstimulation to MT.

3. What is the extraretinal signal that generates depth-sign selectivity in MT? By the design of our Motion Parallax condition, it could be either a vestibular (or proprioceptive) signal related to head movement or a smooth eye movement signal. Our preliminary results (Nadler, Angelaki, & DeAngelis, 2006) indicate that the extraretinal signal is a smooth eye movement command, as has been suggested by human psychophysical studies (Naji & Freeman, 2004; Nawrot, 2003a, 2003b; Nawrot & Joyce, 2006).

4. How is the depth tuning of MT neurons for motion parallax related to their selectivity for binocular disparity? Our preliminary results (unpublished) show that some MT neurons have matched depth-sign preferences for disparity and motion parallax (e.g., both near or both far), whereas other neurons curiously have opposite depth-sign preferences for the two cues. The former neurons could play a role in integrating the two depth cues to achieve greater perceptual sensitivity, as demonstrated psychophysically (Bradshaw & Rogers, 1996). The role of the latter neurons with opposite preferences is unclear, but they might play a role in distinguishing retinal image motion that arises because of the depth structure of the scene from image motion that arises due to the motion of objects in the scene. Area MT should provide an excellent model system for studying how depth cues are integrated both perceptually and neurally.

Conclusion

The past decade has seen a dramatic increase in our knowledge of the neural basis of depth perception. New cortical areas have been found to represent binocular disparities, new representations of both disparity and motion parallax information have been uncovered, the first topographic maps of binocular disparity have been measured, and the first causal links between neural activity and depth perception have been established. During this period, the collective efforts of several laboratories have established 3D vision as a highly productive model system for understanding the neural basis of perception. Here I have summarized some of the work from area MT that has contributed to our current knowledge and that helps to provide a roadmap for future studies. One of the great remaining challenges, which is applicable to almost any sensory or motor system, is to understand how neural representations are specialized in different areas and how these specialized representations guide behavior.

ACKNOWLEDGMENTS I thank several former members of my laboratory who have conducted the research described here, including Takanori Uka, Ben Palanca, Jerry Nguyenkim, and Jacob Nadler. I also thank Dora Angelaki, who has been a valuable collaborator on some of this work.

34 Multisensory Integration for Heading Perception in Macaque Visual Cortex

DORA E. ANGELAKI, YONG GU, AND GREGORY C. DEANGELIS

ABSTRACT The brain combines different sources of sensory information to optimize perception. Information from different sensory modalities is often seamlessly integrated into a unified percept with improved behavioral performance. Here we summarize the first attempt to understand the neural basis of multisensory cue integration in the context of a behavioral task in which cues are combined according to statistically optimal predictions. We describe multisensory cue integration in the macaque extrastriate visual cortex using a simple heading discrimination task in which monkeys were asked to judge their direction of self-motion using visual (optic flow) and extraretinal (vestibular) cues. Results suggest that rhesus macaques and humans use similar computational principles for combining multiple sensory cues and that these principles can be accounted for by the properties of individual neurons in multisensory cortical areas.

A fundamental aspect of our sensory experience is that information from different modalities is often seamlessly integrated into a unified percept. Examples of multisensory cue integration include a number of well-known sensory illusions, such as the McGurk effect (McGurk & MacDonald, 1976), ventriloquism (Bertelson & Radeau, 1981), and the illusion of self-motion triggered by visual motion, known as *vection* (Previc, 1992). Combining sensory inputs can improve behavioral performance on a number of tasks, including object recognition (Molholm, Ritter, Javitt, & Foxe, 2004), stimulus detection (Frassinetti, Bolognini, & Ladavas, 2002), and localization (Hairston et al., 2003).

Recently, understanding of multisensory integration has gained momentum, as several psychophysical studies have shown that human observers combine sensory cues according to a statistically optimal weighting scheme derived from Bayesian probability theory (Mamassian, Landy, & Moloney, 2002; Kersten, Mamassian, & Yuille, 2004; Knill & Pouget,

2004). The basic concept is that there exists inherent uncertainty in the information that is available to our senses, as well as in the encoding of that information by our sensory apparatus. Consequently, perceptual judgments should rely on computations involving conditional probability density functions, sensory likelihoods, and prior probability functions that are consistent with the Bayesian framework (Clark & Yuille, 1990; Knill & Pouget, 2004). Assuming Gaussian distributions of the underlying sensory information, independent noise sources, and broad prior distributions relative to the individual cue likelihoods, it is predicted that an optimal estimator (in terms of minimizing the variance of the final estimate) will combine sensory information using a rule that weights the cues according to their reliability (Ernst & Banks, 2002; Knill & Saunders, 2003). As a result, weaker cues would have a lower weighting in the bimodal estimate. In addition, the variance of the bimodal estimate (σ_{bi}^2 , as assessed by psychophysical performance) should be lower than that of the unimodal estimates, $\sigma_{1,2}^2$, as given by (see figure 34.1)

$$\sigma_{bi}^2 = \sigma_1^2 * \sigma_2^2 / (\sigma_1^2 + \sigma_2^2) \quad (1)$$

These predictions have been tested in human psychophysical experiments using a number of different paradigms (van Beers, Sittig, & Gon, 1999; Ernst & Banks, 2002; Knill & Saunders, 2003; Alais & Burr, 2004; Hillis, Watt, Landy, & Banks, 2004). The basic result is remarkably consistent across studies: When combining multiple sensory cues, humans perform as nearly optimal Bayesian observers. Yet no direct neural correlates of these phenomena have been available, in part owing to the lack of a suitable animal model for combined behavioral and electrophysiological experiments in the context of cue integration. Rather, studies of multisensory integration at the neuronal level have often been performed in either anesthetized or passively fixating animals, and the pioneering studies of Stein and colleagues emphasized nonlinearity (superadditivity) as the hallmark of multisensory integration (Meredith & Stein, 1983, 1986, 1996; Wallace, Wilkinson, & Stein, 1996).

DORA E. ANGELAKI and YONG GU Department of Anatomy and Neurobiology, Washington University School of Medicine, St. Louis, Missouri

GREGORY C. DEANGELIS Department of Brain and Cognitive Sciences, Center for Visual Science, University of Rochester, New York

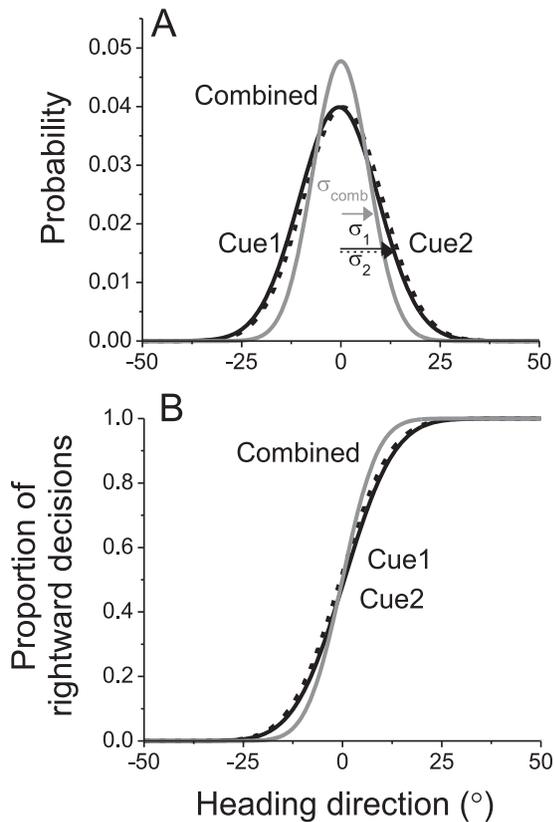

FIGURE 34.1 Schematic illustration of one of the predictions of optimal cue integration. (A) Probability density functions (sensory likelihoods) corresponding to two cues: cue 1 (solid curve, e.g., vestibular) and cue 2 (dashed curve, e.g., visual). It is predicted that the bimodal probability distribution (gray curve) will be narrower than those for the individual cues (equation 1). This improvement will be largest when the two single cues have the same standard deviation (σ). (B) Expected performance for an ideal observer judging heading on the basis of the probability distributions in panel A. In this case, the threshold in the combined (bimodal) condition is predicted to be lower than both single-cue thresholds. (Modified with permission from Ernst & Banks, 2002.)

Here we summarize the first attempt to understand the neural basis of multisensory cue integration in the context of a behavioral task in which cues are combined according to the statistically optimal predictions. We describe multisensory cue integration in the macaque extrastriate visual cortex using a simple heading discrimination task in which monkeys are asked to judge their direction of self-motion using visual (optic flow) and extraretinal (vestibular) cues (figure 34.2A).

Perception of heading from optic flow and vestibular signals

How do we perceive our direction of self-motion through space? To navigate effectively through a complex three-dimensional environment, we must accurately estimate our own motion relative to objects around us. Self-motion per-

ception is an intriguing problem in sensory integration, requiring the neural combination of visual signals (e.g., optic flow), vestibular signals regarding head motion, and perhaps somatosensory and proprioceptive cues (Dichgans & Brandt, 1974; Hlavacka, Mergner, & Schweigart, 1992; Hlavacka, Mergner, & Bolha, 1996). In particular, patterns of image motion across the retina (optic flow) can provide strong cues to self-motion, as is evidenced by the fact that optic flow alone can elicit the illusion of self-motion. As early as 1875, Ernst Mach described self-motion sensations (i.e., circular and linearvection) induced by visual stimuli. Since then, several other studies have characterized the behavioral observation that large-field optic flow stimulation induces self-motion perception (Brandt, Dichgans, & Koenig, 1973; Berthoz, Pavard, & Young, 1975; Dichgans & Brandt, 1978). Although self-motion perception generally involves the analysis of observer translation and rotation, we shall limit our scope here to translational movements. Thus the central issue we explore is how we compute our direction of heading.

Many visual psychophysical and theoretical studies have shown that optic flow provides powerful cues to heading (Gibson, 1950) and have examined how heading can be computed from optic flow (Warren, 2003). In parallel, independent information about the motion of our head or body in space can arise from the vestibular system. Specifically, vestibular signals provide information about the angular and linear accelerations of the head in space (Angelaki, 2004; Angelaki & Cullen, 2008) and thus provide important cues to self-motion estimation. A role of the vestibular system in the perception of self-motion has long been acknowledged (Guedry, 1974, 1978; Benson, Spencer, & Stott, 1986; Telford, Howard, & Ohmi, 1995).

In one such heading discrimination task, the subject experiences forward motion with a small leftward or rightward component. At the end of each trial, the task requires an eye movement to report whether the subject experienced leftward or rightward motion (figure 34.2A). Both humans (Smith, Bush, & Stone, 2002) and monkeys (Gu, DeAngelis, & Angelaki, 2007) can be quite accurate in discriminating their heading direction in the absence of optic flow, with thresholds that can be as small as 1–3 degrees during motion in darkness. These threshold values during motion in darkness are comparable to (although larger than) those described in visual heading discrimination tasks (Warren & Hannon, 1990; Royden, Banks, & Crowell, 1992; van den Berg & Brenner, 1994; Stone & Perrone, 1997). Vestibular heading thresholds increase more than ten-fold after bilateral labyrinthectomy (figure 34.2B, solid symbols), suggesting that vestibular information is critical for heading discrimination. Although some recovery was seen over the first few days postlesion, thresholds remained elevated when measured 3–6 months following the lesion (Gu et al., 2007). In contrast, labyrinthectomy had a very modest effect on visual

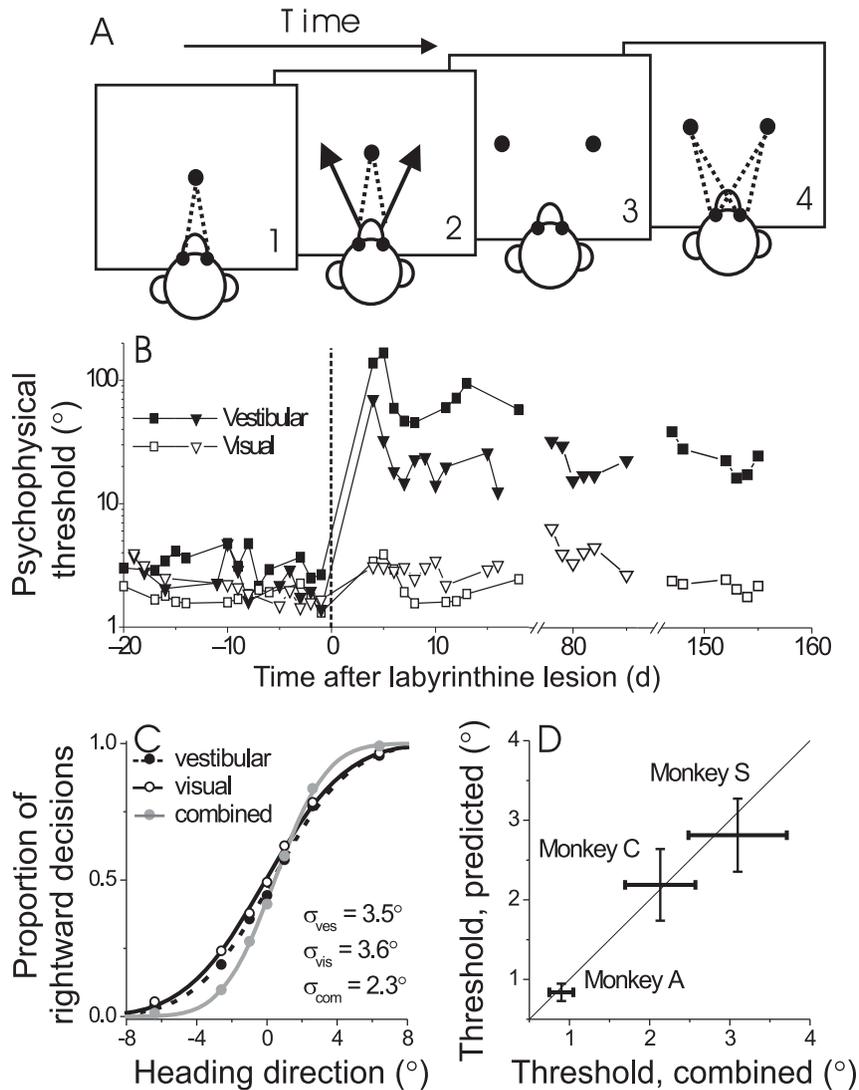

FIGURE 34.2 Heading discrimination task and behavioral performance. (A) Task layout. Monkeys were seated on a motion platform and were translated within the horizontal plane to provide vestibular stimulation. A projector mounted on the platform displayed images of a three-dimensional star field and thus provided optic flow information. After fixating a visual target, the monkey experienced forward motion with a small leftward or rightward component and subsequently reported his perceived heading (“left” versus “right”) by making a saccadic eye movement to one of two targets. (B) Daily psychophysical thresholds before and after bilateral labyrinthectomy (0 marks the day of surgery). Data obtained during the heading discrimination task in the absence of optic flow (solid

symbols) are compared with those obtained when the heading was defined exclusively by optic flow (open symbols). Data from two animals are shown with different symbols (Gu et al., 2007). (C) Comparison of behavioral performance in one animal under unimodal (vestibular: dashed curve, visual: solid curve) and bimodal (gray curve) conditions. Notice the steeper slope of the psychometric function in the combined condition as compared to the single-cue (visual and vestibular) conditions. (D) Comparison of the average psychophysical threshold obtained in the combined condition with that predicted based on statistically optimal cue integration. Data are shown for three animals. (Parts A and B replotted from Gu et al., 2007.)

heading thresholds where the animals remained stationary and heading was specified solely by optic flow (figure 34.2B, open symbols).

To test whether macaques, like humans, combine sensory cues according to a statistically optimal, Bayesian-style weighting scheme, an experiment was performed in which heading was specified not only by optic flow alone or inertial motion alone, but also by bimodal stimulation when congru-

ent visual and vestibular cues were presented together. Three stimulus conditions were randomly interleaved within a single block of trials: (1) a vestibular condition, in which heading was defined solely by inertial motion cues by translating the animal on a motion platform; (2) a visual condition, in which heading was defined solely by optic flow provided by a projector that was mounted on the platform; and (3) a combined condition consisting of congruent inertial

motion and optic flow cues. Each movement trajectory, either real (vestibular condition) or visually simulated (visual condition), had a duration of 2 s and consisted of a Gaussian velocity profile (for details, see Gu, Watkins, Angelaki, & DeAngelis, 2006).

Average behavior, in the form of psychometric functions, from one of the animals is illustrated in figure 34.2C. Note that the reliability of the individual cues was roughly equated during training by reducing the coherence of the visual motion stimulus such that visual and vestibular thresholds were approximately equal (figure 34.2C, open/solid circles and solid/dashed curves). This balancing of the two cues is crucial, as it affords the maximal opportunity to observe improvement in performance under cue combination (Ernst & Banks, 2002). In the combined condition (figure 34.2C, gray circles and curve), the monkey's heading threshold was substantially smaller, as evidenced by the steeper slope of the gray curve. If the monkey combined the two cues optimally, as predicted by Bayesian cue integration principles, thresholds should be reduced by approximately 30% under cue combination (equation 1). That bimodal behavioral thresholds are similar to the optimal cue integration predictions is illustrated in figure 34.2D for data from three animals. Thus, like humans, macaques can combine multiple sensory cues nearly optimally to improve perceptual performance.

This demonstration of near-optimal cue integration in the monkey's behavior provides a unique opportunity to search for the neural basis of Bayesian inference at the level of individual neurons and populations of neurons. In identifying candidate populations of neurons that integrate visual and vestibular signals for self-motion perception, we seek neurons that are tuned for direction of motion in optic flow fields and that carry vestibular signals related to the direction of head motion through space. As will be summarized next, such visual/vestibular convergence occurs in multiple cortical areas. In contrast, responsiveness to optic flow is generally absent in subcortical areas with vestibular-related activities, including the brain stem vestibular and deep cerebellar nuclei (Bryan, Meng, DeAngelis, & Angelaki, 2007) and primate thalamus (Meng, May, Dickman, & Angelaki, 2007). In the following, we first briefly summarize what has been previously known regarding visual/vestibular convergence in the macaque cortex; we then describe in more detail how MSTd neurons respond in the context of the multimodal heading discrimination task.

Responses of primate cortical neurons to optic flow and vestibular stimuli

Optic flow-sensitive neurons have been found in the dorsal portion of the medial superior temporal area (MSTd) (Tanaka et al., 1986; Duffy & Wurtz, 1991, 1995), ventral intraparietal area (VIP) (Schaafsma & Duysens, 1996;

Bremmer, Duhamel, Ben Hamed, & Graf, 2002; Bremmer, Klam, Duhamel, Ben Hamed, & Graf, 2002), posterior parietal cortex (7a) (Siegel & Read, 1997), and superior temporal polysensory area (STP) (Anderson & Siegel, 1999). In particular, neurons in MSTd/VIP have large visual receptive fields and are selective for optic flow patterns similar to those seen during self-motion (MSTd: Tanaka et al., 1986; Tanaka, Fukada, & Saito, 1989; Duffy & Wurtz, 1991, 1995; Bradley, Maxwell, Anderson, Banks, & Shenoy, 1996; Lappe, Bremmer, Pekel, Thiele, & Hoffmann, 1996); (VIP: Schaafsma & Duysens, 1996; Bremmer, Duhamel, et al., 2002). Importantly, electrical stimulation of MSTd or VIP has been reported to bias heading judgments that are based solely on optic flow (Britten & van Wezel, 1998, 2002; Zhang & Britten, 2003). MSTd/VIP neurons are also selective for motion in darkness, suggesting that they receive vestibular inputs (Duffy, 1998; Bremmer, Kubischek, Pekel, Lappe, & Hoffmann, 1999; Bremmer, Duhamel, et al., 2002; Schlack, Hoffmann, & Bremmer, 2002; Gu et al., 2006; Chen, Henry, DeAngelis, & Angelaki, 2007; Takahashi et al., 2007).

Using a custom-built virtual reality system, the heading selectivity of MSTd (Gu et al., 2006; Takahashi et al., 2007) and VIP (Chen et al., 2007) neurons has recently been quantified in three dimensions. Inertial motion (vestibular) signals were provided by translating a motion platform, and optic flow (visual) signals were provided by a projector that was mounted on the platform and rear-projected images onto a screen in front of the monkey. Approximately 60% of MSTd neurons were significantly tuned for heading under both the visual and vestibular stimulus conditions. These convergent MSTd cells fell into one of two groups: (1) "congruent" neurons, which had similar visual/vestibular preferred directions, thus signaled the same motion direction in three-dimensional space under both unimodal stimulus conditions, and (2) "opposite" neurons, which preferred nearly opposite directions of heading under visual and vestibular stimulus conditions (Gu et al., 2006). The response modulation of MSTd neurons during inertial motion (vestibular condition) was indeed shown to be of labyrinthine origin, as MSTd cells were no longer tuned during inertial motion following bilateral labyrinthectomy (figure 34.3) (Gu et al., 2007; Takahashi et al., 2007).

Notably, responsiveness to both visual (optic flow) and vestibular stimulation is generally not present within more traditionally considered areas of "vestibular cortex" (Fredrickson & Rubin, 1986; Fukushima, 1997; Guldin & Grusser, 1998). Three main cortical areas have been characterized as either exhibiting responses to vestibular stimulation and/or receiving short-latency vestibular signals (trisynaptic through the vestibular nuclei and the thalamus). They are (1) area 2v, located in the transition zone of areas 2, 5, and 7 within the intraparietal sulcus (Fredrickson,

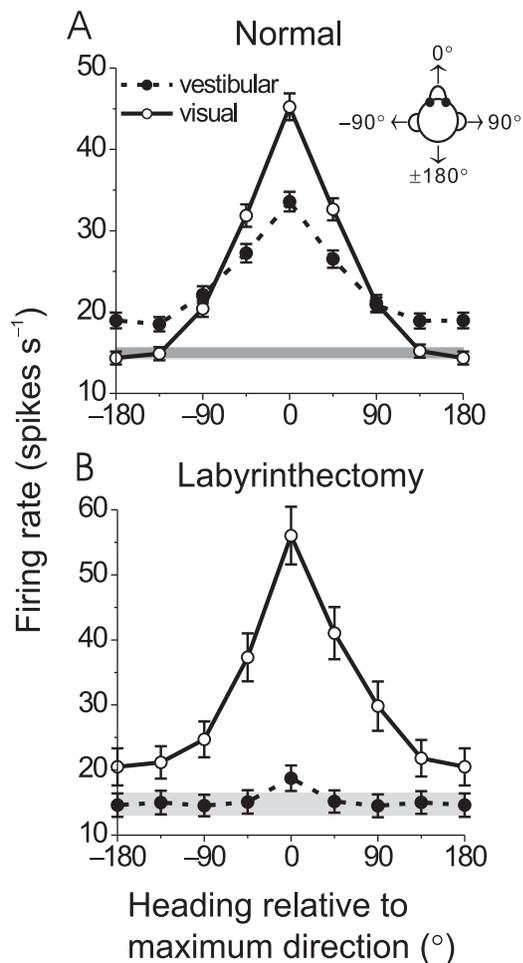

FIGURE 34.3 Comparison of visual and vestibular population tuning curves (*A*) before and (*B*) after labyrinthectomy. Visual responses (open circles and solid lines) of each neuron were shifted to align the peaks of all tuning curves at 0° prior to averaging across the population. Vestibular responses (solid circles and dashed line) were also averaged across neurons after being aligned to the vestibular maximum response direction. Gray bands in both panels indicate the average spontaneous firing rate \pm standard error. (Modified from Gu et al., 2007.)

Scheid, Figge, & Kornhuber, 1966; Schwarz & Fredrickson, 1971a, 1971b; Buttner & Buettner, 1978); (2) the parietoinular vestibular cortex, located between the auditory and secondary somatosensory cortices (Grusser, Pause, & Schreier, 1990a, 1990b); and (3) area 3a, located within the central sulcus extending into the anterior bank of the precentral gyrus (Odkvist, Schwarz, Frederickson, & Hassler, 1974; Guldin, Akbarian, & Grusser, 1992). Preliminary results suggest that these areas are unlikely to play important roles in visual/vestibular cue integration for heading perception because of the absence of responses to optic flow (Chen et al., 2006; Chen, Henry, DeAngelis, & Angelaki, 2007). Instead, the extrastriate visual cortical areas MSTd and VIP appear to be more likely candidates for visual/vestibular cue integration for heading perception.

Thus, in summary, a handful of studies have examined how cortical neurons integrate visual and vestibular signals to code heading direction. Although these studies clearly establish the presence of both visual and vestibular signals in areas MSTd and VIP, they are limited by the fact that neuronal responses during unimodal or bimodal visual/vestibular stimulation were obtained while monkeys either were passively fixating a target or were freely allowed to make eye movements in darkness. Yet to probe the neural basis of multisensory cue integration and the neural correlates of Bayesian inference, neural activity needs to be measured in the context of a behavioral task that requires the subject to report his/her perception of self-motion. To make concrete links between neural activity and self-motion perception, we must record and/or manipulate neural activity during such tasks. Next we describe such an experiment.

Responses of MSTd neurons during unimodal and bimodal variants of the heading discrimination task

Having established robust cue integration behavior in macaques (figures 34.2C and 34.2D), we recorded from single neurons in area MSTd while monkeys performed the heading discrimination task. To identify multimodal neurons, we measured heading-tuning curves in the horizontal plane under both single-cue conditions while animals maintained visual fixation. Figures 34.4A and 34.4B show data from two example multimodal neurons with clear tuning under both single-cue conditions. The neuron in figure 34.4A preferred leftward (negative) headings for both stimuli and was classified as a “congruent” cell. In contrast, the neuron in figure 34.4B preferred leftward headings under the visual condition (solid line) and rightward headings under the vestibular condition (dashed line) and was classified as an “opposite” cell. (Note that heading directions are referenced to either the real or simulated self-motion; thus similar tuning in the visual and vestibular conditions defines a congruent cell.)

Over the much narrower range of headings sampled during discrimination, the unimodal tuning of these example neurons was monotonic in all three stimulus conditions (figures 34.4C and 34.4D). For the congruent cell (figure 34.4C), heading tuning became steeper in the combined condition. In contrast, the tuning curve became flatter in the combined condition for the opposite cell (figure 34.4D). To compare neuronal and behavioral sensitivity more directly, we used signal detection theory (Green & Swets, 1966; Britten, Shadlen, Newsome, & Movshon, 1992) to quantify the ability of an ideal observer to discriminate heading on the basis of the activity of a single neuron (figures 34.4E and 34.4F, symbols). We fitted these neurometric data with cumulative Gaussian functions (figures 34.4E and 34.4F, smooth curves) and defined the neuronal threshold as the standard deviation of the Gaussian. The smaller the

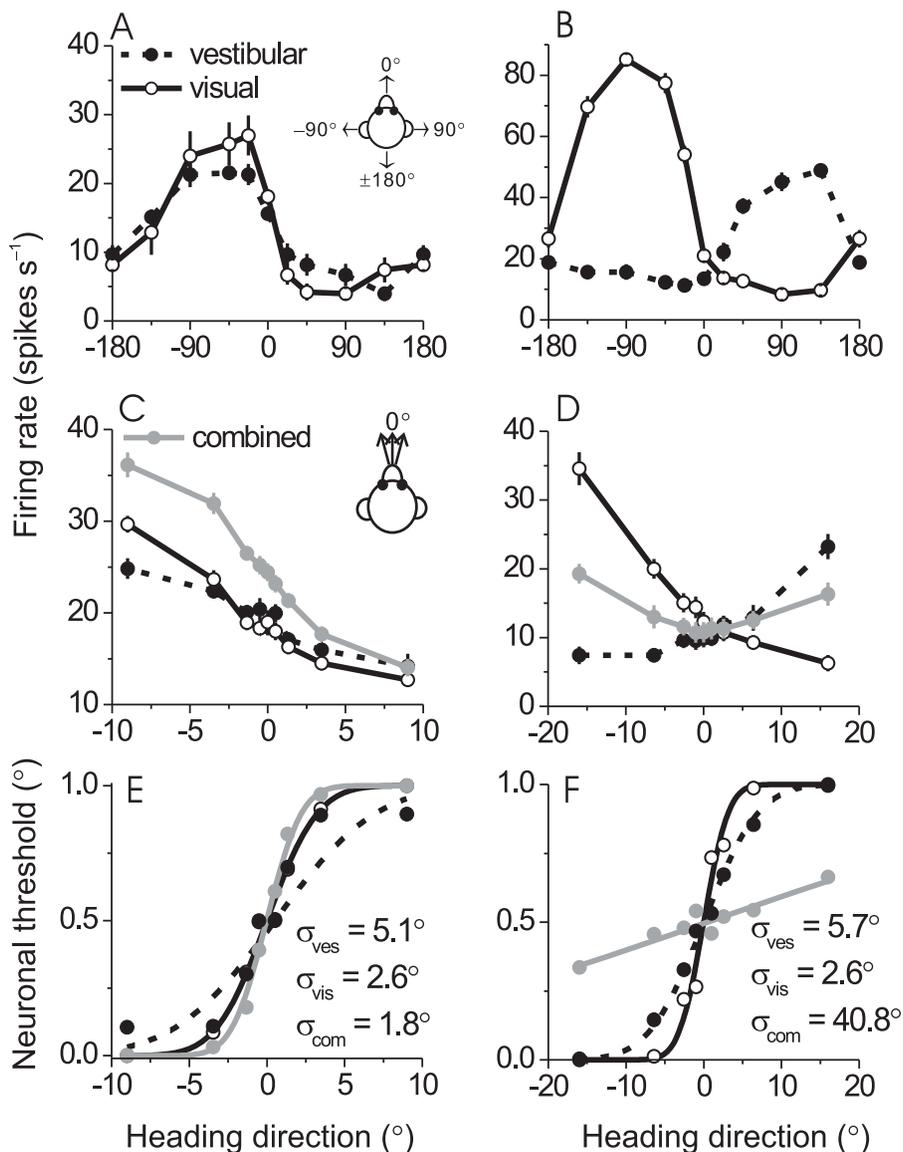

FIGURE 34.4 Heading sensitivity in area MSTd. (A, B) Heading-tuning curves of two example neurons with (A) congruent and (B) opposite visual/vestibular heading preferences. Negative angles correspond to leftward headings; positive numbers illustrate rightward directions. (C, D) Responses of the same neurons to a narrow

range of heading stimuli presented while the monkey performed the discrimination task. (E, F) Neurometric functions computed by ROC analysis for the same two neurons. Smooth curves show best-fitting cumulative Gaussian functions. (Modified from Gu et al., 2008.)

threshold, the steeper is the neurometric function and the more sensitive the neuron is to subtle variations in heading. For the congruent neuron in figure 34.4E, the neuronal threshold was smallest in the combined condition (gray symbols and lines), indicating that the neuron could discriminate smaller variations in heading when both cues were provided. In contrast, for the opposite neuron in figure 34.4F, the reverse was true: the neuron became less sensitive in the presence of both cues (gray symbols and lines).

The effect of visual/vestibular congruency on neuronal sensitivity during bimodal stimulation held across the whole

population of neurons. To summarize this dependency, a quantitative index of visual/vestibular congruency (CI) was established that ranged from +1, when visual and vestibular tuning functions have a consistent slope (figure 34.4A), to -1, when they have opposite slopes (figure 34.4B). We then computed, for each neuron, the ratio of the neuronal threshold in the combined condition to the threshold expected if neurons combine cues optimally according to equation 1. A significant correlation was seen between the ratio of combined to predicted thresholds and CI (figure 34.5A), such that neurons with large positive CIs (congruent cells, black circles) had thresholds close to the optimal

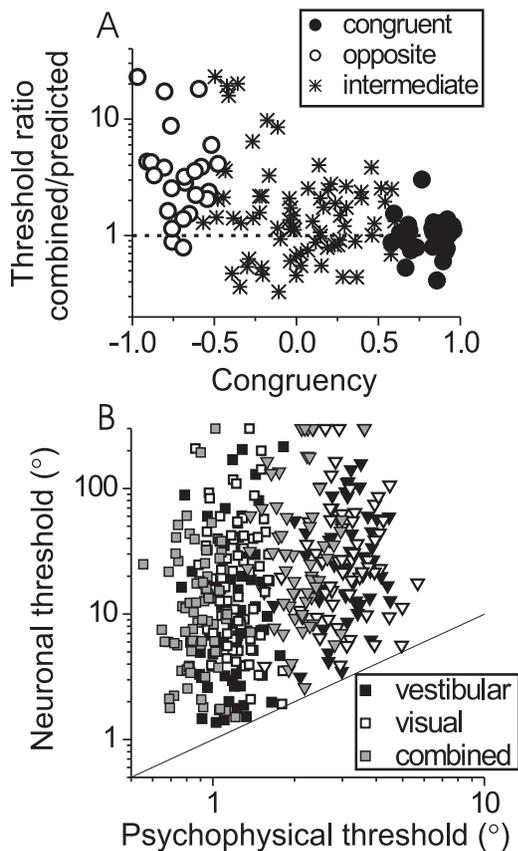

FIGURE 34.5 Neuronal sensitivity of MSTd neurons. (A) Neuronal sensitivity under cue combination depends on congruency of visual and vestibular tuning. The ordinate in this scatterplot represents the ratio of the threshold measured in the combined condition to the prediction from optimal cue integration. The abscissa represents the congruency index of heading tuning for visual and vestibular responses (CI). Asterisks denote neurons for which the CI is not significantly different from zero. At the two extremes, neurons with CIs significantly larger than 0 were defined as *congruent* cells (solid symbols), whereas neurons with CIs significantly lower than 0 were defined as *opposite* cells (open symbols). Dashed horizontal line: threshold in the combined condition is equal to the prediction. (B) Comparison of neuronal and psychophysical thresholds. Each datum represents one recording session, with solid, open, and gray symbols denoting the vestibular, visual, and combined conditions, respectively (squares and triangles represent data from two animals). Most data points lie well above the diagonal, indicating that most neurons are less sensitive than the monkeys. Only the most sensitive neurons have thresholds comparable to that of the animal. (Modified from Gu et al., 2008.)

prediction (ratios near unity). Thus the average neuronal thresholds for congruent MSTd cells followed a pattern similar to the monkeys' behavior. In contrast, combined thresholds for opposite cells were generally much higher than predicted from optimal cue integration (figure 34.5A, open circles), indicating that these neurons became less sensitive during cue combination.

Notably, only the most sensitive neurons rivaled behavioral performance, whereas most neurons were substantially

less sensitive than the animal's behavior, and this was true under both unimodal and bimodal stimulation (figure 34.5B). To perform the task based on MSTd activity, the monkey must therefore either pool responses across many neurons or rely more heavily on the most sensitive neurons (Parker & Newsome, 1998). Note that the stimulus range in our task was not tailored to the tuning of individual neurons, such that many neurons have large thresholds mainly because the tuning curve was flat over the range of headings tested during discrimination.

Correlations with behavioral choice

If monkeys rely on area MSTd for heading discrimination, the results of figure 34.5A suggest that they selectively monitor the activity of congruent cells and not opposite cells. To test this hypothesis, we computed choice probabilities (CPs) (Britten, Newsome, Shadlen, Celebrini, & Movshon, 1996) to quantify whether trial-to-trial fluctuations in neural firing rates were correlated with fluctuations in the monkeys' perceptual decisions (for a constant physical stimulus). A significant CP greater than 0.5 indicates that the monkey tends to choose the neuron's preferred sign of heading (leftward versus rightward) when the neuron fires more strongly. Such a result is thought to reflect a functional link between the neuron and perception (Britten et al., 1996; Parker & Newsome, 1998; Krug, 2004). Notably, although MSTd is classically considered visual cortex, vestibular CPs were significantly larger than chance (Gu et al., 2007). Moreover, vestibular signals were consistently correlated with heading percepts irrespective of congruency (figure 34.6A).

In contrast, perhaps surprisingly, CPs were overall smaller under the visual and combined conditions (0.52 in both cases, compared to 0.55 for the vestibular condition). These CPs, when averaged across the whole MSTd population, are small because, like neuronal thresholds, CPs in the visual and combined conditions depend on congruency (figures 34.6B and 34.6C). Specifically, congruent cells tended to have positive CPs (>0.5), and opposite cells tended to have negative CPs (<0.5) or CPs near zero. Paradoxically, neurons with a significant CP less than 0.5 increase their firing rates when the monkey chooses their nonpreferred direction. Note that because the description of visual CPs as larger or smaller than 0.5 is based on visual response tuning, opposite MSTd neurons would consistently have positive (>0.5) CPs when expressed relative to the cell's vestibular preference. This finding suggests that visual responses may be decoded relative to the vestibular preference of the neurons. Perhaps most important, congruent cells were much more strongly correlated with monkeys' heading judgments in the combined condition than were opposite cells, consistent with the idea that the animals might have selectively monitored congruent cells to achieve near-optimal cue integration.

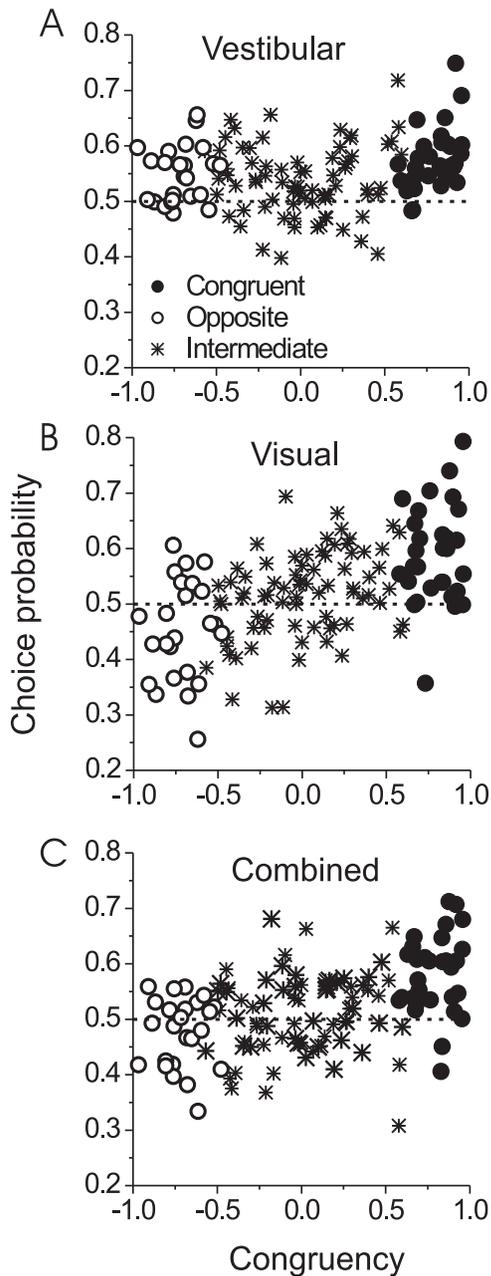

FIGURE 34.6 Correlations between MSTd responses and perceptual decisions depend on congruency of tuning. Choice probability (CP) data are plotted as a function of congruency index (CI) for each MSTd neuron tested in the (A) vestibular, (B) visual, and (C) combined conditions. Congruent, opposite, and intermediate neurons are classified as in figure 34.5. (Modified from Gu et al., 2008.)

In summary, by simultaneously monitoring neural activity and behavior, it has been possible to study neural mechanisms of multisensory processing under conditions in which cue integration is known to take place perceptually. In addition to demonstrating near-optimal cue integration by monkeys, a population of neurons has been identified in area MSTd that could account for improvement in psycho-

physical performance under cue combination. These findings implicate area MSTd in sensory integration for heading perception and establish an excellent model system for studying the detailed mechanisms by which neurons combine different sensory signals and dynamically reweight these signals to optimize performance as the reliability of cues varies (Knill & Pouget, 2004). However, because the reliability of the visual and vestibular cues was not varied in these experiments, it is currently unclear whether monkeys and MSTd neurons dynamically reweight these cues, as predicted by statistically optimal cue integration schemes. While experiments are currently underway to test this very important prediction of Bayesian cue integration in trained animals (Fetsch, Angelaki, & DeAngelis, 2007), we next summarize results from a simpler experiment in which the reliability of the visual cue was varied during neural recordings in a passively fixating animal (Morgan, DeAngelis, & Angelaki, 2008). This experiment sought to characterize the mathematical rule by which MSTd neurons combine their visual and vestibular inputs. Specifically, we asked whether bimodal responses in MSTd are well fit by weighted linear sums of unimodal responses or whether a nonlinear combination rule is required. Moreover, we asked whether the weights that neurons apply to these cues change with the relative reliabilities of the two cues.

Dependence on cue reliability

As a first step to investigate how cue reliability modulates visual/vestibular cue integration, we compared unimodal responses to eight evenly spaced directions (45 degrees apart) in the horizontal plane with bimodal responses to the 64 possible combinations of these eight vestibular and visual headings, including eight congruent and 56 incongruent (cue-conflict) presentations. In all conditions, monkeys were simply required to maintain fixation during stimulus presentation. For each unimodal stimulus (visual and vestibular), tuning curves were constructed by plotting the mean response versus heading direction, as illustrated for an example congruent cell in figure 34.7 (tuning curves along the left ordinate and abscissa). For the bimodal stimuli, in which each response is associated with both a vestibular heading and a visual heading, responses have been illustrated as two-dimensional contour maps with vestibular heading along the abscissa and visual heading along the ordinate (figure 34.7). At 100% visual coherence, bimodal responses often more strongly reflected the visual unimodal tuning preference, as indicated by the horizontal band of high firing rates (figure 34.7A).

Lowering visual coherence, by reducing the proportion of dots carrying the motion signal (Takahashi et al., 2007; Morgan et al., 2008), altered both the unimodal visual responses and the pattern of bimodal responses (figures 34.7B and 34.7C). In both cases, the visual heading tuning

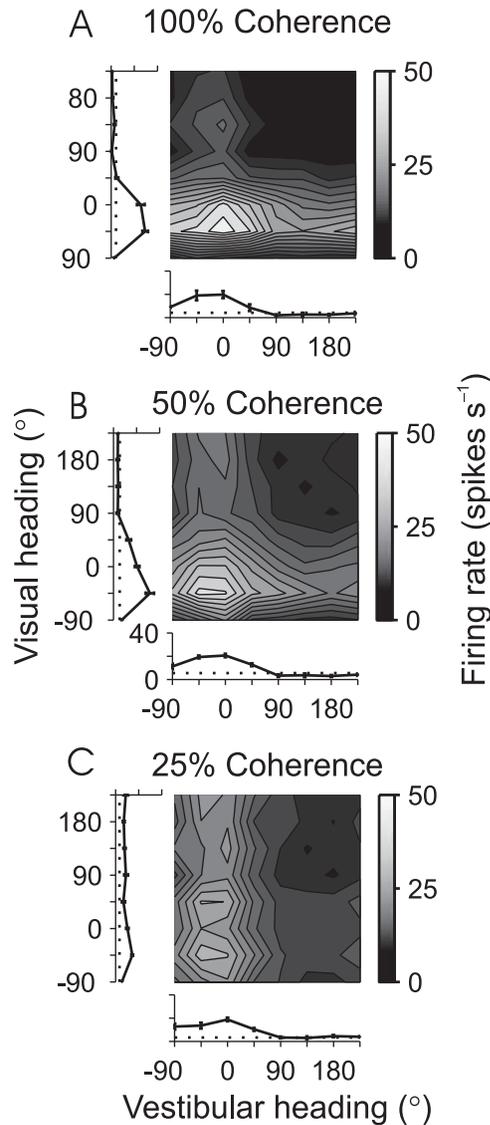

FIGURE 34.7 Comparison of unimodal and bimodal tuning for a congruent MSTd cell, tested at three motion coherences. Grayscale maps show mean firing rates as a function of vestibular and visual headings in the bimodal condition (including all 64 possible combinations of eight visual headings and eight vestibular headings). Tuning curves along the left and bottom margins show mean (\pm standard error of the mean) firing rates versus heading for the unimodal visual and vestibular conditions, respectively. (A) Bimodal responses at 100% coherence are visually dominated. (B) Bimodal responses at 50% coherence show a balanced contribution of visual and vestibular cues. (C) At 25% coherence, bimodal responses appear to be dominated by the vestibular input. (Replotted with permission from Morgan et al., 2008.)

(tuning curve along ordinate) remained similar in shape and heading preference, but the peak-to-trough response modulation was reduced at 50% and 25% coherence. Simultaneously, the transition from visual dominance to vestibular dominance is clearly evident in the bimodal responses as a function of coherence. Although visually dominated at

100% coherence (horizontal band in figure 34.7A), bimodal responses became progressively more influenced by the vestibular cue as coherence was reduced. At 50% coherence, the presence of a clear symmetric peak suggests well-matched visual and vestibular contributions to the bimodal response (figure 34.7B). As visual coherence was further reduced to 25%, vestibular dominance is observed, the bimodal response taking the form of a vertical band aligned with the vestibular heading preference (figure 34.7C).

Bimodal responses were adequately fit by a weighted linear sum of responses from the vestibular and visual conditions, with weights w_{visual} and $w_{\text{vestibular}}$ describing the strength of the contributions of each unimodal input to the bimodal response (Morgan et al., 2008). Given that the relative influences of the two cues on the bimodal response changes with motion coherence, as shown in figure 34.7, an important question then arises: Do the weights with which each neuron combines its vestibular and visual inputs remain fixed as coherence changes, the decreased visual influence in the bimodal tuning being simply due to the weaker visual responses at lower coherences? Alternatively, do the weights given to the vestibular and visual inputs change with the relative reliabilities of the two cues? In the former scenario, the multisensory combination rule used by MSTd neurons is independent of cue reliability, whereas in the latter scenario, neurons modify their combination rules when the quality of the sensory cues changes. Quantitative analyses support the latter possibility. In particular, as compared to 100% coherence, vestibular weights at 50% coherence shifted toward larger values (figure 34.8A), and visual weights shifted toward smaller values (figure 34.8B). This result is further illustrated for neurons recorded at multiple coherences: Visual weights increased, whereas vestibular weights declined with increasing motion coherence (figures 34.8C and 34.8D).

These results, showing that MSTd neurons give less weight to their visual inputs when optic flow is degraded by reducing motion coherence, might contribute to the observation in human psychophysical studies that the influence of a cue depends on the relative reliability of that cue compared to others (Ernst & Banks, 2002; Battaglia, Jacobs, & Aslin, 2003; Alais & Burr, 2004). However, we cannot yet speak to the temporal dynamics of this reweighting because we presented different motion coherences in separate blocks of trials. Further experiments are necessary to investigate whether neurons reweight their inputs on a trial-by-trial basis.

Conclusion

The past decade has seen a dramatic increase in our understanding of the computational principles that characterize human multisensory perception. Yet little is currently known about the neural mechanisms that underlie probabilistic

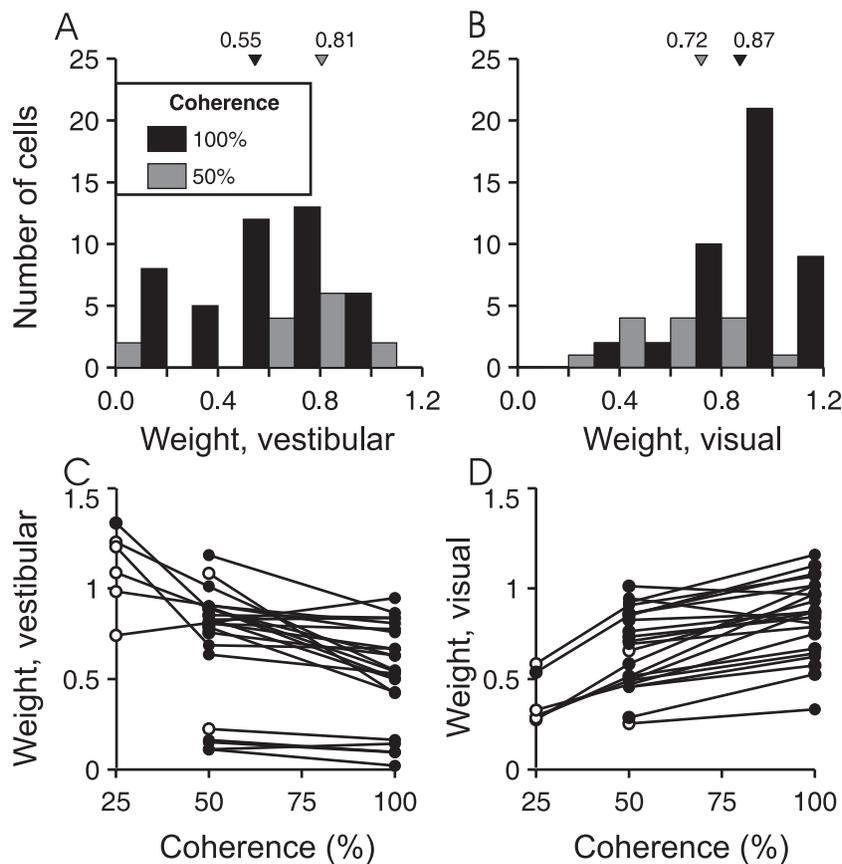

FIGURE 34.8 Dependence of vestibular and visual weights on visual motion coherence. Vestibular and visual weights for each MSTd neuron were derived from linear fits to bimodal responses like those in figure 34.7. (A, B) Histograms of vestibular and visual weights computed from data at 100% (black) and 50% (gray) coher-

ence. Triangles are plotted at the medians. (C, D) Vestibular and visual weights are plotted as a function of motion coherence. Data points are coded by the significance of unimodal visual tuning (open versus solid circles). (Replotted with permission from Morgan et al., 2008.)

multisensory integration and Bayesian inference in general. Here, we have summarized recent findings of neurons in extrastriate visual cortex that might mediate visual/vestibular cue integration for heading perception. Although some critical experiments have not yet been conducted, results to date suggest that rhesus macaques and humans use similar computational principles for combining multiple sensory cues and that these principles may be accounted for by the properties of individual neurons in multisensory cortical areas. Multiple questions remain: How distributed are these representations of multisensory integration at the neuronal level? What are the mechanisms by which neurons reweight their inputs according to reliability? Are the responses of sensory cells consistent with the encoding of probability distributions? Finally, how are these sensory signals read out from population responses, and how much of the necessary computations take place in sensory representations versus decision-making networks?

35 Visual Stability during Saccadic Eye Movements

CONCETTA MORRONE AND DAVID BURR

ABSTRACT We frequently reposition our gaze by making rapid ballistic eye movements called *saccades* to position the fovea on objects of interest. While the strategy is highly efficient for the visual system, allowing it to analyze the whole visual field with the high resolution of the fovea, it poses several problems for perception. Saccades cause rapid, large-field motion on the retina, potentially confusable with large-field motion in the external world. They also change the relationship between external space and retina position, confounding information about visual direction. Much effort has been made in recent years to attempt to understand the effects of saccades on visual function. Electrophysiological, imaging, and psychophysical evidence suggests that saccades trigger two distinct neural processes: a suppression of visual sensitivity, specific to motion analysis, probably mediated by the magnocellular pathway, and a gross perceptual distortion of visual space just before the repositioning of gaze. While our knowledge of how the visual system copes with the potentially damaging effects of continual saccadic eye movements has increased considerably over the past few decades, many interesting avenues of research remain open.

Vision is always clear and stable, despite continual saccadic eye movements, that is, ballistic movements of the eyes that reposition our gaze two to three times a second. Saccades may be made deliberately, but normally they are automatic and pass unnoticed. An observer at a sporting event, someone conversing with a companion, or a person reading a book usually makes many saccades without knowing that they have occurred. Not only does the actual movement of the eyes escape notice; so too does the motion of images as they sweep across the retina and the fact that gaze itself has been repositioned. The world seems to stay put. Comparable image motion that is produced externally, rather than by movements of the observer's own eyes, has an alarming effect on the observer's sense of stability. The problem of visual stability is an old one that has fascinated many scientists, including Descartes, von Helmholtz, Mach, and Sherrington, and indeed goes back at least to the 11th-century Persian scholar Alhazen: "For if the eye moves in front of visible

objects while they are being contemplated, the form of every one of the objects facing the eye . . . will move on the eyes as the latter moves. But sight has become accustomed to the motion of the objects' forms on its surface when the objects are stationary, and therefore does not judge the objects to be in motion" (Alhazen, 1083). But only recently have the tools become available to monitor eye movements accurately and to measure their effects qualitatively.

The problem of visual stability can be broadly divided into three separate issues: Why we do not perceive the *motion* of the retinal image produced as the eye sweeps over the visual field? How do we cope dynamically "on-line" with the continual changes in the retinal image produced by each saccade? How (and where) do we construct a stable *spatiotopic* representation of the world centered in real-world external coordinates from the successive "snapshots" of each fixation? Although the problem of visual stability is far from solved, tantalizing progress has been made over the last few years, some of which will be highlighted in this chapter.

Saccadic suppression

Part of the general problem of visual stability is why the fast motion of the retinal image generated the movement of the eyes completely escapes notice. Comparable wide-field motion generated externally is highly visible and somewhat disturbing (Burr, Holt, Johnstone, & Ross, 1982). It has long been suspected that vision is somehow suppressed during saccades (Holt, 1903), but the nature of the suppression has remained elusive. Now it is clear that the suppression is neither a "central anaesthesia" of the visual system (Holt, 1903), nor a "gray-out of the world" due to fast motion (Campbell & Wurtz, 1978; Dodge, 1900; Woodworth, 1906), as this motion is actually visible—extremely so at low spatial frequencies (Burr & Ross, 1982). What happens is that some stimuli are actively suppressed by saccades while others are not. Stimuli of low spatial frequencies are very difficult to detect if flashed just prior to a saccade, while stimuli of high spatial frequencies remain equally visible (Burr et al., 1982; Volkmann, Riggs, White, & Moore, 1978). *Equiluminant* stimuli (varying in color but not luminance) are not suppressed during saccades and can even be enhanced (Burr,

CONCETTA MORRONE Department of Physiological Sciences, University of Pisa, and Scientific Institute Stella Maris, Pisa, Italy
DAVID BURR Department of Psychology, University of Florence, Italy; School of Psychology, University of Western Australia, Perth, Australia

Morrone, & Ross, 1994), implying that the parvocellular pathway, essential for chromatic discrimination, is left unimpaired, while the magnocellular pathway is specifically suppressed.

Saccadic suppression follows a specific and very tight time course, illustrated in figure 35.1A (replotted from Diamond, Ross, & Morrone, 2000). Sensitivity for seeing low-spatial-frequency, luminance-modulated stimuli declines 25 ms before saccadic onset, reaching a minimum at the onset of the saccade, then rapidly recovering to normal levels 50 ms afterward. Does the suppression result from a central non-visual “corollary discharge” signal (discussed in the next section), or could it result simply from the visual “masking” effects? This would seem unlikely, as great care was taken to ensure a uniform surround. However, the question is important, so to be certain that the saccade itself was essential for the suppression, we simulated saccadic eye movements by viewing the stimulus setup through a mirror that could be rotated at saccadic speeds. When the background was uniform, with minimal visual referents, the simulated saccades had little or no effect on sensitivity (open symbols of figure 35.1A).

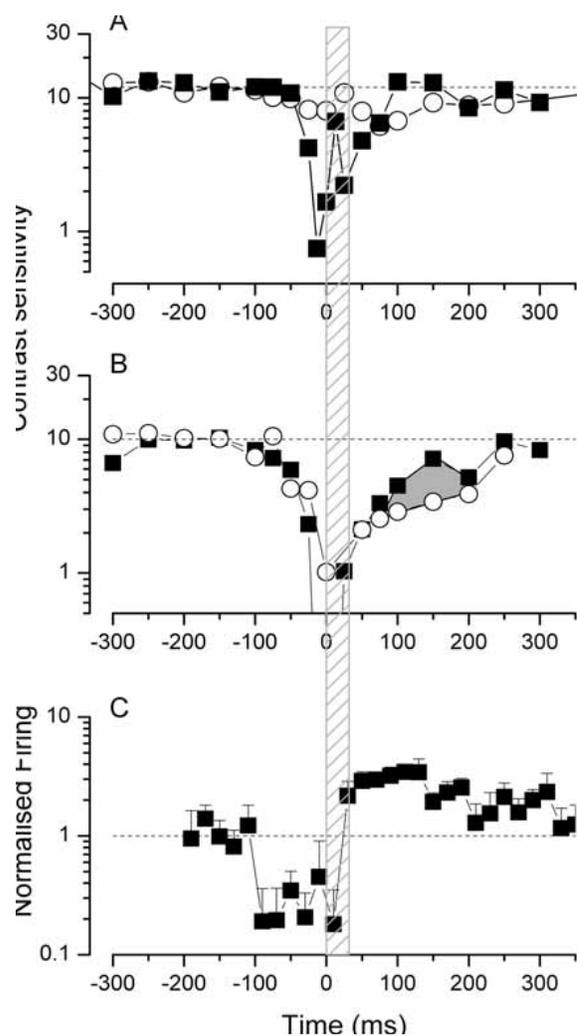

But that is not to say that masking does not occur under more natural conditions. When the test stimulus is embedded within a textured screen, simulated saccades do decrease contrast sensitivity (figure 35.1B). Indeed, the maximum suppression is nearly as great as that caused by real saccades and lasts much longer. This suggests that after the saccade,

sensitivity is greater than that expected with comparable motion without the saccade, possibly implying a post-saccadic facilitation (consistent with the physiology).

That real saccades cause a different pattern of results from simulated saccades shows that suppression results at least in part from an active, extraretinal signal. Interestingly, the amount of suppression varies with age, being much stronger in adolescent children than in adults (Bruno, Brambati, Perani, & Morrone, 2006), even though in adolescence, motion perception and masking are largely adultlike (Maurer, Lewis, & Mondloch, 2005; Parrish, Giaschi, Boden, & Dougherty, 2005). This indicates that the mechanisms that mediate suppression are still developing at this age. Because the saccadic motor system is also not completely mature during adolescence (Fischer, Biscaldi, & Gezeck, 1997), this is further evidence that the extraretinal signal that is responsible for mediating the saccadic suppression may be linked to the motor system.

Psychophysical studies indicate that saccadic suppression occurs early in the visual system (Burr et al., 1994), at or before the site of contrast masking and before low-level

FIGURE 35.1 The effect of saccades on human contrast sensitivity and firing rate in monkey MT. (A) Solid squares show contrast sensitivity for discriminating (in two-alternative forced choice) the brightness of a brief, low-frequency, luminance-modulated grating patch as a function of time relative to saccadic onset. The background was of mean luminance, with very few visual referents present. Sensitivity is severely reduced (by more than a log-unit) at saccadic onset. The open circles show measurements made in identical conditions, but instead of making a saccade, a mirror moved at the same speed and amplitude as the saccade; this had very little effect on sensitivity. (B) As for panel A, except that the background was a high-contrast random check pattern. With a structured background, the simulated saccade did reduce visibility, presumably by masking, with the effect lasting longer than it did for a real saccade. The gray-shaded area indicates the region where sensitivity was greater during the saccade than in fixation. (C) Firing rate of a typical MT neuron in an awake monkey in response to stimulation to a brief stimulus, as a function of time relative to saccadic onset. The pattern of the response is similar to the psychophysical results of panel A; the timing does not match exactly, but this is only one cell, not an average, and does not take neural latencies into account. The enhancement after the saccade may allow for the more rapid recovery from masking during real rather than simulated saccades (the difference between the solid and open symbols in panel B). (Reproduced with permission from Diamond et al., 2000; Ibbotson et al., 2008.)

motion processing (Burr, Morgan, & Morrone, 1999). Thilo, Santoro, Walsh, and Blakemore (2003) addressed this question more directly with a clever electrophysiological technique. Replicating an old study by Riggs, Merton, and Morton (1974), they showed that visual phosphenes produced by electrical stimulation of the eye are suppressed during saccades. But phosphenes of cortical origin—V1 or V2—generated with the technique of transcranial magnetic stimulation were not suppressed. This strongly suggests that saccadic suppression occurs early, before the site of generation of cortical phosphenes, probably within the lateral geniculate nucleus (LGN) or perhaps within V1 itself. A recent functional resonance magnetic imaging (fMRI) (Sylvester, Haynes, & Rees, 2005) study that measured blood oxygen level-dependent (BOLD) activity of LGN while subjects made saccades over a field of constant illumination (to avoid the generation of spurious retinal motion) showed a clear suppression in both LGN and V1, reinforcing early suggestion of saccadic suppression in the dark in V1 (Bodis-Wollner, Bucher, & Seelos, 1999). There is also fMRI evidence for postthalamic modulation by saccades. BOLD activity to luminance stimuli is relatively suppressed compared with that of chromatic stimuli during saccades, but the attenuation varies between areas (Kleiser, Seitz, & Krekelberg, 2004), being strong in MT—as expected—but also strong in V4, a cortical area that receives more parvocellular than magnocellular input. There is also evidence of suppression in higher neural levels, in areas that are normally associated with attention (Bristow, Haynes, Sylvester, Frith, & Rees, 2005, Kleiser et al., 2004). This is interesting, as it could be the suppression of the high-order “attention-related” areas that prevents the sense of motion entering into awareness, causing startle.

The electrophysiology of saccadic suppression is more complex. Electrophysiological studies show that the majority of cells in V1 respond vigorously to the movement created by saccades; however, some cells do not respond to saccade-created motion but only to real motion in the external world. These cells are the minority, about 10% in V1, 15% in V2, and 40% in V3A (Galletti & Fattori, 2003; Wurtz, 2008). Recently, Reppas, Usrey, and Reid (2002) have shown that voluntary saccades induce profound changes in the response of LGN cells, particularly magno-cells. Activity is depressed around the time of the saccade, and there is also a larger and long-lasting enhancement after the saccade. There is also clear evidence for a strong suppression in the colliculus and pulvinar that could be important for the suppression of fast motion (Wurtz, 2008).

Perhaps the data that can be most readily compared with the psychophysical sensitivities are those of Ibbotson, Crowder, Cloherty, Price, and Mustari (2008), who measured responsiveness of MT/MST cells to a brief stimulus, like that used in the psychophysics experiments. An example

cell is replotted in figure 35.1C. This cell showed a very strong and robust suppression before the start of the saccade, followed by a clear enhancement lasting some 200 ms after the termination of the saccade. While it is difficult to make a quantitative comparison between psychophysical threshold measurements (figure 35.1A) and the firing rate of one representative MT cell (figure 35.1C), it is interesting that modulation of MT/MST response follows a time course similar to that of sensitivity for a brief low-spatial frequency stimulus, presumably detected by magnocellular/MT-MST pathways. The very strong postsaccadic enhancement of MT cells could explain the relatively higher sensitivity after real saccades compared with after simulated saccades (the difference between open and solid symbols of figure 35.1B). Another interesting result reported for MT neurons is that in addition to being suppressed, many neurons seem to reverse their preferred direction selectivity (Thiele, Henning, Kubischik, & Hoffmann, 2002). This odd behavior could be important in “canceling” motion information, helping to keep the world still.

To conclude, it is not surprising that saccadic suppression should occur at different levels. Many basic sensory phenomena, such as gain control, occur not at a single site but at virtually every possible location: photoreceptors, retinal ganglion cells, LGN cells, and cortex (Shapley & Enroth-Cugell, 1984). Indeed, the parallels between saccadic suppression and contrast gain control are strong, suggesting that they might share similar mechanisms. During saccades, the temporal impulse response to luminance, but not to equiluminant, stimuli becomes faster and more transient (Burr & Morrone, 1996). LGN (Reppas et al., 2002) and MT/MST (Ibbotson et al., 2008) cells show a similar response pattern, with faster and more transient impulse response functions during saccades. These results suggest that saccadic suppression might act by attenuating the contrast gain of the neuronal response, causing a faster impulse response (Shapley & Victor, 1981). Changing contrast gain makes neurons less responsive to low-contrast stimuli, decreasing the effectiveness of the spurious noise caused by the saccade, hence facilitating their recovery to normal sensitivity. The fact that saccadic suppression operates via gain control mechanisms is consistent with the fact that the M-pathway is selectively suppressed, as M cells have much stronger gain control mechanisms than P cells (Sclar, Maunsell, & Lennie, 1990). This would certainly be an elegant and economical solution to the problem of saccadic suppression, taking advantage of mechanisms that are already in place for other functions. The idea that gain control explains both the suppression and rapid recovery during saccades has been implemented in a model that simulates quantitatively the time course of contrast sensitivity in normal and simulated saccade (Diamond et al., 2000). In this view, saccadic suppression subserves two important roles: the suppression of image motion, which

would otherwise be disturbing, and the rapid return to normal sensitivity after the saccade.

Dynamic updating of internal spatial maps

Besides the (relatively) simple problem of suppressing the motion caused by the fast-moving image on the retina, the brain must also take into account the saccadic movement when determining the instantaneous position of objects in space. Like Alhazen, von Helmholtz (1866) recognized that “the effort of will involved in trying to alter the adjustment of the eyes” could be used to help stabilize perception. Models based on similar ideas of compensation of eye movements were proposed in the 1950s by Sperry (1950) with the concept of corollary discharge and by Von Holst and Mittelstädt (1954) with the concept efference copy: The effort of will of making the eye movements (corollary discharge) is subtracted from the retinal signal to cancel the eye movement and stabilize perception. Now we know that retinal motion signal cannot be easily compensated, given the sophisticated analysis performed by motion detectors. However, there is evidence for the existence of a corollary discharge signal that must be instrumental in maintaining visual stability.

Considerable psychophysical evidence exists for a corollary discharge in humans, going back to the 1960s, when Leonard Matin and others reported large transient changes in spatial localization at the time of saccades. When asked to report the position of a target that was flashed during a saccade, subjects mislocalized it, primarily in the direction of the saccade (Honda, 1989; Mateeff, 1978; Matin & Pearce, 1965). The localization error is typically on the order of half the saccadic size. Later, Mateeff and Honda measured the time course and showed that the error starts about 50 ms before the saccadic onset and continues well after fixation is regained. The error before the saccadic onset has been taken as an indication of the existence of a slow and sluggish corollary discharge signal that compensates partly for the eye movement; the internal representation of the position and the actual position of the gaze do not match and errors in the localization of a brief target are generated.

We have examined saccadic mislocalization in photopic conditions using equiluminant stimuli (that remain visible during saccades). This approach revealed a bizarre result: At the time of saccades, visual space is not so much shifted in the direction of the saccade but *compressed* toward the saccadic target (Morrone, Ross, & Burr, 1997; Ross, Morrone, & Burr, 1997) (see figure 35.2A). Objects that are flashed at saccadic onset to a range of positions, from close to fixation to positions well beyond the saccadic target, are all perceived at or near the saccadic target. The effect is primarily parallel to the saccade direction (Ross et al., 1997), although a small compression is also observed in the orthogonal direction

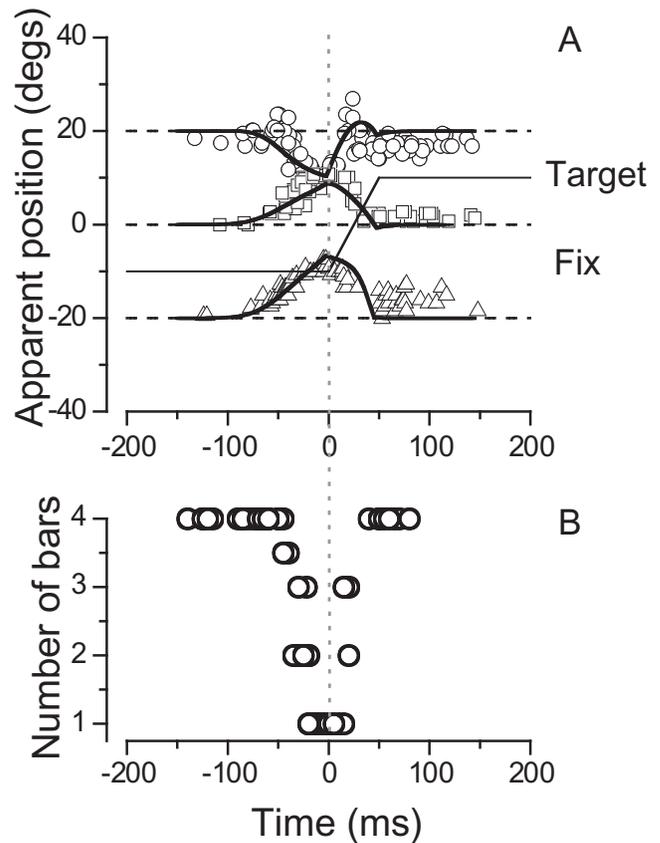

FIGURE 35.2 Effect of saccades on apparent bar position and number. (A) Perceived position of narrow green bars, briefly flashed on a red background at various times relative to the onset of a saccade from -10 to $+10$ degrees. The physical position of the bars (shown by the dashed lines) could be -20 degrees (for the triangle symbols), 0 degrees (square symbols), and 20 degrees (round symbols). The effect of the saccades (maximal at saccadic onset) is to shift the apparent position of the bar toward the saccadic target, where the eyes land. For stimuli at 0 or -20 degrees the shift is in the direction of the saccade, but for stimuli at $+20$ degrees the shift is in the other direction. In all cases, the shift is toward the saccadic landing point. (B) Reported number of bars seen, as a function of presentation time (relative to saccadic onset). A variable number of bars (0, 1, 2, 3, or 4) were presented simultaneously in positions straddling 10 degrees either side of the saccadic target site. The results reported here are for trials in which four bars were presented; but when presented near saccadic onset, the four collapse onto each other, so only one was seen. The other bars were not suppressed, because one bar was always reported as one, and zero bars were reported as zero (no false positives). (Reproduced with permission from Ross et al., 1997.)

(Kaiser & Lappe, 2004). These results are intriguing because they indicate that the process described mathematically by a simple translation of the internal coordinate system is not plausible; perhaps the system cannot perform the transformation of space without additional perceptual costs.

Figure 35.2B shows that saccadic compression is so strong that four bars spread over 20 degrees are perceived as being fused into a single bar. Discrimination of shape (Matsumiya

& Uchikawa, 2001) or colors (Lappe, Kuhlmann, Oerke, & Kaiser, 2006) of the bars is still possible, but counting them and perceiving them in separate positions are not. Sometimes the shape or orientation of the flashed object can also change, appearing smaller and more vertical (for horizontal saccades), although these effects have been harder to quantify. The fact that the feature itself is not lost or compressed suggests that the mislocalization occurs at a relatively high level of analysis after feature extraction.

It has been suggested that saccadic compression occurs only when visual references are present and is absent in the dark (Lappe, Awater, & Krekelberg, 2000). However, subsequent studies (Awater & Lappe, 2006) have shown that this is not necessarily true. In the dark or in a transient dark condition achieved by a brief blackout on saccadic onset, compression does occur but can be obscured because in these conditions, there is also a mislocalization of the saccadic target (Morrone, Ma-Wyatt, & Ross, 2005). When this is taken into account, compression occurs in both light and dark, with and without visual references. Several studies have shown that visual references per se (such as scattered points on the monitor) do not affect compression. However, presenting the same brief stimulus twice perisaccadically, even to different retinal locations, greatly reduces mislocalization (Cai, Pouget, Schlag-Rey, & Schlag, 1997; Morrone et al., 1997; Pola, 2007; Sogo & Osaka, 2002), suggesting that the visual system has a mechanism for maintaining positional constancy of objects across saccades.

A related phenomenon is that if the saccadic target is displaced after the saccade has been initiated, the displacement (of up to 30% saccade size) is not noted (Bridgeman, Hendry, & Stark, 1975). However, if there is a brief gap in the reappearance of the target in the displaced position, the displacement is immediately apparent (Deubel, Schneider, & Bridgeman, 1996). This observation led to the idea that the system assumes object stability in the absence of contrary information, probably by comparing presaccadic and post-saccadic positions with some form of short-term memory buffer. These results suggest that the visual system does take advantage of static visual references to help maintain stability across saccades, but the details of how these are selected are stored in some form of memory buffer of limited capacity have yet to be determined.

It has recently been argued that the insensitivity to saccadic target displacement (Bridgeman et al., 1975) can be explained by optimal sensorimotor integration between the retinal signal and extraretinal corollary discharge signals (Niemeier, Crawford, & Tweed, 2003). At the time of saccades, spatial information about eye position, which is necessary to localize objects in external space, is unreliable. Therefore spatial information during this period is given less weight than is information before and after the saccade. The transient distortions of the kind shown in figure 35.24 may

also be consistent with statistically optimal, or “Bayesian,” integration of information. A recent study has shown how this could be the case, by studying audiovisual integration during saccades. Auditory stimuli are usually far more difficult to localize in space than are visual stimuli. When vision and sound are in conflict, vision dominates (the “ventriloquist effect”) as predicted by optimal integration. However, when visual stimuli are artificially degraded by blurring, audition can dominate (Alais & Burr, 2004), again consistent with optimal integration. Because saccades have little effect on auditory space perception (Harris & Lieberman, 1996), they are a useful tool to study saccadic mislocalization. Indeed, audiovisual stimuli (bars and beeps presented together in the same spatial position) are mislocalized much less than are visual stimuli that are presented alone, suggesting that visual information is given a low weight during saccades, and this can lead to mislocalization of transient stimuli (Binda, Bruno, Burr, & Morrone, 2007). Not only does the idea explain qualitatively the mislocalization, it explains quantitatively the mislocalization of bimodal audiovisual stimuli over the whole time course relative to saccade onset (figure 35.3).

Binda, Bruno, and colleagues (2007) go on to develop a Bayesian model of saccadic mislocalization, simply assuming, like Niemeier and colleagues (2003), an increase in noisiness of the eye position signal at the time of saccades. At this stage, the model accounts only for the shift in the direction of the saccade, not the accompanying compression. This would require a further assumption, such as a “prior” or “default rule,” for objects to be seen at the fovea. While this seems reasonable and has been suggested in other contexts (Deubel, Schneider, & Bridgeman, 2002; MacKay, 1973), it remains speculation at this stage.

So the functional role of spatial compression remains unclear. However, it is interesting that saccadic compression is positively correlated with peak saccadic velocity: Individuals with high saccadic velocity show large compression, while subjects with slow saccadic velocity show mainly a shift in the saccadic direction (but the effect is not related to the spurious visual motion). This suggests a strong link between perception at the time of saccades and the motor system, probably mediated by the corollary discharge signal. It is also interesting to note that the temporal dynamics of saccadic mislocalization are very similar to those of saccadic suppression (compare figures 35.1 and 35.2), indicating a common mechanism, probably the corollary discharge signal. It would be interesting to test whether there is a correlation between saccadic velocity and the magnitude of suppression.

Saccades cause dramatic perceptual localization illusions, but when subjects are required to indicate their response by a motor action—secondary saccades or blind hammering—their responses are near-veridical (Hallett & Lightstone,

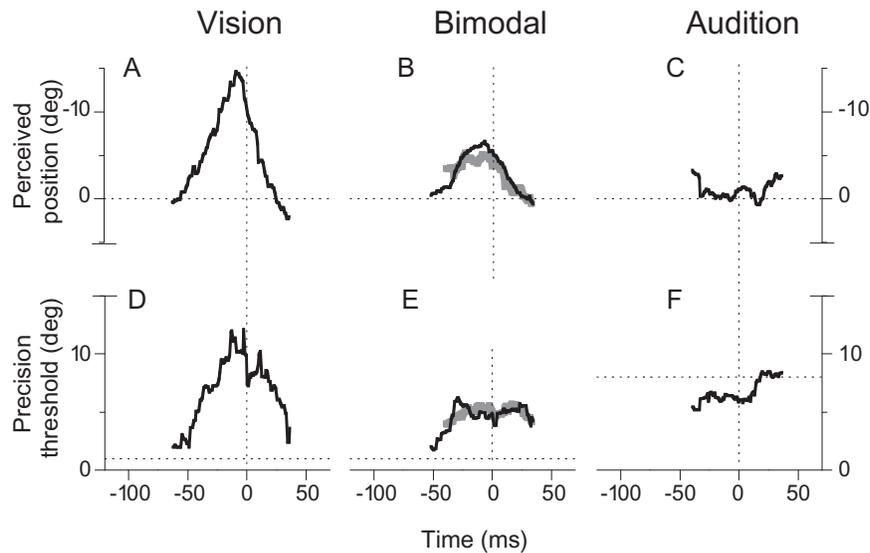

FIGURE 35.3 Illustration of how saccadic mislocalization can result from optimal “Bayesian” fusion. In a two-alternative forced choice, subjects were asked to report whether a perisaccadic test bar that was displayed midway between fixation and saccadic target seemed to be located to the right or left of a presaccadic probe bar. (For full details, see Binda, Bruno, et al., 2007.) Psychometric functions were fitted to these data to give an estimate of perceived position and also of precision of localization. The upper curves show how perceived position varied with time (relative to saccadic onset). Visual stimuli presented on their own (A) showed the characteristic mislocalization, like that of figure 35.1A. Auditory stimuli were not at all affected by the saccade (C). However, when

the sound was played contemporaneously with the bar display, the mislocalization of the bar was reduced (B). The lower curves show the localization thresholds. Again, sound was unaffected by saccades, but the precision of visual localization was reduced drastically near saccadic onset. During the bimodal audiovisual presentation, precision improved to the extent of being better than either the visual or auditory unimodal localization precision. Indeed, this performance, both for perceived position and for precision thresholds, was very close to the Bayesian prediction, indicated by the thick gray line. The dotted horizontal lines indicate performance during fixation. (Reproduced with permission from Binda, Bruno, et al., 2007.)

1976a, 1976b; Hansen & Skavenski, 1977, 1985). Other studies (e.g., Bridgeman, Lewis, Heit, & Nagle, 1979) also reported that subjects can point accurately to targets that were displaced perisaccadically, even though the subject did not perceive the change in target position. However, a few experiments have failed to replicate the original dissociation between motor accuracy and perceptual error during saccades, reporting localization errors for both tasks (Bockisch & Miller, 1999; Dassonville, Schlag, & Schlag-Rey, 1992, 1995; Honda, 1991; Miller, 1996; Schlag & Schlag-Rey, 1995). Recently, Burr, Morrone, and Ross (2001) and Morrone, Ma-Wyatt, and Ross (2005) reported a clear dissociation between verbal reports and blind pointing for saccadic compression. The plot of figure 35.4 shows that briefly flashed stimuli were perceived clearly in false positions, causing the characteristic compression (solid symbols); but when asked to point blindly at the stimuli, with the screen temporally obscured by liquid crystal shutter, observers did so veridically (open symbols).

Interestingly, analogous effects have been reported in audition. Although saccadic eye movements do not affect the localization of tones, saccadic head movements do (Leung, Alais, & Carlile, 2008). Sounds are compressed toward the endpoint of the head turn. However, if subjects are ask to

point to the apparent sound source (by head turn), the compression disappears, as it does for vision (Burr et al., 2001).

However, for visual judgments, introducing clearly visible postsaccadic references under normal lighting conditions causes both verbal report and pointing to show compression. This suggests that vision has access to two maps, one subject to distortion and the other not. The motor map shows no compression except when visual references remain in view for a substantial time after saccade, indicating that these maps are updated postsaccadically, while for perceptual judgments, the updating occurs before and during the actual saccade. Both maps contribute to determining the weight given to each map. Perhaps the popular distinction between conscious perception and action (Goodale & Milner, 1992; Trevarthen, 1968) is at best an oversimplification.

But where in the brain do these maps reside? Is there any evidence that a dynamically updated spatiotopic map actually exists? Electrophysiological studies have reported several transient perisaccadic phenomenon. In the lateral intraparietal cortex (LIP), receptive fields change positional selectivity (Duhamel, Colby, & Goldberg, 1992) just before a monkey makes a saccadic eye movement, anticipating the change in gaze. This is illustrated in figure 35.5A, showing the response of an LIP cell to stimuli flashed to the receptive field position

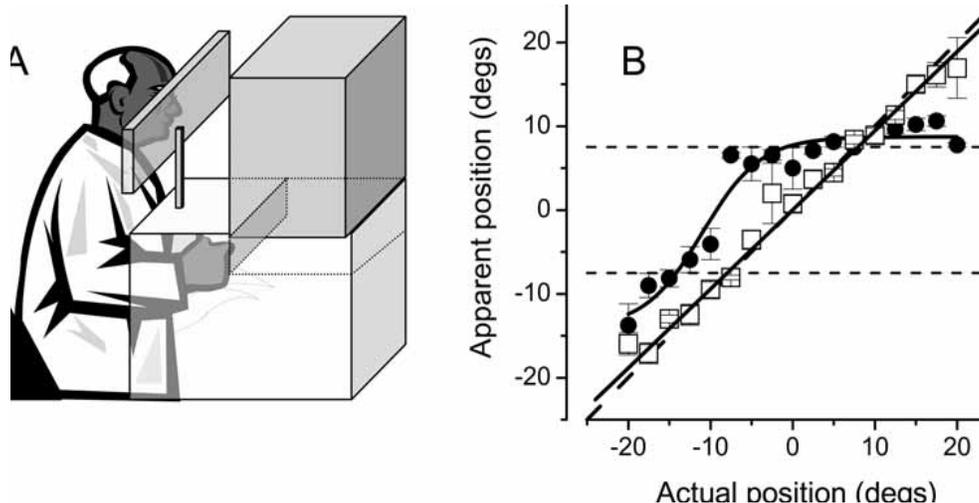

FIGURE 35.4 No spatial compression for motor responses. (A) Subjects viewed a cathode-ray tube monitor through a liquid crystal shutter. On command, they made a 15-degree saccade from -7.5 to $+7.5$ degrees (dashed lines in panel B), and a bar was briefly displayed just prior to saccadic onset. Shortly after the saccade was completed, the shutter closed, and subjects responded by jabbing at the touch screen with a brisk ballistic movement, the hand being

hidden from view. (B) The open squares show the results for the jabbing response for stimuli presented just prior to saccadic onset ($-30 < t < 0$ ms). The responses are near veridical. The solid circles show results for verbal reports, under identical conditions. As shown in figure 35.2, there is a very strong compression, with all stimuli within 10 degrees of the saccadic target seen at saccadic target. (Reproduced with permission from Burr et al., 2001.)

and what will become the receptive field after the saccade has been made (“future receptive field”). Note that the response in the current receptive field starts to reduce and that in the future receptive field starts to increase, long before the eye has actually moved to reposition the retinal image. This is termed *predictive remapping*.

This phenomenon occurs not only in LIP, but also in many other visual areas, including the superior colliculus (Walker, Fitzgibbon, & Goldberg, 1995) and area V3 (Nakamura & Colby, 2002), with area V4 showing a somewhat different behavior (Tolias et al., 2001). It has even been suggested that 10% of neurons in primary visual cortex (V1) show dynamic updating of receptive fields (Nakamura & Colby, 2002). The origin of the phenomenon has been studied in the frontal eye field (FEF), and firm evidence demonstrates that it is mediated by a corollary discharge signal, probably originating in the colliculus and mediodorsal thalamus (Sommer & Wurtz, 2002, 2006). Deactivation of the nucleus abolishes the predictive updating of the receptive field. The corollary discharge signal arrives nearly 100 ms before the updating starts in the FEF, indicating the complexity of the reorganization.

Despite these recent efforts, there are several aspects of the remapping phenomenon that remain unclear. For example, between the time that the neuron starts to respond to stimuli in the updated position and when it regains post-saccadically retinotopic specificity, are receptive fields anchored in a transiently craniotopic map? Do the receptive fields undergo changes in size during the remapping? Are the neurons that are susceptible to remapping randomly

intermingled with those that do not remap, or is there some specific organization?

Clever psychophysical studies have also demonstrated remapping in humans (Burr & Morrone, 2005; Melcher, 2005, 2007), by studying the spatial selectivity of visual aftereffects. Most aftereffects are spatially selective. But is the selectivity in retinotopic or spatiotopic coordinates? By imposing a saccade between the adaptor and the test, Melcher was able to show that the selectivity was *both* retinotopic and spatiotopic. The degree to which adaptation was spatiotopic varied with the complexity of the aftereffect. Simple adaptation aftereffects, like contrast (thought to be mediated by primary visual cortex) were primarily retinotopic, while more complex aftereffects (such as faces) were primarily spatiotopic; aftereffects of intermediate complexity, like the tilt aftereffect, were both retinotopic and spatiotopic.

Adaptation techniques (Melcher, 2007) can also be used to reveal the dynamics of the updating, by briefly presenting the test just prior to a saccade (figure 35.5B). Long before the saccade, adaptation is maximal when test and adaptor are presented to the same position, at fixation, with very little adaptation at the position of saccadic target. However, when the test is presented perisaccadically but before the eyes have moved, the maximum adaptation occurs for tests near saccadic target, the position that will correspond to the adapted retina after the eyes have moved. The similarity of the time courses of the adaptation and the response of the LIP neuron strongly imply that Melcher’s experiment reveals the psychophysical counterpart of the “predictive remapping.” At present, it is still uncertain exactly how this transient

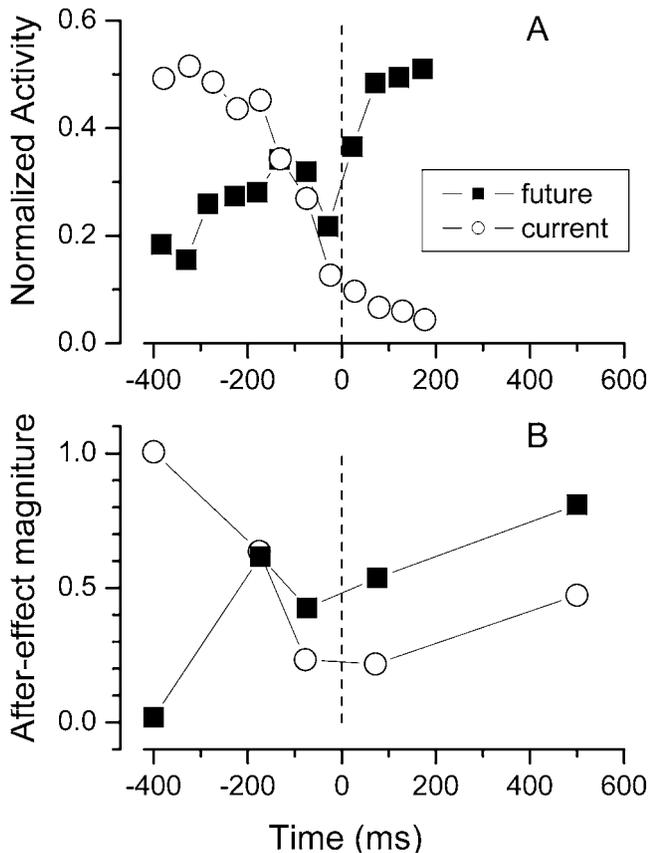

FIGURE 35.5 Predictive remapping in an LIP cell and human observers. (A) The response of a “remapping” cell of area LIP of the macaque around the time of the saccade to brief stimuli displayed in the “current” (presaccadic) receptive field (open circles) and to stimuli flashed in what will become its receptive field after the saccade is made. The response to stimuli in the current receptive field begins to decrease before the eyes actually move. Around the same time, the response in the “future” position begins to increase, long before the eyes have actually displaced the receptive field. (B) An experiment showing analogous behavior in human psychophysics. Subjects adapted to a tilted grating, then measured the aftereffect to a grating presented in the same (retinal) position (“current,” open circles) or to the position that will correspond to the retinal position of the adaptor after a saccade has been made (“future,” solid squares). Long before the saccade, there is no adaptation in the future field, and there is full adaptation in the current field (normalized to unity). Like the cell firing rate, adaptation effects in the current field begin to reduce, and those in the future field begin to increase, before the eyes have actually moved. Well after the saccade is terminated, the effects do not drop completely to zero, because this position corresponds to the spatiotopic position of the adaptor, and orientation adaptation has a spatiotopic component (Melcher, 2005). (Reproduced with permission from Kusunoki & Goldberg, 2003, Melcher, 2007.)

updating of receptive fields leads to visual stability, but it is clearly important to test the future activity before the direct input will excite the neuron after the saccade. It could bridge the perception between the two fixations, but can this phenomenon explain perisaccadic mislocalizations?

The dynamics of the remapping receptive field is also very similar to that of perisaccadic mislocalization (figure 35.2), suggesting that a common mechanism could be driving all these phenomena. However, there are several problems in relating the two sets of data quantitatively. Within a framework of labeled-line theory, a neuron that is placed in a specific anatomical position in a cortical map will, when stimulated, signal the presence of a stimulus at that position. However, if it responds presaccadically to a stimulus falling in the *future* receptive field (one displaced in the direction of the saccade), it should still signal this stimulus location as being in the normal location, that is shifted in the direction *opposite* to the saccade: but the results (figures 35.2 and 35.3) show that the primary result is the perception of a shift in the same direction of the saccade. There are two possible schemas to resolve this apparent contradiction. The first is to consider that the remapped activity of the future receptive field is the neuronal response of the corollary discharge signal, mapped in retinal coordinates (Binda, Bruno, et al., 2007). This activity is present only if a visual stimulus is present; it is active only when important information needs to be updated, reducing also the complexity of the phenomenon. Within this framework, the addition (fusion) of this activity with the retinotopic activity of visual cortex could generate the shift of apparent positions in the appropriate direction, as we have recently demonstrated for the audio-visual targets (figure 35.3). The other possibility is to consider that the remapped neuronal activity is not referred to the exact time of the stimulus presentation but is read after the saccade is complete, in a form of *postdiction* (Eagleman & Sejnowski, 2000). This would also imply that perceptual time should be altered by saccades, as indeed it is (see below).

At the time of the saccade, the timing of the neuronal response changes dramatically. In all cells of areas V3A and FEF that remap during saccades, their remapped response is faster than that during fixation (Nakamura & Colby, 2002). Similarly, the latencies of neurons in areas MT and MST are shorter in response to real saccade than to simulated saccades (Price, Ibbotson, Ono, & Mustari, 2005). These effects have psychophysical implications: Saccades cause a compression, and even an inversion, of perceived time (Morrone, Ross, & Burr, 2005). When asked to compare the perceived duration of a temporal interval presented around the time of a saccade with one presented 2 s afterward, subjects judged it much shorter, about half the duration (figure 35.6). Again the time course of this distortion is quite tight and, after taking into account the duration of the stimuli, similar to that of the spatial compression.

Preliminary data (Binda, Burr, & Morrone, 2007) also indicate that the perceived time at saccadic onset, measured using an auditory tone, is delayed about 100 ms, while about 50 ms before saccade, the latency is reduced by about 20 ms, consistent with the inversion of time data and with

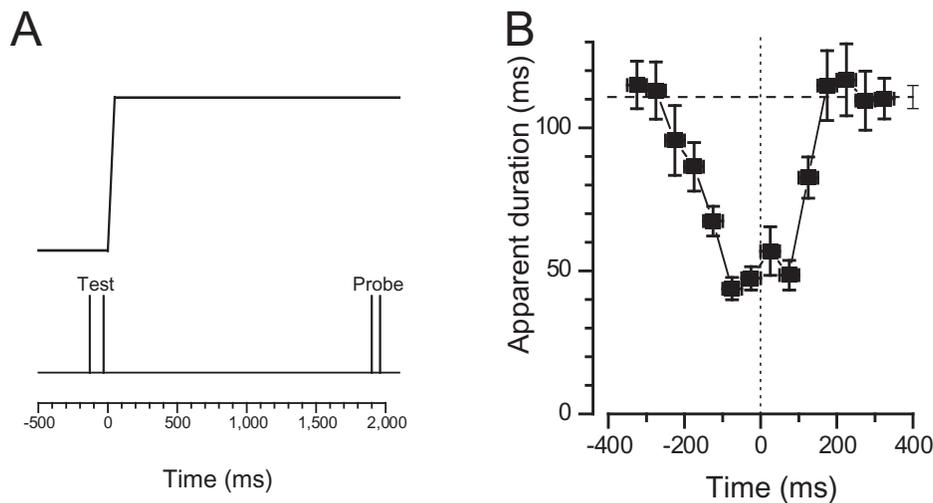

FIGURE 35.6 Time is also compressed during saccades. (A) The subject was asked to compare the duration of the interval of two test flashes (separated by 100 ms) with a postsaccadic probe of variable duration that appeared 2 s later. (B) The apparent duration was then calculated from psychometric functions. Around the time

of saccadic onset, apparent duration was about half the physical duration. The dashed line shows the duration match during fixation. (Reproduced with permission from Morrone, Ross, & Burr, 2005.)

the fact that during the remapping neuronal latency became shorter about 40 ms, explaining the inversion. In addition, they also indicate that stimuli that are presented at saccadic onset are coincident with stimuli presented soon after saccades, facilitating the interpretation of their position in the postsaccadic coordinate system.

Space and time are generally studied separately and thought of as separate and independent dimensions. However, as we have observed, both space and time undergo severe transient distortions at the time of saccades, as objects become compressed toward the saccadic target (Ross et al., 1997), and perceived temporal durations are severely shrunk (Morrone, Ross, and Burr, 2005). As was discussed above, the relationship between perceptual shifts and receptive field updating is far from clear, and compression of time and of space is even more difficult to understand. Nevertheless, we can advance a few firm properties that might help to explain compression. As the transient changes both in space and in time follow very similar dynamics, they might well be manifestations of a common neural cause, a distortion in the space-time metric (Morrone, Ross, & Burr, 2005). Compression of relative distances in space and time are consistent with a reduction of spatial and temporal sampling. This is also one of the few concepts that would explain the perisaccadic increase in sensitivity for size (Santoro, Burr, & Morrone, 2002) and duration (Morrone, Ross, & Burr, 2005) judgments.

If together with the undersampling, the receptive field becomes transiently oriented in space-time such that stimuli presented before the saccade and near the fixation are integrated with stimuli presented later for position far from fixa-

tion, we could provide a description of the origin of all perisaccadic phenomena. The rotation in space and time of the neuronal selectivity is a concept that has strong and important analogies to the physical rotation on space and time that occurs in motion at relativistic speeds, discussed in detail elsewhere (Morrone, Ross, & Burr, 2008). Unfortunately, the dynamics of the changes in receptive fields during saccades are not yet well enough described to pursue this idea much further at present.

Transsaccadic integration and craniotopic maps

Our normal experience comes from the information derived from one fixation being transferred to the next, even when a particular object or part of the scene becomes hidden. Theories about transsaccadic integration have abounded over the past decades. Early ideas (e.g., Jonides, Irwin, & Yantis, 1982) assumed a “transsaccadic memory buffer” that accumulated high-precision information from each saccade to construct a detailed representation of the world (like pinning tails on a donkey). These ideas fell out of favor, largely because of the implicit implication that the visual system must construct some form of stable Cartesian theater to be viewed by a homunculus. More recent theories have swung to the opposite extreme, assuming that perceptual stability depends, paradoxically, on the lack of internal representation of the world (O’Regan & Noe, 2001). Observers are largely insensitive to transsaccadic changes in the visual scene, questioning how much detailed visual information can be gleaned by making an eye movement on demand; many have assumed that no visual memory is necessary at all (Findlay & Gilchrist,

2003; McConkie & Zola, 1979; Tatler, 2001). In practice, however, it is still necessary for the brain to know where to look for the information that it needs, since eye movements are not random and are rarely wasted in natural tasks (Land, Mennie, & Rusted, 1999; Najemnik & Geisler, 2003). Thus some information about the layout of the scene and the position of important objects must somehow be represented and accumulated across saccades. There is clear evidence showing that at least three or four objects are transferred successfully across saccades even in the absence of allocentric cues (Prime, Niemeier, & Crawford, 2006).

Recently, Melcher and Morrone (2003) showed that transsaccadic integration occurs for motion signals that are individually below threshold (and hence are not perceived when presented alone). Two periods of coherent horizontal motion (150 ms each) were shown successively, separated by sufficient time to allow for a saccadic eye movement between them. On some blocks of trials, subjects saccaded across the stimulus between the two motion intervals; on others, they maintained fixation above or below the stimulus. Thresholds were similar in the two conditions, showing that the motion signals were temporally integrated across the saccade—but only when the two motion signals were in the same position in space, indicating that the brain must use a mechanism that is anchored to external rather than retinal coordinates. Importantly, the methodology excluded cognitive strategies or verbal recoding, since the motion signals presented before and after the saccade were each well below the conscious detection threshold; only by summing the two signals could motion be correctly discriminated.

Another example of craniotopic mechanisms is the demonstration of spatially specific adaptation of event-time (Burr, Tozzi, & Morrone, 2007), showing that adaptation to a fast-moving (20 Hz) spatially localized grating decreases the apparent duration of gratings that are presented to that part of the visual field (in external space) but not to other spatial locations.

Because of the spatial selectivity of individual neurons, the response of primary and secondary visual cortex forms a *map* (Morgan, 2003), similar in principle to that imaged on the retinae (except for distortions due to magnification of central vision). This *retinotopic* representation, which changes completely each time the eyes move, forms the input for all further representations in the brain. So a major question is how this retinotopic representation becomes transformed into the *spatiotopic* representation that we perceive, anchored in stable real-world coordinates.

Electrophysiological studies have shown that neurons in specific areas of associative visual cortex, including V6 (Galletti, Battaglini, & Fattori, 1993) and VIP (Duhamel, Bremmer, BenHamed, & Graf, 1997), do show the spatiotopic selectivity that we would expect to exist; their tuning is invariant of gaze, unlike areas V1 and V2 (that provide

their input). Unfortunately, the exact transformation from retinal to spatiotopic coordinates is not yet fully understood, although the suggestion has been made that Bayesian fusion of the retinal signal with eye position signals is sufficient in principle to generate spatiotopic maps, probably acting via eye position–dependent modulation of the neural response, also referred to as *gain fields* (Pouget, Deneve, & Duhamel, 2002; Snyder, Grieve, Brotchie, & Andersen, 1998; Zipser & Andersen, 1988).

Functional magnetic resonance imaging has also indicated the existence of spatiotopic coding in human cortex, both in LO (McKyton & Zohary, 2006), an area deputed to the analysis of objects and in MT+ (d'Avossa et al., 2007; Goossens, Dukelow, Menon, Vilis, & van den Berg, 2006). Using stimuli similar to those used by Melcher and Morrone, our group has reported that the response of a portion of human MT complex varies with gaze position in a way that is consistent with spatiotopic coding. The results are illustrated in figure 35.7. With gaze fixed in the centre of the screen, both areas V1 and MT show spatial selectivity, responding only when the stimuli are presented to the contralateral field (figures 35.7A and 35.7B). However, if the stimulus is fixed (in the center) and its retinal projection varied by varying gaze, the results are different. V1 still responds only to the contralateral stimulus, but MT responds to both ipsilateral and contralateral stimuli, equally strongly. Further experiments suggested that MT actually shifts its receptive fields to cause spatiotopic coding.

However, it must be pointed out that this result is currently controversial, and contrary results have been reported. Gardner, Merriman, Movshon, and Heeger (2008) report that under the conditions of their experiment, the response of MT is retinotopic rather than spatiotopic. One interesting difference between the two studies is that in Gardner and colleagues' experiment (but not in d'Avossa and colleagues' experiment) attention was directed toward the fovea. We have recently replicated the conditions of their experiment and shown that when attention is withdrawn from the stimulus, the spatiotopic mapping changes to a retinotopic mapping (Crespi et al., 2009). Why attention should be necessary for the remapping is far from clear, but this suggests the operation of normalizing gain control. Fully understanding this mechanism will be an interesting future challenge.

The fact that spatiotopic (or at least craniotopic) coding is more common in the dorsal area might suggest that it could be used for the action system. As was discussed above, the action system seems to update spatial maps much later than the perceptual system does. Perhaps the updating of craniotopic maps takes time but leads to more robust coding of information, explaining the resistance of this system to saccadic mislocalization. The perceptual system, on the other hand, might operate not with a complete map anchored in external coordinates but with ensembles of neurons with

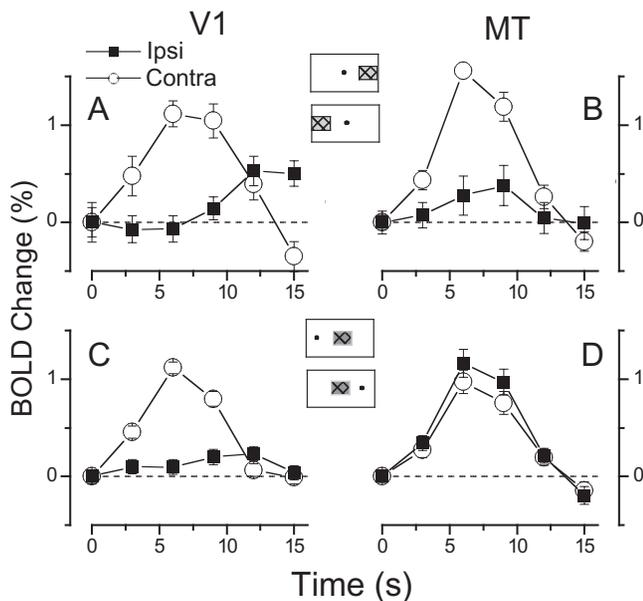

FIGURE 35.7 The dependence of MT response on gaze. (A, B) BOLD responses for areas V1 (A) and MT (B) to ipsilateral (solid squares) and contralateral (open circles) stimulation, keeping gaze fixed at screen center (see icons). In all conditions, subjects were required to discriminate the direction of motion to keep sustained attention on the stimulus. As expected, both areas respond strongly only to contralateral stimulation. (C, D) Response of V1 (C) and MT (D) to ipsilateral and contralateral stimulation varying gaze; the stimulus was in screen center, and the subject fixated to the left or right of it (see icon). The response pattern of V1 was unchanged, suggesting that V1 is selective only to retinal position, irrespective of gaze. However, the response pattern of MT was quite different, now being strong for both ipsilateral and contralateral stimulation, suggesting that it is selective to the position of the stimulus on the screen, not on the retina. (Reproduced with permission from d'Avossa et al., 2007.)

receptive fields anchored in retinotopic coordinates but transiently shifted just before each saccade (like the neuron of figure 35.5). This transient updating on each saccade might be sufficient to maintain a useful perceptual representation that is not actually in spatiotopic coordinates that take longer to develop.

The important conclusion from these and related studies is that the visual system does combine information from one fixation to the next but that this process is not like sticking postage stamps on a tailor's dummy: detailed "snapshots" are not integrated within a transsaccadic buffer that preserves the external metric (Jonides et al., 1982). Indeed, such a scheme could be problematic, as scenes do change continuously as objects move and rotate. Inappropriate *pixelwise* integration could lead to very weird percepts, like cubist art. Transsaccadic integration does not occur at the pixel level, but after a certain amount of visual processing, so attributes such as form, orientation, motion, and even complex entities such as faces are integrated across fixations. This in itself does not solve the problem of visual stability, but it could

provide a basis for visual continuity with ever-changing retinal input. It might well be that the two processes—dynamic receptive field updating and craniotopic coding—collaborate in the selection of the important information to be integrated. The remapping neurons are primed before the eye movement actually occurs, so they can determine whether the information of successive fixations should be integrated. Perhaps if activation during remapping were constant, then craniotopic receptive fields could receive a switch signal allowing information to be integrated transsaccadically. If the remapping neurons do not respond, the switch could open, vetoing the integration of craniotopic receptive fields, so they accumulate new information starting afresh. Within this schema, both the integration across saccades and perisaccadic mislocalization might involve the same mechanisms to obtain a stable vision across separate glances without fusion of local, pixel-like visual details.

Conclusion

Seeing is usually believing. For about two-thirds of our waking lives, we perceive objects where vision tells us they are, which, more often than not, coincides with their actual position. In the remaining time, the visual system sends us erroneous spatial information, presumably because it is engaged in correcting the troublesome consequences of eye movements on retinal afferences. When this happens, we disbelieve visual information. If available, spatial cues from other senses become dominant; if we have to act, we use the robust representation of the craniotopic system without attempting to update it dynamically. If vision is the only signal that is present, we deform our concept of space and of time to make sense of it and to not miss visual information for more than one-third of our waking time.

36 Optimal Estimation in Sensory Systems

EERO P. SIMONCELLI

ABSTRACT A variety of experimental studies suggest that sensory systems are capable of performing estimation or decision tasks at near-optimal levels. In this chapter, I explore the use of optimal estimation in describing sensory computations in the brain. I define what is meant by optimality and provide three quite different methods of obtaining an optimal estimator, each based on different assumptions about the nature of the information that is available to constrain the problem. I then discuss how biological systems might go about computing (and learning to compute) optimal estimates.

The brain is awash in sensory signals. How does it interpret these signals so as to extract meaningful and consistent information about the environment? Many tasks require estimation of environmental parameters, and there is substantial evidence that the system is capable of representing and extracting very precise estimates of these parameters. This is particularly impressive when one considers that the brain is built from a large number of low-energy, unreliable components, whose responses are affected by many extraneous factors (e.g., temperature, hydration, blood glucose and oxygen levels).

The problem of optimal estimation has been well studied in the statistics and engineering communities, in which a plethora of tools have been developed for designing, implementing, calibrating, and testing such systems. In recent years, many of these tools have been used to provide benchmarks or models for biological perception. Specifically, the development of signal detection theory led to widespread use of statistical decision theory as a framework for assessing performance in perceptual experiments. More recently, optimal estimation theory (in particular, Bayesian estimation) has been used as a framework for describing human performance in perceptual tasks.

In this chapter, I will explore the use of optimal estimation in describing sensory computations in the brain. In the first half, I will define what I mean by optimality and will develop three quite different formulations for obtaining an optimal

estimator. In the second half, I will ask how biological systems might go about computing optimal estimates. This is not intended as a complete review of this rich multidisciplinary topic, and I apologize in advance to the many authors whose important contributions I have neglected to mention. Instead, my purpose is to clarify and resolve a number of myths and misunderstandings about optimal estimation and to offer a personal perspective on the relationship between these concepts and the design and function of biological sensory systems.

Definition and formulations of optimal estimation

A common problem for systems that must interact with the world (including both biological organisms and human-made devices) is that of obtaining estimates of environmental properties, x , from sensory measurements, m . An *estimator* is simply a deterministic function, $f(m)$, that maps measurements to values of the variable of interest. If x is a binary variable, then the estimator reduces to a decision function. Generally, the measurements are assumed to be corrupted by noise, which could arise from a number of sources, including the signal itself (e.g., the quantization of light into photons, when one is interested in knowing the light intensity), the transduction mechanism, or variability within the neurons that are transmitting and computing with this information (see Faisal, Selen, & Wolpert, 2008), for a recent review of noise in the nervous system).

Our primary question is: How does an organism select and implement a good estimator or (more optimistically) the best estimator? To address this, we will have to state explicitly what we mean by *best*. The traditional statistical formulation of the best estimator is the one that minimizes the average value of a predefined loss (cost) function, $L(x, f(m))$. The loss function specifies the cost of generating an estimated value of $f(m)$ when the true value is x . It is generally assumed to be positive and equal to zero only when the estimate is equal to the true value.

REGRESSION FORMULATION Suppose we wanted to build a machine that could perform optimal estimation of x , given a noisy measurement m .¹ We can imagine “training” this

EERO P. SIMONCELLI Center for Neural Science and Courant Institute of Mathematical Sciences, New York University, New York, New York

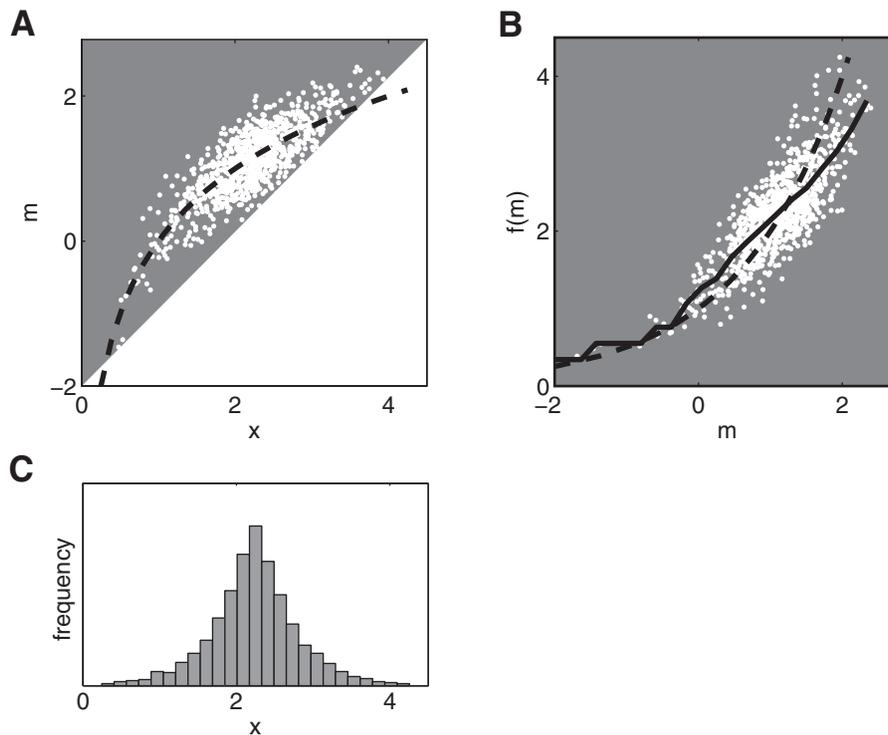

FIGURE 36.1 Regression formulation of the optimal estimation problem, illustrated for a one-dimensional signal and measurement. (A) The measurement process (also known as the *encoding* process). We assume a set of data pairs (plotted points), $\{x_n, m_n\}$, indexed by $n \in [1, 2, \dots, N]$, representing true signal values and associated noisy measurements. The dashed line indicates the average measurement as a function of the true signal value. (B) The estimation (or *decoding*) process. The estimator $f(m)$ maps measure-

ments back to estimated signal values. The optimal estimator (solid line) does this so as to minimize a specified loss function. Note that this need not be (and is generally not) the inverse of the average measurement function (dashed line). Note also that the optimal estimator will depend on the signal values that are included in the data set, which are summarized by the histogram shown in panel C. (See color plate 49.)

machine by showing it many signal-measurement pairs, $\{x_n, m_n\}$. Typically, we imagine that each measurement arises from its associated true value through some sort of noisy transformation. Figure 36.1A illustrates such a set of training data.

An estimator, f , attempts to invert the measurement process, mapping measurements m back to signal values x (figure 36.1B). This mapping is deterministic: Each measurement leads to a unique estimate. But if we hold the signal value fixed and make a set of estimates (each arising from a different measurement), these estimates will fluctuate because of the variability in the underlying measurements. The optimal estimator is the one that minimizes the average loss over these examples:

$$f_{\text{opt}} = \arg \min_f \frac{1}{N} \sum_n L(x_n, f(m_n))$$

We will refer to this as a “regression” estimator; a special case is the linear regression solution, which arises when L is the squared error. An example optimal estimator is indicated by the solid line in figure 36.1B. Note that this transformation is not the same as the inverse of the transformation to average measurements (i.e., the inverse of the dashed line shown in figure 36.1A).

Of course, the precision with which we can constrain the function f depends on how much data we have. Loosely speaking, the usual approach is to restrict f to be sufficiently simple (e.g., smooth, or defined by a small number of parameters) that the available data will constrain it properly. For example, the estimator shown in figure 36.1B was computed by binning the data (as a function of m) and computing the best estimate value for each bin. More formally, we might specify a restricted set of possible functions (denoted \mathcal{F}) from which the solution will be selected.² Finally, note that the solution we obtain will depend on the *distribution* of data. If the set of training examples includes many x values clustered in a particular region of the space, then the average loss will contain many terms from that region, and the optimization process will thus attempt to reduce the estimation errors there, typically at the expense of larger errors elsewhere. This suggests that the training examples should be selected to represent the distribution of values that might be encountered in the environment.

The regression formulation is appealing because it is simple and intuitive. Its primary limitation is that it requires *supervised* training. That is, obtaining an optimal estimator

relies on a training set of noisy measurements, m_n , each accompanied by its corresponding correct signal value, x_n . Supervised learning for estimation and classification problems has been well studied. A standard example is the problem of learning an input-output relationship with a simplified network of artificial neurons, for which the optimal solution may be obtained by backpropagation (essentially, a form of stochastic gradient descent on the objective function). But this requires large amounts of data, especially when learning multidimensional functions.

From the biological/behavioral perspective, a fully supervised training paradigm also seems implausible. Although most organisms absorb enormous amount of sensory data during their lifetimes, the information that they receive regarding “correct” answers would seem to be relatively sparse. For example, consider the problem of estimating the distance to a nearby object on the basis of visual input. We can compare our estimate to the one that is obtained by reaching out and touching the object. But the amount of this kind of feedback we receive seems vastly insufficient to train the enormous cascade of neurons that are involved in estimating distances from visual input. Similarly, optimization through natural selection (with surviving organisms passing preferred solutions to their offspring genetically) seems implausible, both because of the time required and because genetic material seems unlikely to contain sufficient information to encode even a fraction of the detailed connectivity of those neurons.

Instead, it seems that evolution has endowed the brain with powerful capabilities for *unsupervised* learning (based on noisy measurements alone) and that this is used to supplement and bolster the supervised learning that may be used in the relatively infrequent cases for which the correct answers are known. Unsupervised learning is a heavily studied topic in machine learning (e.g., Hinton & Sejnowski, 1999), and methods have been developed for learning patterns in data, mostly for purposes of optimal coding or clustering/categorization. Perhaps less well known is the fact that optimal estimators may also be written in unsupervised form. To explain this, I will turn first to a probabilistic formulation of the problem.

PROBABILISTIC (BAYESIAN) FORMULATION When we describe optimality in terms of minimizing an objective function over a training data set, we usually have in mind that this set is representative of future data we will encounter. This notion may be formalized by describing both the training and future data as samples randomly drawn from a common probability distribution. The law of large numbers tells us that as the number of data pairs grows, the original regression objective function will converge to the expected value (mean) of the loss function, integrated over all possible combinations of x and m :

$$f_{\text{opt}} = \arg \min_f \iint P(x, m) L(x, f(m)) dx dm$$

Unlike the regression formulation, which is written directly in terms of data, the probabilistic formulation is written in terms of a continuous probability density. Since this formulation effectively results from assuming infinite amounts of data, the smoothness constraint that was necessary for selecting an estimator in the regression case is now optional.

The probabilistic objective function may be simplified by using the definition of conditional probability to rewrite the joint density as a product of the marginal density of m and the conditional density of x given m (known as the *posterior* distribution):

$$f_{\text{opt}} = \arg \min_f \int P(m) \int P(x|m) L(x, f(m)) dx dm$$

If the estimator is unrestricted, then we may ignore the outer integral and optimize the estimator separately for each measurement value:

$$f_{\text{opt}}(m) = \arg \min_f \int P(x|m) L(x, f(m)) dx$$

That is, for each measurement, the best estimate is the one that minimizes the expected value of the loss function over the posterior distribution for that measurement.

Finally, the posterior distribution may be rewritten in terms of densities that are more naturally associated with the process from which the data arise. Specifically, we can describe measurement noise using a conditional probability $P(m|x)$. This *measurement density* expresses the probability of m for each value x of the signal. If we think of it the other way around, holding the measurement fixed and reading off a function of the signal, this is known as a *likelihood function*. Now Bayes’ rule can be used to express the posterior in terms of the measurement density and the *prior* distribution $P(x)$, which expresses the probability of occurrence of value x in the world:

$$f_{\text{opt}}(m) = \arg \min_f \int \frac{P(m|x)P(x)}{P(m)} L(x, f(m)) dx \quad (1)$$

An example of the Bayesian solution, based on the same distributions that were used to generate the data in figure 36.1, is illustrated in figure 36.2. To provide some intuition, it is worth mentioning several well-known special cases.

Quadratic error (least squares) solution The most common case used in the engineering community is the *least squares* loss function, $L(x, f(m)) = (x - f(m))^2$. In this case, the optimal estimate (which can be derived by differentiating the objective function and setting equal to zero) is simply the mean of the posterior:

$$f_{\text{LS}}(m) = \int x P(x|m) dx$$

It is worth mentioning that in the special case of a jointly Gaussian probability density over signal and measurement,

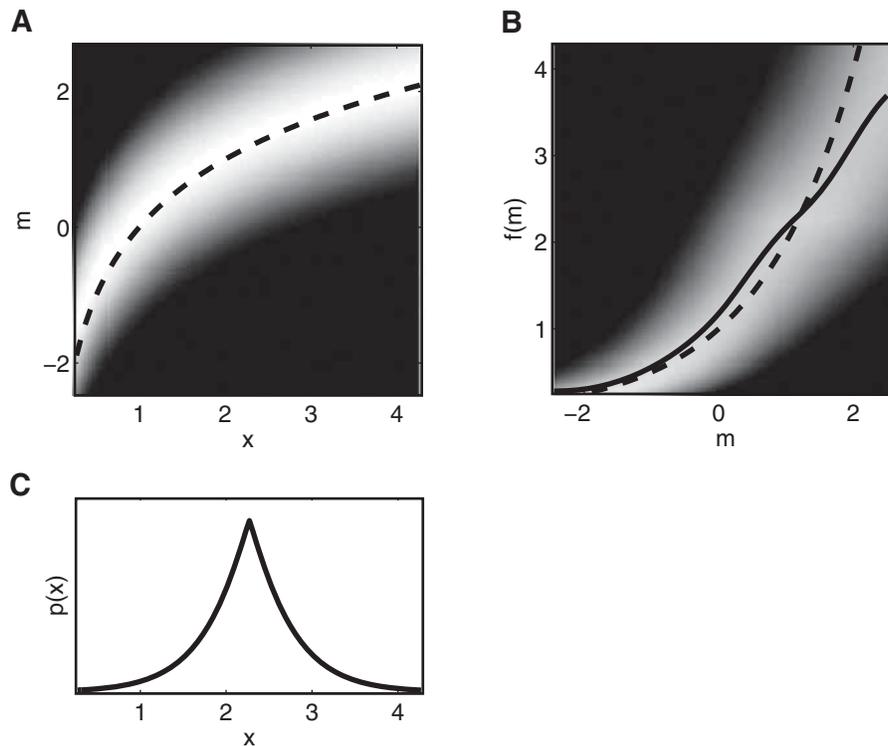

FIGURE 36.2 Bayesian formulation of the optimal estimation problem. (A) The measurement density, $P(m|x)$, shown as a gray-scale image, where intensity indicates log probability. The dashed line indicates the mean of the density as a function of x . (B) The

posterior density, $P(x|m)$. The solid line indicates the mean of the density, and the dashed line indicates the (inverted) mean of the measurement density in panel A. (C) the prior density, $P(x)$. (See color plate 50.)

this solution turns out to be a linear function of the measurement (the solution is the same as that of our next example).

Linear estimator, quadratic error Now consider what happens when the estimator is restricted to be a linear function of the measurement. The *linear least squares* solution is

$$f_{\text{LLS}}(m) = \frac{\sigma_{xm}}{\sigma_{mm}} m$$

The linear solution relies only on the cross-correlation between signal and measurement and between the measurement and itself, and not on full knowledge of the posterior density. This result extends naturally to multidimensional inputs or outputs.

Maximum probability solution Suppose that the loss function penalizes all errors equally except for the correct answer (which incurs no penalty). Then the solution is the maximum of the posterior density, known as the *maximum a posteriori* (MAP) estimator:

$$f_{\text{MAP}}(m) = \arg \max_x P(x|m)$$

In summary, the probabilistic formulation expresses the estimation problem in terms of four natural ingredients:

- The prior, $P(x)$, which represents the probability of encountering different signal values in the world

- The measurement density, $P(m|x)$, which represents the (probabilistic) relationship between the signal and measurement
- The loss function, $L(x, f(m))$, which represents the cost of making errors
- The family of functions \mathcal{F} from which the estimator is to be chosen. (This ingredient might not be required for the Bayesian solution, which effectively operates under conditions of infinite data.)

Note that although the regression solution of the previous section was developed directly from pairs of input-output data, it is also implicitly relying on these same ingredients. Specifically, it is effectively based on the joint probability density of signal and measurement, which is equivalent to the product of the prior likelihood. And as was stated in the previous section, it also requires the specification of a loss function and a family of functions from which the solution is to be drawn.

It is worth emphasizing the most obvious implication of this ingredient list, since it is often misunderstood. Optimality is not a fixed universal property of an estimator but one that depends on each of these defining ingredients; statements about optimality that do not fully specify the ingredients are therefore relying on hidden assumptions. For example, many authors assume that optimality implies that

an estimator must be unbiased (that is, on average, computes the correct value). But many well-known optimal estimators exhibit bias (in fact, all of the estimator examples mentioned above can exhibit bias, depending on the specific choices of prior and measurement densities).³

Despite the appealing decomposition of the problem into intuitively sensible ingredients, the probabilistic formulation has drawbacks. In particular, the reliance of the regression solution on supervised training data has been replaced with reliance on knowledge of two abstract probability densities. Since the measurement density is a property of the sensory system, we might imagine learning it from a set of calibration measurements or assuming that it is a fixed property of the device. On the other hand, the Bayesian formulation is often criticized for reliance on the unknown (and perhaps unknowable) prior distribution,⁴ and this criticism is further inflamed by the many examples in the literature that introduce a prior as an ad hoc function that may be freely chosen to make the solution tractable. In the view set out here, the prior is meant to capture the statistical structure of some aspect of the world, an assumption that is only slightly stronger than the assumption that the training data in the regression estimator are representative of future data that the system will need to process.

UNSUPERVISED LEARNING OF OPTIMAL ESTIMATORS The Bayesian view assumes that all ingredients of the problem, including the prior, are known. If the prior is meant to correctly represent the distribution of signal values in the world, it must presumably be learned from measurements. Engineers who need to design real systems generally follow one of several practical solutions: (1) Directly measure the distribution of signal values that might be encountered by the device, and use a model of this empirical distribution for the prior; (2) assume a prior distribution of some parametric form, and then adjust the parameters so as to best explain the observed distribution of noisy measurements; or (3) assume an estimator of some parametric form and adjust this directly to improve performance on observed data. The first solution requires a separate set of uncorrupted signal measurements and therefore does not seem relevant to biological systems, which are presumably able to make measurements only through the same noisy sensors from which they will be making their estimates. The second solution is generally known as *empirical Bayesian* estimation, since the prior is obtained from noisy training data. The third solution, as described, is simply the regression solution, which relies on supervised training data in order to measure and optimize the estimator performance. Remarkably, it can sometimes be rewritten in an unsupervised form. Below, I will consider the second and third solutions in more detail.

The empirical Bayes formulation assumes a prior of a known parametric form,⁵ optimizes the parameters to fit the

(noisy) measurements, and then uses this optimized prior to obtain the estimator (by minimizing equation 1). The prior parameters are typically chosen to make the observed data as consistent as possible with the model, and this is usually achieved in practice by maximizing the probability of the observed data:

$$\theta_{\text{opt}} = \arg \max_{\theta} \prod_n \int P_{\theta}(x) P(m_n | x) dx$$

Beyond the potential difficulties associated with computing this optimization, the introduction of this probabilistic cost function is a bit inconsistent, since the prior that best explains the data is not necessarily the one that will lead to the best estimator. Nevertheless, empirical Bayes solutions are often quite successful in situations in which the data are sufficient to strongly constrain the prior parameters.

The third solution mentioned above can, in some cases, be obtained from unsupervised training (Raphan & Simoncelli, 2007). As such, we will refer to it as *unsupervised regression*. The derivation of the general form is somewhat complex, but the simplest case (due to Stein, 1981) arises in the context of an additive Gaussian noise model and a squared-error loss function and can be written quite simply. Stein showed that the mean squared error in this case can be rewritten in a form that depends only on the measurements and not the signal:

$$\begin{aligned} \iint P(x, m) [x - f(m)]^2 dx dm \\ = \int P(m) [g(m)^2 + 2\sigma^2 g'(m) + \sigma^2] dm, \end{aligned}$$

where $g(m) = f(m) - m$, and σ is the standard deviation of the additive Gaussian noise (assumed to be known). This remarkable result implies that the squared error may be approximated by averaging over measured (noisy) data without knowledge of the correct answers (i.e., unsupervised) and with no assumption about the prior, $P(x)$. This implies that we can select an optimal estimator f (or, equivalently, g) by minimizing the integrand above, averaged over a set of noisy measurement data. As with the original regression solution, the estimator must be restricted sufficiently (e.g., drawn from some parametric family) that it can be constrained by the available data. Analogous expressions can be derived for a number of other measurement probabilities, (Raphan & Simoncelli, 2007).

In both the empirical Bayesian and unsupervised regression formulations, we have exchanged the supervised data pairs required by the standard regression solution for unsupervised data and a known (or previously calibrated) description of the measurement density, $P(m|x)$. We can thus view these solutions as a compromise between the data-oriented regression form and the more abstract Bayesian form. A summary of the ingredients that are required by each of the optimal estimators introduced thus far is provided in table 36.1.

TABLE 36.1

Ingredients required for specifying/learning various formulations of optimal estimator

	Measurement Values $\{m_n\}$	Signal Values $\{x_n\}$	Measurement Probability $P(m x)$	Signal Probability $P(x)$	Loss Function L	Estimator Family \mathcal{F}
Regression	✓	✓			✓	Parametric
Bayesian			✓	✓	✓	
Empirical Bayesian	✓		✓	Parametric	✓	
Unsupervised (e.g., Stein) regression	✓		Restricted		Quadratic	Parametric

Ingredients required for specifying/learning various formulations of optimal estimator (see text for definitions). Checkmarks indicate that the ingredient is required but unrestricted. Unlabeled spaces indicate that the ingredient is not needed. Note that the unsupervised regression estimator has been derived only for certain specific measurement densities.

Based on Raphan & Simoncelli (2007).

Optimal estimation in the brain

In this section, we ask how the optimal estimation formulations developed in the previous section can be used in modeling biological sensory systems and how these models can be tested experimentally. These questions can be addressed at many levels, and in this short chapter, I will not attempt to provide a complete overview. Rather, I will describe few published results and try to explain what I see as some of the more important challenges that we currently face in this endeavor.

The concept that sensory perception arises through the fusion of incoming sensor measurements with one's prior experience is often attributed to Hermann von Helmholtz (1925). Although his descriptions are qualitative and do not mention noise or loss functions, they do capture the essence of the Bayesian formulation described in the previous section. This interpretation of perception seems to have lain dormant from von Helmholtz's day until the 1950s, when E. T. Jaynes, a statistically minded physicist, submitted an article to *IRE Transactions on Information Theory*, in which he proposed that Bayesian estimation might be used as a framework for modeling sensory transformations (Jaynes, 1957). The journal rejected the article (on the grounds that it was too speculative), and the concept appears to have lain dormant for another 30 years! In the interim, perceptual psychologists began using signal detection theory as a framework for analyzing psychophysical data (Green & Swets, 1966) and for providing an upper bound on performance. This methodology often does not include explicit loss functions and rarely includes a prior, but the formalization nevertheless represents an important step toward the optimal estimation framework.

PERCEPTUAL BAYESIANISM In the 1980s and 1990s, there was a dramatic revival of the Bayesian methodology across many fields, and perceptual science was one of these. A variety of experiments have aimed to test optimality of human estimation judgments by comparing performance to

an "ideal observer" model (e.g., Barlow, 1980; Geisler, 1989; Kersten, 1990; Knill, Field, & Kersten, 1990). A number of reviews document the activity to date (Knill & Richards, 1996; Maloney, 2002; Mamassian, Landy, & Maloney, 2002; Kersten, Mamassian, & Yuille, 2004; Körding, 2007), and this endeavor has been expanded by recent activity in "neuroeconomics," a cross-disciplinary enterprise that aims to characterize decision-making and more general behavioral processes with respect to prior probabilities and reward contingencies (Glimcher, Camerer, Poldrack, and Fehr, 2008).

What does it mean to say that a human subject is performing optimally? As I have emphasized in the first part of this chapter, the definition of the word *optimal* requires specification of a set of ingredients: the measurement probability, the prior, the loss function, and (in some cases) a family of estimators. Specifying these ingredients for a human observer performing a particular task is often difficult or impossible. For example, specifying the measurement probability requires knowledge of how the signal of interest is represented within the brain (including a specification of the noise). In some experiments, investigators have incorporated noise into the stimulus, which can provide insights into the properties of internal noise (and thus the measurement probability) (e.g., Pelli & Farell, 1999; Körding & Wolpert, 2004). The specification of an appropriate family of estimators should be determined by the set of computations that can potentially be performed by neurons, but we currently lack a detailed description of this set.

The loss function can pose more substantial difficulties. Subjects may differ inherently in the way they behave in an experimental situation (e.g., consider personality traits such as risk aversion versus thrill-seeking). Even in cases in which the investigator attempts to control for this by building a loss function directly into the design of the experiment (for example, by paying/penalizing subjects for correct/incorrect answers), one does not know a priori whether or how the subject will learn and internalize these costs, what type

of training (e.g., supervised versus unsupervised) this would require, and how long it would take.

Last, consider the prior, for which one can ask the same questions as were asked for the loss function (whether/how a subject internalizes it, what type of training is required, over what time scales). We might imagine that the observer operates according to a prior that was obtained over a relatively slow timescale (much longer than the duration of a typical experiment, say, on a developmental or evolutionary timescale). In this case, the investigator might attempt to measure it from the environment (or derive it from a model of the environment). At the other extreme, we might imagine that the subject's internal prior is quite flexible and that over the duration of the experiment, the subject internalizes the distribution of stimuli that have been presented. In fact, many experiments are designed so that the subject can learn the distribution of signal values over a set of training trials.

In the context of learning a prior, one apparent paradox seems worth mentioning. Adaptation to stimuli that persist for timescales of seconds or minutes has been found, for every sensory modality and for a wide range of stimulus configurations, to produce substantial changes in subsequent perception. For example, adaptation to a visual stimulus, say, of a given orientation, induces biases in the perceived orientation of subsequently viewed stimuli. These biases are generally *repulsive*: The perceived orientation of a postadaptation stimulus is pushed away from that of the adaptor. If we were to interpret the adaptation as a means by which the system updates its prior probability distribution for orientation, we might expect that heavy exposure to the adapting stimulus would cause an increase in the internally represented prior probability of that stimulus, which should then lead to an *attractive* bias in subsequent perception! Thus adaptation over these timescales appears to be inconsistent with learning of prior probabilities. An alternative interpretation, still within the Bayesian framework, is that adaptation effects correspond to a change in the likelihood function (Stocker & Simoncelli, 2006b).

Given the difficulty of specifying the ingredients of an optimal estimator, one can consider an alternative experimental approach for exploring optimal estimation theories of perception. Specifically, one can ask: For what choices of ingredients would the subject's behavior be considered optimal? The trial-averaged estimates of a human subject do not place a sufficient constraint on the problem to answer this question. In particular, the average response of an estimator does not uniquely determine the prior, likelihood, and loss function that could have been used to define it. But if one assumes, say, a quadratic loss function and measures not just the average response but the full distribution of estimates, then it is possible to extract a prior (Paninski, 2006) or both the likelihood and prior (Stocker & Simoncelli, 2006a) from the psychophysical data.

Ultimately, it seems important to move beyond the initial question of *whether* an observer is optimal to examine the prior and cost conditions under which the observer may be considered optimal, and the flexibility of that optimality. Given that the estimators must operate under changing conditions, we'd like to know: (1) which ingredients of the problem may be learned or adjusted, and what type of adjustments can be made (e.g., Körding & Wolpert, 2004), (2) what type of learning is possible (e.g., supervised, unsupervised, direct verbal communication), (3) over what time scales this learning occurs, and (4) whether the observer is able to switch between estimators (or ingredients of estimators, such as the prior) that have been previously learned (e.g., Körding & Wolpert, 2004; Maloney & Mamassian, 2009).

PHYSIOLOGICAL IMPLEMENTATION In addition to interpreting perception in the context of optimal estimation, we can consider how such optimal computations might be implemented in the brain. The responses of sensory neurons are commonly described in terms of their selectivity to particular parameters of the stimulus. In most cases, no single neuron is responsible for encoding a stimulus parameter. Instead, the parameter is jointly represented by a population of neurons with different tuning properties; therefore any estimate of the parameter requires a combination of information across many cells, if not the whole population. Over the past 20 years, the theoretical neuroscience community has been exploring the means by which neural responses might be optimally "read out" to explain behavior (e.g., Georgopoulos, Schwartz, & Kettner, 1986; Bialek, Rieke, de Ruyter van Steveninck, & Warland, 1991; Anderson & van Essen, 1994; Seung & Sompolinsky, 1993; Potters & Bialek, 1994; Salinas & Abbott, 1994; Sanger, 1996; Snippe, 1996; Shadlen, Britten, Newsome, & Movshon, 1996; Rieke, Warland, de Ruyter van Steveninck, & Bialek, 1997; Rieke & Baylor, 1998; Zhang, Ginzburg, McNaughton, & Sejnowski, 1998; Zemel, Dayan, & Pouget, 1998; Platt & Glimcher, 1999; Gold & Shadlen, 2000; Simoncelli, 2003; Pouget, Dayan, & Zemel, 2003; Bialek & van Steveninck, 2005; Jazayeri & Movshon, 2006).

It is worth noting that despite my emphasis on the probabilistic formulation of the problem, computation of optimal estimates does not necessarily require that the brain explicitly represent or compute probabilities. As was described in the previous section, given the four ingredients of the optimal estimation problem, an estimator is just a fixed deterministic function that maps noisy measurements to estimated values. If these ingredients are fixed and unchanging, the brain could learn to compute the optimal estimator using either regression or one of the two unsupervised methods described previously and would not need to explicitly calculate or represent probabilities!

In general, we imagine that the ingredients of the optimal estimation problem *do* change; the loss function is typically task-dependent, the prior may change gradually (or even suddenly, for example, when the observer moves into a different environment), and the measurement probability may also change (owing to physiological changes in the neural substrate). But even under these conditions, the solution need not explicitly require the calculation or representation of probabilities. If the prior and/or measurement probabilities are parametric, then the optimal estimator is just a function that depends on those parameters. In this case, the parameters may be computed from previous measurements, either through supervised regression or by using the empirical Bayesian formulation. Again, this does not require explicit representation of probabilities.

Although explicit probability representation is not required for optimal estimation, much published work assumes it. A simple means of encoding probabilities, suggested by a number of authors (e.g., Hinton, 1992; Foldiak, 1993; Simoncelli, 1993; Anderson & van Essen, 1994; Sanger, 1996; Gold & Shadlen, 2000; Weiss & Fleet, 2002; Eliasmith & Anderson, 2002; Sahani & Dayan, 2003; Simoncelli, 2003; Barber, Clark, & Anderson, 2003), assumes that the firing rates of each neuron directly represents the probability (or the log probability) of a particular stimulus parameter value. In this view, the population encodes (either directly or through a set of linear basis functions) a probability distribution over the parameter. Downstream neurons could then explicitly compute an estimate from this population, for example, by computing the population mean (a weighted sum) or peak (winner-takes-all). For example, suppose that the firing rates in a given neural population represent the posterior probability evaluated at a set of different signal values. The mean of the density can be computed as a weighted sum over the responses (the weights will be determined by both the signal values at which the posterior is sampled and the portion of the signal space covered by each neuron). Or subsequent stages could operate on the posterior information, postponing the explicit determination of an estimate until it is needed. In either case, the prior in this model can be adjusted by changing the gain on each of the neurons.

The explicit representation of uncertainty, through the breadth and shape of population responses, and the possibility of linear readout rules are conceptually appealing features of this framework. But a detailed model of this form needs to address the inconsistency of directly representing probability values with neural responses that are noisy (e.g., Sahani & Dayan, 2003). In addition, the responses of many visual neurons do not seem consistent with direct representation of posterior probability. For example, the shape of orientation tuning curves in area V1 neurons is preserved under changes in stimulus contrast. But lowering the stimu-

lus contrast results in larger variance in the estimation of orientation, which implies a broadening of the posterior.

A widely followed alternative formulation represents probabilities implicitly, using the noisy responses of a population of neurons (e.g., Seung & Sompolinsky, 1993; Salinas & Abbott, 1994; Zhang et al., 1998; Zemel et al., 1998; Pouget et al., 2003; Jazayeri & Movshon, 2006; Ma, Beck, Latham, & Pouget, 2006).⁶ Consider a population of N neurons whose responses represent the measurement in an optimal estimation problem. Suppose the mean firing rate of each neuron is determined by a tuning function $f_n(x)$, where x is the stimulus variable of interest. Suppose also that the number of spikes emitted by each of these neurons in a unit time interval to any given stimulus is statistically independent and follows a Poisson distribution. Then the joint likelihood function is the product of the individual Poisson probabilities:

$$P(\vec{r}|x) = \prod_n \frac{f_n(x)^{r_n}}{r_n!} e^{-f_n(x)}$$

where \vec{r} is a vector containing the population spike counts.

At this point, one might use unsupervised (or supervised) regression to learn the optimal estimator from data without specifying or learning a prior probability. Alternatively, we can follow the Bayesian formulation, multiplying the likelihood by a prior $P(x)$, dividing by $P(\vec{r})$, and taking the (negative) log to write the log-posterior density:

$$-\log(P(x|\vec{r})) = \sum_n \log(r_n!) - \log P(\vec{r}) - \sum_n r_n \log(f_n(x)) + \sum_n f_n(x) - \log P(x)$$

Now consider the MAP estimator. The first two terms do not contain the stimulus variable, x , so we can drop them, arriving at an objective function that can be maximized over x to obtain the estimate:

$$E(x) = -\sum_n r_n \log(f_n(x)) + \sum_n f_n(x) - \log P(x)$$

The first term is a sum of the observed spike counts, weighted by the log tuning curve value of each neuron (Zhang et al., 1998; Jazayeri & Movshon, 2006). The second term is the sum of the tuning curves, and the third is the (negative) log of the prior. Much of the previous work on population coding has focused on the special case of orientation representation in V1 neurons or selectivity for motion direction in MT neurons, and in these cases the prior over orientation is typically assumed to be constant, as is the sum of the tuning curves (e.g., Zemel et al., 1998; Jazayeri & Movshon, 2006). These assumptions allow one to ignore the last two terms, and the resulting log-posterior objective function reduces to a simple weighted sum of spike counts, consistent with earlier proposals for linear readout (Bialek et al., 1991; Anderson & van Essen, 1994; Rieke et al., 1997). Note that later stages of processing (i.e., the estimator) presumably

would not have access to the tuning curves, and thus could not compute the linear weights directly by taking the log. Instead, the proper weights could again be learned using unsupervised (or supervised) regression. The linear representation of log probability is especially convenient for fusing independent sources of information, e.g., accumulating evidence over time (Jazayeri & Movshon, 2006; Beck et al., 2008) or combining evidence from multiple modalities (Ma et al., 2006). In these cases, one wishes to multiply the associated probability densities, which can be done by simply adding spike counts.

Rather than assuming a constant prior and sum of tuning curves, a more general solution could embed the prior into the measurements by arranging that the sum of the tuning curves is equal to the log of the prior:

$$\sum_n f_n(x) = \log P(x)$$

(Note: A precise form of this proposal would need to limit the smallest probability that could be represented.) Under these conditions, the last two terms cancel each other, and the full log-posterior may again be computed as a linear function (i.e., a weighted sum) of the spike counts. This is effectively a strategy for embedding the prior into the measurements, and is more efficient than encoding priors with spiking responses of another set of neurons (Ma et al., 2006). This solution would require that the brain adjust the tuning curves so as to sum to the log prior, which is essentially a resource allocation problem: Neurons should be adjusted so as to properly “cover” the distribution of inputs, assigning more resources (i.e., a higher total spiking response, which corresponds to an expenditure of more metabolic energy) to inputs that occur more frequently. This adjustment could be achieved by changing either their response gains, the overlap between their tuning curves, the widths of their tuning curves, or some combination of these.

In the probabilistic representation described above, a single optimal estimate can be computed by appropriately combining information over the entire population. Implementing this in the brain would presumably require creation of a redundant population of neurons to linearly recode the implicit representation into an explicit one (that is, a population whose responses equal the posterior or log posterior), from which a maximum (or mean) could be selected. Although this sort of explicit estimation has been assumed by many of the previously mentioned publications, it seems to me wasteful of neural resources, and not robust to the additional noise that would be introduced by neurons computing and representing the estimate. It seems more likely that the brain leaves the representation probabilistic and implicit, performing further calculations in a way that is consistent with this (e.g., Ma et al., 2006). Taking this *principle of delayed estimation* to its extreme, we could hypothesize that estimates need only be made explicit when the information

reaches the motor system and the animal must execute an action (e.g., reaching out to grasp an object). At that point, the estimate is “computed” by a bone, which responds by moving according to the collective activity of all the muscle fibers that are pulling on it! One case that may be an exception to this is that of a binary estimate (i.e., a decision), for which the log-posterior need only be computed at two different values (rather than a continuum). Experimental evidence suggests that the firing rates of neurons in parietal cortex may represent such values directly (e.g., Platt & Glimcher, 1999; Gold & Shadlen, 2000).

Conclusions

Optimal estimation provides a formal framework for investigating and interpreting perceptual capabilities. The definition of the optimal estimator does not specify a fixed universal function but depends on four fundamental ingredients: the ensemble of input signals over which it is to be optimal, the (probabilistic) relationship between the signal and the measurement, the cost of misestimation, and the family of estimation functions from which the solution is to be chosen. In a biological system, these ingredients may change over time (especially the prior and loss function) and therefore presumably need to be learned and continually updated on the basis of recent input. I have reviewed three different formulations for developing an optimal estimator, each making different assumptions about the means by which these ingredients are obtained.

The basic formalism that I have presented here is highly oversimplified. In particular, I have sidestepped several important features of sensory systems that need to be incorporated in a full solution:

- Sensory computations occur in cascades of neural populations, and each of these presumably performs some transformations on the signals that are received from its afferents and introduces additional noise. The designation of a particular population as the “measurement” is therefore somewhat artificial.
- Sensory computations occur over time. Many optimal estimation problems can be rewritten in a form that can be computed incrementally (the classical solution in statistical signal processing is known as the *Kalman filter*), and such solutions have been used to model temporal aspects of neural processing (e.g., Rao & Ballard, 1997; Denève, Duhamel, & Pouget, 2007).
- Many sensory inference computations depend on information beyond the measurements and the prior, such as inputs from multiple sensory modalities or feedback in the form of attentional signals, or from emotional or cognitive centers. It might be possible to formalize these effects as a contextual form of prior (Jaynes, 2003).

In summary, the challenge for future research is to develop optimal estimation solutions that can be plausibly mapped onto brain architecture, that are flexible and adaptive, that may be cascaded (with additional noise introduced at each stage of the cascade), and that can be learned in a primarily unsupervised setting. The time seems ripe for this. A long tradition of rigorous study in statistical inference has been developed and refined into engineering tools. The use and development of these have recently been accelerated by new methods and algorithms that have arisen in the machine learning community. Coupling these with a new generation of experimental measurement technologies (especially those for obtaining responses from groups or populations of neurons simultaneously) leads me to conclude that we are on the verge of fundamental advances in our understanding of sensory processing.

ACKNOWLEDGMENTS Thanks to Alan Stocker, Mehrdad Jazayeri, Martin Raphan, and the section editors, Tony Movshon and Brian Wandell, for helpful comments and suggestions. This work was financially supported by the Howard Hughes Medical Institute, the National Institutes of Health (EY018003), and the Sloan-Swartz Center for Theoretical Visual Neuroscience at New York University, but the views expressed herein are my own.

NOTES

1. Throughout, x and/or m can be scalar-valued or vector-valued quantities. For example, m might represent responses of a population of neurons.
2. A more sophisticated solution would adjust the smoothness of the estimator adaptively to the amount of data. This issue of model complexity and its relationship to learning from data is fundamental to the study of machine learning.
3. Bias can arise because the estimator is restricted to lie in a family that does not include the best solution. But it can also arise due to asymmetries in the posterior (e.g., due to the influence of a prior) or cost function, in which case it should be viewed as desirable. E. T. Jaynes (2003) described the insistence on unbiased estimators as a “pathology of orthodox statistics.”
4. By presenting the Bayesian and regression formulations side by side, I hope to alleviate some of the tensions between the Bayesian and “frequentist” viewpoints. (See Jaynes, 2003, for further discussion.)
5. A less well-known form of empirical Bayes estimation arises from rewriting the estimator directly in terms of the distribution of measurements, which can be approximated from the observed data (Miyasawa, 1956). This form may be derived from the prior-free estimator described previously (Raphan & Simoncelli, 2007).
6. Note that this formulation is encoding the uncertainty due to the noise in the population response, but not the noise or structural ambiguities in the input (e.g., Sahani & Dayan, 2003).

Introduction

SCOTT T. GRAFTON AND EMILIO BIZZI

HUMANS MOVE with a purpose. Thus the study of motor systems requires more than just the description of movement control. It demands a broad perspective based on anatomical, functional, and computational principles to describe how the nervous system can enable goal-directed behavior. The challenge in solving this problem remains daunting because the intrinsic neural codes that are used to generate motor actions are not fully known, the principles that lead to optimal performance are only just beginning to be modeled, and the system is nonstationary in that adaptation and skill learning appear continuously and on many time scales. The section on motor systems addresses this challenge by the inclusion of complementary approaches, spanning many levels of analysis.

The section begins with a review of motor primitives by Bizzi and Mussa-Ivaldi. This is a critical solution to the degrees-of-freedom problem in limb movement. There are an infinite number of possible muscle activation patterns that could lead to similar movements. How does the nervous system constrain this redundancy? Motor primitives simplify the problem by reducing muscle activations to a set of muscle groups that can be combined, analogous to the mixing of basis functions, to generate characteristic limb movements.

Anatomical studies in the chapter by Dum and Strick extend their previous work demonstrating distinct output channels from different parts of the basal ganglia to distinct cortical areas. New work reveals distinct output channels from the cerebellar nuclei to cortex as well. The existence of distinct cortical projects from basal ganglia and the cerebellum has many important functional implications and could explain the diverse semiology of deficits in patients with lesions to either the basal ganglia or the cerebellum. Alternative models of basal ganglia function, based on both clinical and physiological evidence, are reviewed in greater

detail in the chapter by Graybiel and Mink. They present recent evidence for dopamine mediated learning mechanisms, action selection processes and on-line control within the basal ganglia. Particular emphasis is placed on the selection of action based on prior experience combined with contextual information that might influence choice.

Shadmehr and Krakauer consider the problem of action dynamics more broadly. They consider patients with lesions of the cerebellum, parietal cortex, and basal ganglia and interpret their deficits in terms of computational processes such as state estimation, optimization, prediction, cost, and reward. From this evidence, they argue for relative specialization by which the cerebellum builds internal models that predict sensory outcome of motor commands and correct motor commands, the parietal cortex is used for state estimation, and the basal ganglia are needed for learning costs and rewards associated with sensory states.

Evidence for a unique role of the parietal cortex in state estimation, that is, the integration of vision and somatosensory information with motor command is considered in the chapter by Mulliken and Andersen. They emphasize the role of the parietal cortex for generating a forward model that predicts the sensory consequences of a movement. This prediction is likely to be used in a number of action-relevant processes, including on-line control, evaluating performance with a desired outcome, canceling reafferent input, and mental simulation and determining agency.

The computational methods used in state estimation merge sensory feedback and ongoing motor commands into a common theoretical framework. These different sources of

information are traditionally considered to represent solutions to very different computational problems. Perception has to do with inferring the state of the world given sensory data and action with generating motor commands that lead to a task goal. In his chapter, Todorov summarizes how these two problems are in many ways related. Sensory inference and motor prediction can be united in a single computational framework. With this, it is possible to explore computational similarities and differences between the two systems.

The overlap between perception and action at the neural level is considered in the chapter by Rizzolatti, Fogassi, and Gallese. Using the mirror neuron as a core mechanism for representing an action that is either executed or perceived, they present evidence that extends this general mechanism to humans, where it could be used to understand intentions in others. Impairment of this process might explain some of the clinical deficits that are seen in autism spectrum disorders.

In the final chapter in this section, Grafton, Aziz-Zadeh, and Ivry consider the importance of hierarchical representation as an organizing principle for understanding how people are capable of creating as well as recognizing the meaning of complex, goal-oriented action. They review functional and behavioral evidence in human experiments of hand-object interactions, bimanual control, and the integration of semantics into action planning. The results support the existence of a highly flexible control hierarchy rather than a strict anatomical hierarchy for organizing complex motor behavior.

37 Neurobiology of Coordinate Transformations

EMILIO BIZZI AND FERDINANDO A. MUSSA-IVALDI

ABSTRACT A broad variety of motor plans and concomitant control actions can be expressed by the superposition of force fields representing the mechanical effects of motor synergies. This principle of superposition may lead to the execution of motor plans by controlling the nonlinear dynamics of the body in the presence of redundant muscles and degrees of freedom.

From movement planning to execution

A critical issue in the generation of motor behavior concerns the hierarchical organization of movement planning and movement execution. This concept is derived from engineering notions of modular control by which the problem of movement is decomposed into subproblems that can be addressed separately. One of the great complications of the movement control problem is that any given goal can be reached by a multiplicity of means. If the goal is to move the hand from point A to point B, a variety of paths can be chosen; a variety of trajectories in joint space can be utilized to realize the path. As an example, consider the simple task of reaching for a glass of water on a table. To reach for it, the brain must generate a temporal sequence of activations of the arm muscles. The pattern of neural impulses that controls the contraction of each muscle can be thought of as “coordinates” in an abstract geometrical space (Holdefer & Miller, 2002). In this space, the goal of reaching the glass can be represented as a point whose coordinates are the muscle activations needed to perform the appropriate reach. What happens to these motor coordinates—and to the goal of reaching the glass in the space of muscle activities—if our body moves to another position, such as from standing to sitting? To reach the glass, the arm must now move in a different way, and the muscles must be driven by different commands. As a consequence, the coordinates of the goal of reaching the glass in the space of muscle activities are changed. This is what mathematicians call a *coordinate transformation*, a computation that can be of quite considerable

complexity, given the many different ways in which one may have to activate the muscles to reach the same point in space.

A basic concept in many fields of science, including systems-level neuroscience, is the concept of a coordinate system (Bishop & Goldberg, 1980). A coordinate system is a system of numbers that, taken together, identify the location of a point in space. The space could be the ordinary three-dimensional space in which we move, or it could be an abstract space with a larger or even infinite number of dimensions that may be placed in correspondence with a physical system. For example, the posture of a marionette may be represented by specifying each of its joint angles on a separate axis. Thus, the joint angles provide a coordinate system for the marionette. The state of a biological system, such as the human arm, is described within the nervous system by the collection of neural activities that constitute incoming sensory signals and outgoing motor commands. Although there are several possible coordinate systems—actually an infinite number—to describe different sensory and motor signals, these coordinate systems fall quite naturally into three classes: neuromuscular coordinates, joint coordinates, and endpoint coordinates.

ENDPOINT COORDINATES Endpoint coordinates are appropriate for describing the goal of an action and the interaction with the environment. These coordinates may capture the highly regular properties of reaching behavior when the location of the hand is rendered in Cartesian space (Morasso, 1981; Soechting & Lacquaniti, 1981). Morasso (1981) instructed human subjects to point with one hand to different visual targets that were randomly activated (figure 37.1). His analysis of the movements showed two kinematic invariances: (1) The hand trajectories were approximately straight segments, and (2) the speed profile or tangential velocity of the hand for different movements always appeared to have a bell-shaped configuration, as the time needed to accelerate the hand was approximately equal to the time needed to bring it back to rest. Because these simple and invariant features were detected at a different shoulder and elbow angles, these results suggest that planning by the central nervous system (CNS) takes place in terms of hand

EMILIO BIZZI McGovern Institute for Brain Research, Massachusetts Institute of Technology, Cambridge, Massachusetts

FERDINANDO A. MUSSA-IVALDI Department of Physiology, Northwestern University Medical School, Chicago, Illinois

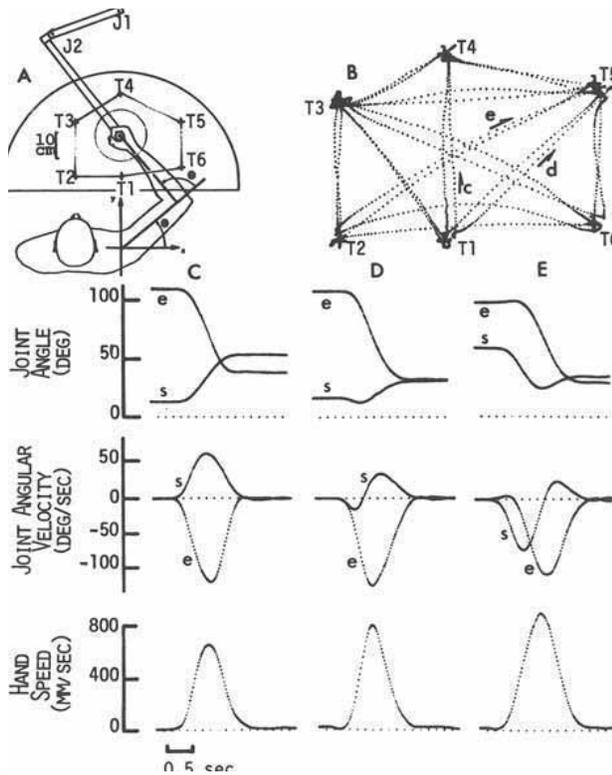

FIGURE 37.1 (A) Plan view of a seated subject grasping the handle of the two-joint hand-position transducer (designed by N. Hogan). The right arm was elevated to shoulder level and moved in a horizontal work space. Movement of the handle was measured with potentiometers located at the two mechanical joints of the apparatus (J1, J2). The subject was positioned so that J1 lay on the Y -axis. A horizontal semicircular plate located just above the handle carried the visual targets. Six visual target locations (T1–T6) are illustrated as crosses. The digitized paths between targets and the curved path were obtained by moving the handle along a straight edge from one target to the next and then along a circular path; movement paths were reliably reproduced. (B) A series of digitized handle paths (sampling rate: 100 Hz) performed by one subject in different parts of the movement space. The subject moved his hand to the illuminated target and then waited for the appearance of a new target. Targets were presented in random order. Arrows show direction of some of the hand movements. (C, D, E) Kinematic data for three of the movements the paths of which are shown in B. Letters show correspondence (e.g., data under C are for path c in B). Abbreviations: e, elbow joint; s, shoulder (angles measured as indicated in A). (From Bizzi E., and Abend, W. K., 1983, *Motor Control Mechanisms in Health and Disease*, J. E. Desmedt, ed. New York: Raven Press.)

motion in space. Here, the hand is regarded almost as a disembodied object whose movements are planned by the CNS independently of the geometrical and mechanical properties of the arm and its muscles. Morasso's observations were extended to more complex curved movements performed by human subjects in an obstacle avoidance task (Abend, Bizzi, & Morasso, 1982). Again, kinematic invariances were present in the hand and not in the joint motion. Later, Flash and Hogan (1985) showed that the kinematic behavior

described by Morasso (1981) and Abend and colleagues (1982) could be derived from a single organizing principle based on optimizing endpoint smoothness. A different view was offered by Kawato and coworkers (Uno, Kawato, & Suzuki, 1989), who proposed that the shape of movement trajectories is not explicitly planned but is rather a side effect of the CNS optimizing a dynamical variable: the rate of change of joint torque. However, the observation that movement trajectories are recovered when the movement is perturbed by a force field (Shadmehr & Mussa-Ivaldi, 1994) reinforced the idea that the CNS recovers the trajectory of the hand by producing the torques that are needed to compensate for the external forces. This supports the notion of planning in endpoint coordinates.

MUSCLE COORDINATES Muscle coordinates (Holdefer & Miller, 2002) afford the most direct representation for the motor output of the central nervous system. A position in this coordinate system may be expressed, for example, as a collection of muscle lengths. Accordingly, a force vector in the same coordinate system is a collection of muscle tensions. The number of actuator coordinates depends upon how detailed is the model of control under consideration. Unlike generalized coordinates, actuator coordinates do not constitute a system of mechanically independent variables; one cannot set arbitrary values to muscle lengths without eventually violating a kinematic constraint.

At the most detailed level, individual motor units may be considered as actuator elements. In this case, the order of magnitude of the actuator space can be of the order of 10 or 100,000 dimensions.

JOINT COORDINATES AND THE GENERATION OF FORCES A different way of describing body motions is to provide the set of joint angles that define the orientation of each skeletal segment either with respect to fixed axes in space or with respect to the neighboring segments. This is a well-known representation in robotics and analytical mechanics called *configuration space* (Spong, Hutchinson, & Vidyasagar, 2005). Joint angles are a particular instance of generalized coordinates. Generalized coordinates are independent variables that are suitable for describing the dynamics of a system (Goldstein, 1980; Jose & Saletan, 1998). In particular, the dynamics of limbs such as the human arm are described by systems of coupled differential equations relating the generalized coordinates to their first and second time derivatives and to the generalized forces.

In vector notation, the dynamics equations for a multi-jointed limb are succinctly written as

$$I(q)\ddot{q} + G(q, \dot{q}) + E(q, \dot{q}, t) = C(q, \dot{q}, u(t)) \quad (1)$$

where $q = (q_1, q_2, \dots, q_N)$ is the limb configuration in joint-angle coordinates, \dot{q} and \ddot{q} are respectively the first (velocity) and second (acceleration) time derivatives of q , I is a $N \times N$

matrix of inertia (that is configuration-dependent), $G(q, \dot{q})$ is a vector of centripetal and Coriolis torques (Spong et al., 2005), and $E(q, \dot{q}, t)$ is a vector of external torques, which, in general, depends upon the state of motion of the limb and upon time. The whole left-hand side of equation 1 represents the torque due to the inertial properties of the arm and to the action of the environment (part of which may be considered “noise”). The term $C(\cdot)$ on the right-hand side stands for the net torque generated nonlinearly by the muscles, by the environment (e.g., the gravitational torque), and by other dissipative elements, such as friction. The time-function $u(t)$ is a control vector—for example, a set of neural signals directed to the motoneurons or a representation of a desired limb position at time t . The left-hand side of equation 1 represents the passive dynamics associated with limb inertia. The right-hand side is the applied force, which is the output of a control process. An additional term, not represented in equation (1), is the noise associated with the control signal.

The way in which the CNS implements the dynamic equation (1) has been the focus of a number of investigations in the last 20 years. Through work in humans and monkeys, a number of investigators have put forward the hypothesis that the CNS generates movements and forces by using internal models of the limbs and of the environment with which they come into contact (Thoroughman & Taylor, 2005; Sabes, 2000; Davidson & Wolpert, 2004, Flanagan & Wing, 1997; Kawato & Wolpert, 1998; Krakauer, Ghilardi, & Ghez, 1999; Shadmehr & Mussa-Ivaldi, 1994; Wolpert, Miall, & Kawato, 1998).

Alternative proposals have been made that do not depend on the solution of complicated inverse dynamics problems (Feldman & Latash, 2005). Specifically, it has been proposed that the CNS may transform the desired hand motion into a series of equilibrium positions (Bizzi, Accornero, Chapple, & Hogan, 1984). The forces that are needed to track the equilibrium trajectory result from the intrinsic elastic properties of the muscles and from local feedback loops (Feldman, 1966; Bizzi, Polit, & Morasso, 1976; Hogan, 1984). However, if movements are to be executed with any substantial amount of acceleration, then the inertial forces of the arm have to be taken implicitly into account, as they tend to displace the limb away from the equilibrium trajectory. In this case, some computational mechanism is required to derive the equilibrium trajectory that is adequate to move the hand along the desired trajectory. It is then merely a semantic issue to distinguish this operation from an explicit dynamics computation.

Another view on solving the dynamic equations and to execute a motor plan is the hypothesis that motor behavior of vertebrates is based on simple units (motor primitives) that can be flexibly combined to accomplish a variety of motor tasks. Here is an apt and succinct quote from Cvitanovic (2000), concerning the general problems posed by complex nonlinear dynamics:

Armed with a computer and a great deal of skill, one can obtain a numerical solution to a nonlinear partial differential equation. The real question is; once a solution is found, what is to be done with it? . . . Dynamics drives a given spatially extended system through a repertoire of unstable patterns; as we watch a “turbulent” system evolve, every so often we catch a glimpse of a familiar pattern. For any finite spatial resolution, the system follows approximately for a finite time a pattern belonging to a finite alphabet of admissible patterns, and the long-term dynamics can be thought of as a walk through the space of such patterns, just as chaotic dynamics with a low-dimensional attractor can be thought of as a succession of nearly periodic (but unstable) motions.

The key concept here is that complex behavior may be analyzed by a combination of patterns.

Building blocks for computation of dynamics: Compositionality

In the natural world some complex systems are discrete combinatorial systems—they utilize a finite number of discrete elements to create larger structures. The genetic code and language phenomena are examples of systems in which discrete elements and a set of rules can generate a large number of meaningful entities that are quite distinct from those of their elements. A question of considerable importance is whether this fundamental characteristic of language and genetics is also a feature of other biological systems. In particular, the question is whether the activity of the vertebrate motor system, with its impressive capacity to find original motor solutions to an infinite set of ever-changing circumstances, results from the combinations of discrete elements.

The ease with which we move hides the complexity inherent in the execution of even the simplest tasks. Even movements we make effortlessly, such as reaching for an object, involve the activation of many thousands of motor units in numerous muscles. Given this large number of degrees of freedom of the motor system, a number of investigators have put forward the hypothesis that the CNS handles this large space with a hierarchical architecture based upon the utilization of discrete building blocks whose combinations result in the construction of a variety of different movements (Arbib, 1981; Tsetlin, 1973). In particular, investigators influenced by the AI perspective on the control of complex systems have argued for a hierarchical decomposition with modules, or building blocks, as the most effective way to select a control signal from a large search space (Russell & Norvig, 1995).

The construction of natural motor behavior with muscle synergies

For a long time, investigators have recognized that one of the basic questions in motor performance is whether the cortical motor areas control individual muscles or make use

of synergistically linked groups of muscles (Macpherson, 1991). Given that no natural movement involves just one muscle, any motor act, a fortiori, involves a “muscle synergy,” the question, then, has been whether the synergistic activation of muscles derives from a fixed common neural drive or is merely a phenomenological event of a given motor coordination. The recent introduction of novel computational procedures to extract synergies from large sets of EMG signals in intact behaving animals and humans has opened a different way to approach the issue of synergies (Soechting & Lacquaniti, 1989; Tresch, Saltiel, d’Avella, & Bizzi, 2002; Saltiel, Wyler-Duda, d’Avella, Tresch, & Bizzi, 2001; d’Avella & Tresch, 2002; d’Avella, Portone, Fernandez, & Lacquaniti, 2006).

In 1999, Tresch, Saltiel, and Bizzi developed a computational method to extract synergies from the recorded muscle activations. This method is based on decomposing the observed muscle patterns as simultaneous combinations of a number of synergies. This decomposition is obtained by using an iterative algorithm that is initialized with a set of arbitrary synergies. The nonnegative weighting coefficients of these arbitrary synergies that best predict each response are then found. The synergies are then updated by minimizing the error between the observed response and the predicted response. This process is iterated until the algorithm converges on a particular set of synergies. The algorithm extracts both a set of synergies and the weighting coefficients of each synergy used to reconstruct the electromyogram responses.

Note that there are a number of factorization algorithms to assess the hypothesis that motor behavior might be produced through a combination of a small number of synergies. Tresch, Cheung, and d’Avella (2006) have compared different algorithms and found that in general, most of the algorithms that are used to identify muscle synergies, such as nonnegative matrix factorization, independent component analysis, and factor analysis, perform comparably. When they applied these methods to experimentally obtained data sets, the best-performing algorithms identified synergies that were very similar to one another. These results suggest that the muscle synergies found by a particular algorithm are not an artifact of that algorithm but reflect basic aspects of muscle activation.

The coordination among muscle recruitments expressed by a synergy might also be extended to the temporal domain. This idea has led to the introduction of a novel factorization algorithm (d’Avella & Tresch, 2002) to extract time-varying synergies, that is, the coordinated activations of groups of muscles with specific time-varying profiles. Time-varying synergies can naturally capture specific asynchronous activations of groups of muscles and provide a parsimonious model for the generation of muscle patterns. In fact, once the synergies have been specified, one amplitude scaling coefficient

and one time delay coefficient per synergy are sufficient for generating a muscle pattern. In contrast, the entire time course of the weighting coefficients is required with synchronous synergies.

To directly assess this hypothesis, d’Avella, Saltiel, and Bizzi (2003) examined several motor behaviors in intact, freely moving frogs by recording simultaneously from a large number of hindlimb muscles during locomotion, swimming, jumping, and defensive reflexes (d’Avella et al., 2003; d’Avella & Bizzi, 2005). An iterative algorithm was used to decompose the muscle patterns as combinations of time-varying muscle synergies independently scaled in amplitude and shifted in time. This iterative algorithm finds a set of muscle synergies and, for each muscle pattern, the amplitude and delay of each synergy that minimize the reconstruction error for the entire data set. Figure 37.2 shows the five time-varying synergies that were extracted from all the rectified, low-pass filtered, and integrated (10 ms) EMGs recorded during a total of 2174 jumps, walking cycles, and swimming cycles in three frogs. The five extracted synergies include all 13 muscles. The first three synergies (W_1 , W_2 , and W_3) recruit mainly extensors, while W_4 and W_5 recruit mainly flexors. The most active muscles of synergy W_1 are the hip extensors rectus internus (RI), adductor magnus (AD), and semimembranosus (SM); the knee extensor vastus internus (VI); and the ankle extensors peroneus (PE) and gastrocnemius (GA). The most active muscles of the synergy W_2 are SM, vastus externus (VE), and GA. In W_3 , RI, SM, and VI are the most active. The flexors dominate synergy W_4 with rectus anterior (RA), biceps (BI), and iliopsoas (IP). Synergy W_5 includes mainly semitendinosus (ST) and IP. Note that some of the muscles are present in more than one synergy. The R^2 for the five synergies extracted from the entire data set was 0.78. Thus a large fraction of the total variation of the data was described by a model that has just 10 parameters (five amplitude and five timing coefficients) once the synergies have been determined.

Figure 37.3 shows the reconstruction of muscle patterns (rectified, filtered, and integrated EMGs, *thin line and shaded area*) for a jump, a cycle of walking, and a cycle of swimming as combinations of the five synergies shown in figure 37.2 (*thick line*). The synergy’s amplitude is shown as the height of the rectangles below the EMGs, and the delay coefficients are shown by their horizontal position. The essential features of the three muscle patterns are well captured by scaling in amplitude and shifting in time the five time-varying synergies. In jumping (first column), two of the three extension synergies are active (W_1 and W_3) together with the two flexion synergies (W_4 and W_5). In walking (second column), synergies 1, 3, and 4 appear again, but their amplitude balance and recruitment order are radically different from jumping: W_4 dominates in amplitude, while W_1 and W_3 are

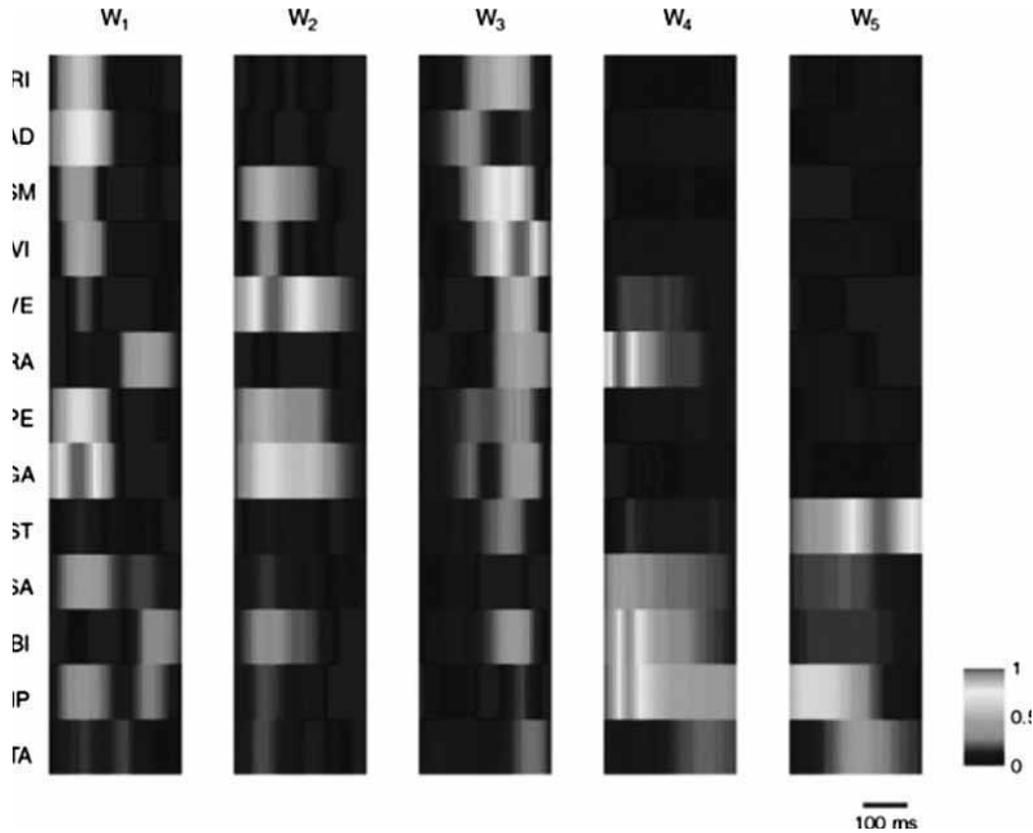

FIGURE 37.2 Time-varying muscle synergies extracted from jumping, swimming, and walking muscle patterns in three frogs. Each synergy (columns W_1 to W_5) represents the activation time course (in color code) of 13 muscles over 30 samples (total duration: 300 ms) normalized to the maximum sample of each muscle. Abbreviations: RI, rectus internus; AD, adductor magnus; SM, semimembranosus; VI, the knee extensor vastus internus; VE,

vastus externus; RA, rectus anterior; PE, the ankle extensors peroneus; GA, gastrocnemius; ST, mainly semitendinosus; SA, semitendinosus; BI, biceps; IP, iliopsoas; TA, tibialis anterior. (From Bizzi, E., Cheung, V. C., d'Avella, A., Saltiel, P., Tresch, M. C., 2008, Combining modules for movement, *Brain Res. Rev.*, 57, 125–133.) (See color plate 51.)

relatively small, and the timing between W_3 and W_4 is reversed. Swimming (third column), in contrast, is dominated by W_2 and to a lesser extent by W_5 .

The examples illustrated by figure 37.3 demonstrate two important points: (1) that the same synergies are found in different behaviors and (2) that different behaviors may be constructed by combining the same synergies with different timing and amplitude.

The examples illustrated in figures 37.2 and 37.3 address the important question of whether the synergies extracted by a computational procedure have biological standing. A compelling criterion is the presence of the same synergy, with its own internal temporal structure, in different behaviors, as illustrated in figure 37.3. Additional evidence supporting the idea that synergies are indeed functional units was shown by Giszter and Kargo (2000). They showed examples of deletions as well as of additions during leg motions in the frog. Kargo and Giszter (2000) showed that the spinalized frog is able to produce corrective movements

in response to unexpected perturbations. They placed an obstacle in the path of the leg and showed that when the leg hit the obstacle, the added synergy was one of the sets of six previously identified synergies.

Other investigators have generated corroborative evidence for modular organization in cats (Lemay, Galagan, Hogan, & Bizzi, 2001; Ting & Macpherson, 2005; Krouchev, Kalaska, & Drew, 2006; Torres-Oviedo et al., 2006) and the turtle (Stein, Oguztoreli, & Capaday, 1986; Stein, McCullough, & Currie, 1998). In addition, results from the study of the muscle patterns during reaching in humans (d'Avella et al., 2006) suggest that this is a general strategy used by all vertebrates for simplifying the control of limb movements.

A clear-cut example of a recombination of synergies is from locomotion with the different limb central pattern generators (CPGs). Each CPG can operate independently, but the four limb CPGs can also be combined in different patterns as in a walk, a trot, or a gallop. On the basis of extensive indirect evidence, Grillner (1981, 1985) suggested that

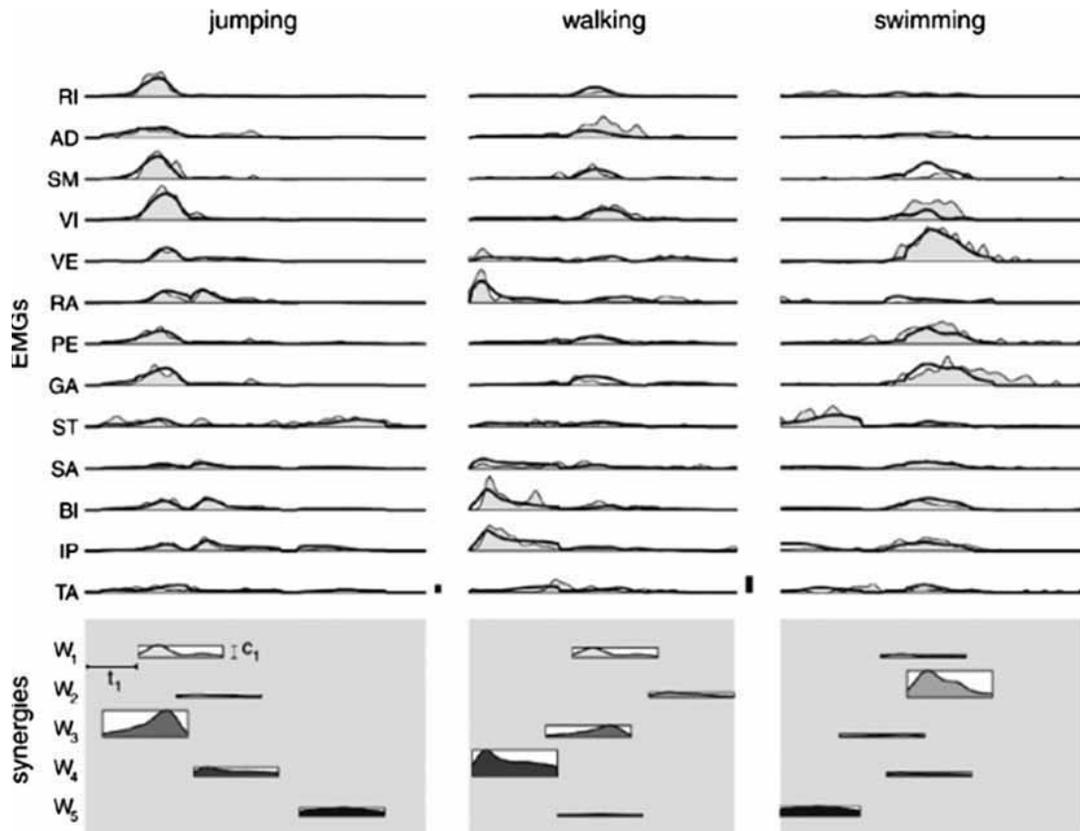

FIGURE 37.3 Examples of reconstruction of EMG patterns as combinations of time-varying muscle synergies. The three columns are examples of a jump, a walking cycle, and a swimming cycle. *Upper section:* The thick line shows the reconstruction of muscle patterns and the shaded area represents the rectified, filtered and integrated EMGs. *Lower section:* The coefficients of the five synergies as the horizontal position (onset delay, t_i) and the height (amplitude,

c_i) of a rectangle whose width corresponds to the synergy duration. The shaded profile in each rectangle illustrates the averaged time course of the muscle activation waveforms of the corresponding synergy. Note the different amplitude scaling used in the three columns. (From Bizzi, E., Cheung, V. C., d'Avella, A., Saltiel, P., Tresch, M. C., 2008, Combining modules for movement, *Brain Res. Rev.*, 57, 125–133.)

each limb CPG can be further subdivided into unit CPGs that control synergist muscles acting at each joint. It has also been proposed that these different unit CPGs or synergies can be the independent target for the supraspinal commands used to design different volitional movements involving a limited set of joints (Grillner, 1985, 2006; Grillner & Zangger, 1979).

In conclusion, the evidence provided by studies from different laboratories and in different species indicates that combining muscle synergies is a strategy that the CNS utilizes for the construction of movements in vertebrates.

Physiological basis of muscle synergies: Modularity in the frog spinal motor system

With microstimulation of the spinal interneuronal regions, Bizzi, Mussa-Ivaldi, and Giszter (1991), Giszter, Mussa-Ivaldi, and Bizzi (1993), and Tresch and colleagues (1999) have provided evidence for a modular organization of the frog's and rat's spinal cord. These experiments found that

only a few distinct types of motor outputs could be evoked by either electrical (Bizzi et al., 1991) or NMDA stimulation (Saltiel et al., 2001). Importantly, when stimulation was applied simultaneously to two different sites in the spinal cord, each of which when stimulated produced a different motor output, the resulting motor output was a simple linear combination of the separate motor outputs (Mussa-Ivaldi, Giszter, & Bizzi, 1994; Lemay et al., 2001). In subsequent experiments, Tresch and colleagues (1999) showed that the motor response evoked from cutaneous stimulation of a particular site on the hindlimb resulted from the weighted combination of a few muscle synergies. When Tresch and colleagues (1999) compared the distinct muscle synergies derived from cutaneous stimulation with the patterns of muscle activation evoked by microstimulation of the frog spinal cord, he found that the two sets of EMG responses were very similar to one another. In addition, the synergies evoked by NMDA were found by Saltiel and colleagues (2001) to be qualitatively similar to those described by Tresch and colleagues (1999). Taken together, these experiments

have provided evidence in support of a spinal modular organization underlying natural behaviors produced by the frog spinal cord.

Translating plans into actions: The mechanical basis for compositionality

The microstimulation studies described above have revealed that the mechanical effect of a muscle synergy is captured by a field of forces that vary both with space and in time. The combination of force fields generated by multiple synergies offers the CNS a way for solving the problem of dynamics (equation 1) in the presence of motor redundancy. Motor redundancy is a common property of multijoint limbs, such as the human arm, in which there are more joint angles than endpoint variables and more muscles than joint angles. Many of the computational problems associated with redundancy are removed by expressing a motor plan as a force field in endpoint coordinates and by approximating this field with a superposition of force fields corresponding to muscle synergies. This is illustrated in more detail by the following argument.

The graph in figure 37.4A highlights the main challenge associated with redundancy of the musculoskeletal apparatus: The transformations between actuator, generalized, and endpoint variables are not invertible and are well defined only in the direction of the arrows. For example, given the angular configuration of the arm, q , it is possible to derive

the position of the hand, r . However the same position of the hand can be reached with different joint angles. Similarly, given the forces exerted by all the muscles on a joint, one derives the net torque while any value of torque can be obtained with an infinite number of muscle force combinations. How is it possible for the CNS to map a desired movement plan, in terms of endpoint behavior, into a corresponding command for the muscles? As shown in figure 37.4B, force fields provide additional pathways that map motions into forces. This shows how mechanics simplifies computations that would be otherwise unmanageable and ill posed. Thus, for example, a muscle synergy determines the force generated by the muscles in response to a stretch applied at any operating length. When multiple synergies are induced by a pattern of motor commands (u in figure 37.4B), their net effect is a field of torque vectors: For each configuration and state of motion of the joints, there is one and only one corresponding torque vector.

The planning of a desired behavior can in turn be expressed as a force field that maps the discrepancy between actual and desired state of the endpoint into a corrective force. In this way, a field of forces that converge on the target and that vanish there provides a detailed specification for the task of reaching a target with the hand. If an obstacle is interposed along the hand path, the concurrent goal of avoiding a collision can be represented as a field of forces that diverge from the obstacle. This mathematical representation has been proven successful in dealing with problems

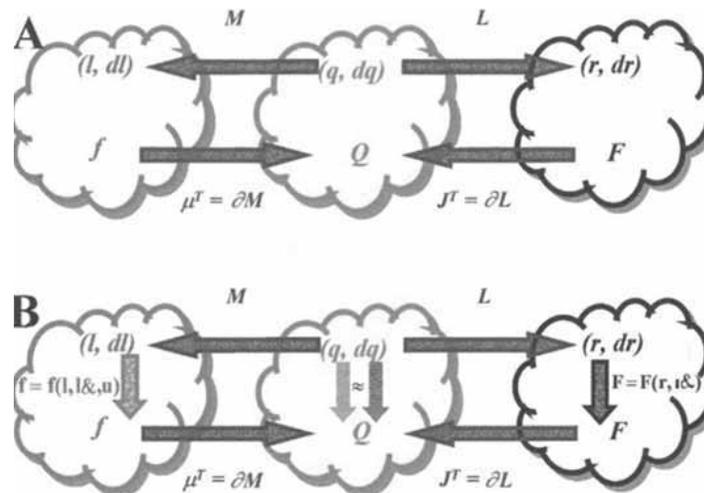

FIGURE 37.4 Coordinate transformations for planning and control of movement in a redundant limb. (A) Kinematic and force transformations for the human arm between muscle coordinates, joint coordinates, and endpoint coordinates. Arrows indicate the directions in which the transformations are well posed. Abbreviations: l , muscle lengths; q , joint angles; r , hand position; F , hand force; Q , joint torque; f , muscle force. M represents the transformation from joint angles to muscle lengths and L the transformation from joint angles to hand position αM and αL are the respective

Jacobian matrices. (B) The vertical arrows map motion variables (position and velocity) onto force variables. They represent force fields. On the left is the force field generated by the muscles. On the right is the force field in endpoint coordinates that represents a desired behavior. Both the endpoint field and the muscle field have a well-defined image in joint coordinates, and the implementation of a desired behavior can be represented as a problem of approximation.

of robot motion planning (Khatib, 1986; Rimon & Koditschek, 1989). Although a literal implementation of this approach within the CNS may seem unlikely, one should observe that when we plan an action, such as reaching for a target, we are specifying not only a point of space but also additional requirements, such as those of remaining at rest at the target and avoiding collisions. Force fields provide a rigorous framework for expressing these concurrent demands by exploiting a mechanism of superposition. It is critical to observe that once a force field is given in endpoint coordinates, it is always possible to translate this field in joint coordinates despite the kinematic redundancy of the arm. The arrows on the right-hand side of figure 37.4B provide a path for this transformation: (1) The joint angles and angular displacements are mapped via the direct kinematics into a corresponding position and displacement of the hand; (2) the planned force field assigns a hand force to this position and displacement of the hand; and (3) the hand force is mapped into the corresponding joint torque by the (direct) Jacobian matrix of the arm.

It is apparent from the above considerations that the fields associated with muscle synergies and the fields associated with the description of a task find a common representation in joint coordinates (more generally, in generalized coordinates). In this common geometrical space, plans can be mapped into action by finding the combination of synergies that generates the best approximation of the planned field (*dashed arrows* in figure 37.4B). This is a process that does not require ill-posed inversions of redundant maps. Most important, force fields provide a way to compose building blocks of planning and building blocks of control through a single straightforward rule of linear summation.

Slotine and Lohmiller (2001) have developed a theoretical analysis of biological and robotic motor control based on the general concept of contraction dynamics (Lohmiller & Slotine, 1998). They pointed out that the mechanisms of biological evolution tend to favor behaviors that are not only successful but also, and most important, stable. The requirement of stability imposes a strong constraint on motor primitives, such as muscle synergies: Successful motor primitives should produce stable behaviors when they are acting individually and also when they operate in combination with other primitives. Convergent force fields such as those generated by spinal circuits satisfy this fundamental requirement. The modularity of control established by these fields has the critical property of ensuring stability to motor behaviors, when individual muscle synergies operate in isolation as well as when they operate in combination with other synergies, resulting in the summation of the respective force fields.

This view goes beyond the execution of a preplanned trajectory, as it allows for uncertainty in the knowledge of the environment and of the limb's mechanical properties

and for a broader concept of motor planning that includes not only the generation of movements, but also the exertion of contact forces. As for the first point, the uncertainty, one should observe that a force field does not specify the accurate requirement of a position or of a trajectory but rather specifies the tradeoff between a desired position (or trajectory) and the force that is exerted in response to a deviation from this desired trajectory.

Optimal control and uncertainty: A computational basis for motor synergies

Once one accepts the general notions that muscles are organized into synergies and that synergies are combined by the CNS to form a repertoire of movements from a simple combinatorial “syntax” (Flash & Hochner, 2005), the next question to address is how these synergies are constructed from a large palette of possible muscle combinations. How does the motor system choose the particular patterns of stereotypical neuromuscular activations that constitute the natural vocabulary of motor primitives? To address this question, Todorov and coworkers (Todorov & Jordan, 2002; Todorov, Li, & Xiuchuan, 2005) have proposed that patterns of motor control arise from the goal of making movements as efficient as possible, given their goal and the constraints in which movements take place. An important constraint arises from motor noise.

The analysis of motor unit activities (Matthews, 1996) suggests a major role of synaptic noise in the excitation of motor neurons. Harris and Wolpert (1998) have proposed that the observed smoothness of natural motions that is observed in different motor behaviors (arm and eye movements, for example) may be accounted for by assuming that the biological controller minimizes the final error while being subject to signal dependent noise. This proposal is based on the idea that violations of smoothness, such as a large swing in a trajectory, are associated with large-amplitude control signals. Given that the signal variance accumulates additively along a movement, the net expected outcome of a jerky motion is a larger variance at the final point. Similar considerations are at the basis of a more general framework that was proposed recently by Todorov and Jordan (2002). They observed that in the presence of redundancy, one may identify within the space of control signals a lower-dimensional “task-relevant” manifold. This contains the combinations of motor commands that have a direct impact on the achievement of the established goal. Because of redundancy, at each point of this manifold, there is a “null space” of control signals that do not affect the execution of the task. For example, when we place the index finger on a letter key, we may do so with an infinite number of arm configurations. A common observation across a variety of behaviors is that variability tends

to be higher in the task-irrelevant dimensions. Todorov and Jordan (2002) consider this to be a direct consequence of optimal feedback control. According to this scheme, the control system aims to minimize the expected error on the final target in the presence of signal-dependent noise. While the outcomes of the optimization may depend upon the specific distribution of variability among the system of actuators, the simulations presented by these authors indicate a general tendency of the control system to place the highest variance in the task-irrelevant dimensions so as to achieve a higher degree of precision in the task-relevant dimensions. This view of the biological control system brings about two important (although yet to be proven valid) concepts:

1. that the control system is not necessarily concerned with the explicit planning of movement trajectories but rather is concerned with the attainment of final goals with the least amount of variance and
2. that the space spanned by the task-irrelevant dimensions plays the role of a “variance buffer,” where the noise generated by the control signals has the largest effect so as to attain a higher performance in the space defined by the task.

Although this is a promising approach, with potentially important implications for the design of biomimetic controllers, the evidence for the explicit planning of trajectories remains rather strong (Dingwell, Mah, & Mussa-Ivaldi, 2002; Mosier, Scheidt, Acosta, & Mussa-Ivaldi, 2005; Flash, 1987; Shadmehr & Mussa-Ivaldi, 1994). It is difficult to reconcile the observation of regularities observed in endpoint coordinates, such as the execution of smooth rectilinear motions of the hand, with properties such as signal-dependent noise that concern the behavior of muscles and joints. To see this, consider a movement of the hand between two targets and suppose that the noise introduced by the shoulder muscles is greater than the noise introduced by the elbow muscles. If the only goal of the controller were to reduce the error on the final target, then the trajectory would be chosen to minimize the activity of the shoulder muscles. Obviously, a different trajectory would be chosen if the elbow muscles were the main source of noise. This prediction appears difficult to reconcile with the observation of smooth and quasi-rectilinear hand paths. Nevertheless, the framework of optimal control is important, as it establishes a direct one-to-one relationship between the goals of an action and the pattern of activations that are best suited to attain this goal. This approach provides “normative models” of motor control (Kording, 2007), which predict behavior based on the optimization of a cost function. This approach can also be used “in reverse” by searching for optimization functions, given a desired behavior. However, this is often seen as a weakness of optimization-based theories, as they

may be fine-tuned to “explain” any observed pattern of behavior. The use of the optimality principle has a long and distinguished history in motor control (Hogan, 1984; Stein et al., 1986; van Beers, Baradua, & Wolpert, 2002). However, more recently, optimal control theory has been considered a promising framework for identifying patterns of meaningful muscle synergies. Chhabra and Jacobs (2006) have used Todorov’s optimal feedback control to derive optimal patterns of joint torques for generating a large repertoire of reaching movements by a simulated arm. Then, as the joint torques are assumed to be produced by antagonist pairs of muscles acting across the shoulder and elbow joint, Chhabra and Jacobs used the nonnegative matrix factorization of d’Avella and colleagues (2003) to identify a set of muscle synergies that are competent to generate the optimal control torques. While this approach provides some general insight on the features of the motor synergies that may arise from optimal control, it is limited by the lack of available knowledge about the relationship between neuromuscular activities and their mechanical outcomes in terms of force. Therefore motor synergies expressed in terms of muscle forces are not easily translated into motor synergies in terms of neural or EMG activities, as in the work of d’Avella and colleagues (2003).

Todorov’s approach to motor synergies (Todorov et al., 2005) is based on stochastic optimal control theory and may not yield an immediate interpretation of neural patterns. However, it has the potential to derive motor synergies based on the combined goals of satisfying optimal performance criteria and of enforcing compositionality. This is possible because the most general solution of optimization problems is obtained—in the continuous domain—by solving a partial differential equation, the Hamilton-Jacobi-Bellman (HJB) equation (Kirk, 1970), which is analogous to the Hamilton-Jacobi equation of classical mechanics and to the Schrödinger equation of quantum mechanics (Goldstein, 1980). The latter allowed deriving atomic structures as superposition of waves, a very primal form of compositionality. Todorov (2006) has recently obtained a similar result for optimal control. He derived a linear formulation of the HJB equation that allows obtaining primitives of control from a system of basis eigenfunctions of a linear operator. In this case, as for the wave functions of Schrödinger, any combination of optimal control policies still satisfies the same optimality condition as the individual policies.

Although a large collection of open issues remains, the combination of computational models based on nonlinear control and optimization theories with more advanced techniques for extracting information from neuromuscular patterns yields the promise of understanding how biological motor behavior is shaped by the interaction of evolutionary process and day-to-day learning mechanisms.

38 Basal Ganglia and Cerebellar Circuits with the Cerebral Cortex

RICHARD P. DUM AND PETER L. STRICK

ABSTRACT What are the functions of the basal ganglia and cerebellum? It is now clear that output of the basal ganglia and cerebellum targets motor, premotor, prefrontal, posterior parietal, and infero-temporal areas of cortex. These connections provide the basal ganglia and cerebellum with the anatomical substrate to influence not only the control of movement, but also many aspects of cognitive behavior like planning, working memory, sequential behavior, visuospatial perception, and attention. Similarly, abnormal activity in specific basal ganglia and cerebellar loops with the cerebral cortex may contribute to a variety of neuropsychiatric disorders, such as schizophrenia, autism, attention-deficit/hyperactivity disorder, and obsessive-compulsive disorder. Thus, defining the cortical targets of the basal ganglia and cerebellum provides important insights into their diverse motor and nonmotor function.

What are the functions of the basal ganglia and the cerebellum? Numerous reports describe the motor deficits associated with damage to these subcortical structures. As a consequence, concepts about basal ganglia and cerebellar function have focused primarily on their contributions to the generation and control of movement. We have used an anatomical approach to examine the macro-organization of basal ganglia and cerebellar connections with the cerebral cortex. In this chapter, we focus on one critical question: Which cortical areas are the target of the outputs from the basal ganglia and the cerebellum? The answers to this question lead to some novel and important insights about basal ganglia and cerebellar function.

Classically, the macro-organization of basal ganglia and cerebellar circuitry is described using a relatively simple hierarchical model. The “input layer” of basal ganglia processing is represented by the striatum (caudate, putamen, and ventral striatum). The functionally analogous level in cerebellar circuits is represented by specific pontine nuclei that send “mossy fiber” inputs to cerebellar cortex. A major source of afferents to the input layers of both circuits origi-

nates from widespread regions of the cerebral cortex, including motor, sensory, posterior parietal, prefrontal, cingulate, orbitofrontal, and temporal cortical areas. The “output layer” of basal ganglia processing is represented by the internal segment of the globus pallidus (GPi), the pars reticulata of the substantia nigra (SNpr), and the ventral pallidum. The comparable structures for cerebellar processing are the three deep cerebellar nuclei: dentate, interpositus, and fastigial. Neurons in the output layers of both circuits send their axons to the thalamus and, by this route, project back upon the cortex. Thus, a major structural feature of basal ganglia and cerebellar circuits is that they form loops with the cerebral cortex (e.g., Kemp & Powell, 1971; Allen & Tsukahara, 1974; Brooks & Thach, 1981). These loops were believed to function largely in the domain of motor control. Indeed, basal ganglia and cerebellar efferents were thought to terminate in a common region of the ventrolateral thalamus that projected largely to the primary motor cortex (M1). Thus these circuits were viewed as a neural substrate for enabling information from a diverse set of cortical areas to influence motor output at the level of M1. This view has been supported by the obvious motor symptoms that can result from basal ganglia and cerebellar dysfunction (for references and reviews, see Brooks & Thach, 1981; DeLong & Georgopoulos, 1981; Bhatia & Marsden, 1994).

Over the past 20 years, an accumulation of information about basal ganglia and cerebellar anatomy has led a number of investigators to challenge this view (e.g., Schell & Strick, 1984; Alexander, DeLong, & Strick, 1986; Goldman-Rakic & Selemon, 1990). It is now clear that basal ganglia and cerebellar efferents terminate in different subdivisions of the ventrolateral thalamus (for a review, see Percheron, François, Talbi, Yelnik, & Fénelon, 1996), which, in turn, project to a myriad of cortical areas. Thus the outputs from the basal ganglia and cerebellum influence more widespread regions of the cerebral cortex than was previously recognized.

On the basis of these and other anatomical results, Alexander and colleagues (1986) proposed that the basal ganglia participate in at least five separate loops with the cerebral cortex. These loops were based in part on their cortical target from the output layer of processing and were designated the skeletomotor, oculomotor, dorsolateral

prefrontal, lateral orbitofrontal, and anterior cingulate circuits. According to this scheme, the output of the basal ganglia has the potential to influence not only the control of movement, but also higher-order cognitive and limbic functions that are subserved by prefrontal, orbitofrontal, and anterior cingulate cortex.

Similarly, Leiner, Leiner, and Dow (1986, 1991, 1993) suggested that cerebellar output is directed to prefrontal as well as motor areas of the cerebral cortex. They noted that in the course of hominid evolution, the lateral output nucleus of the cerebellum—the dentate—undergoes a marked expansion that parallels the expansion of cerebral cortex in the frontal lobe. They argued that the increase in the size of the dentate is accompanied by an increase in the extent of the cortical areas in the frontal lobe that are influenced by dentate output. As a consequence, Leiner and colleagues proposed that cerebellar function in humans has expanded to include involvement in certain language and cognitive tasks.

Attempts to test these proposals and map cerebellar and basal ganglia projections to the cerebral cortex have been hindered by a number of technical limitations. Chief among these are the multisynaptic nature of these pathways and the general inability of conventional tracers to label more than the direct inputs and outputs of an area. To overcome these and other problems, we developed the use of neurotropic viruses (herpes simplex virus type 1 [HSV1] and rabies virus) as transneuronal tracers in the central nervous system of primates (for references and review, see Strick & Card, 1992; Kelly & Strick, 2000, 2003). This tracing method can effectively label a chain of up to three synaptically linked neurons in a single experiment (Kelly & Strick, 2003, 2004). In this chapter, we will review some of the new observations that have come from using viruses to trace basal ganglia and cerebellar loops with the cerebral cortex. These observations have led to important insights about the cortical targets of these circuits and the functional domains they influence.

Primary motor cortex

Our first experiments used retrograde transneuronal transport of HSV1 to examine the organization of basal ganglia and cerebellar outputs to M1 (figure 38.1) (Hoover & Strick, 1993, 1999). We injected virus into physiologically identified portions of M1 (i.e., regions where face, arm, or leg movements were evoked by intracortical stimulation with currents < 25 μ A). Then we set the survival time to allow transneu-

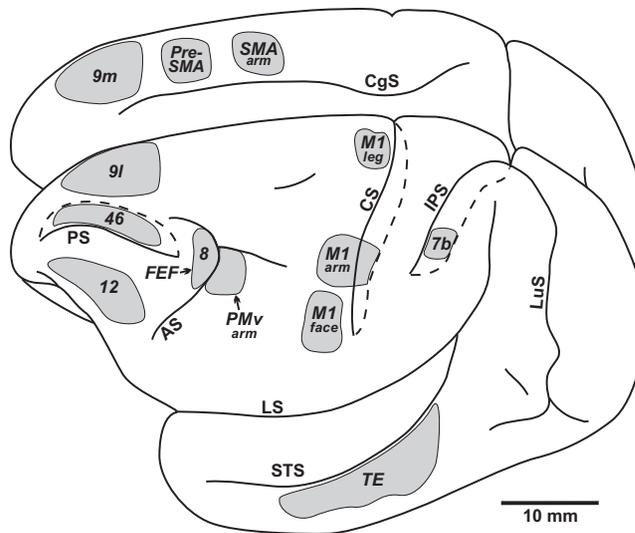

FIGURE 38.1 Virus injection sites in the cerebral cortex. The locations of virus injection sites (*shaded areas*) are shown on a view of the lateral surface and a mirror image of the medial wall of a cebus monkey brain. The numbers 7b, 8, 9m, 9l, 12, and 46 refer to cytoarchitectonic areas. Abbreviations: AS, arcuate sulcus; CS, central sulcus; FEF, frontal eye field; IPS, intraparietal sulcus; LS, lateral sulcus; LuS, lunate sulcus; M1, face, arm, and leg areas of the primary motor cortex; PMv_{arm}, arm area of the ventral premotor area; PreSMA, presupplementary motor area; PS, principal sulcus; SMA_{arm}, arm area of the supplementary motor area; STS, superior temporal sulcus; TE, area of inferotemporal cortex.

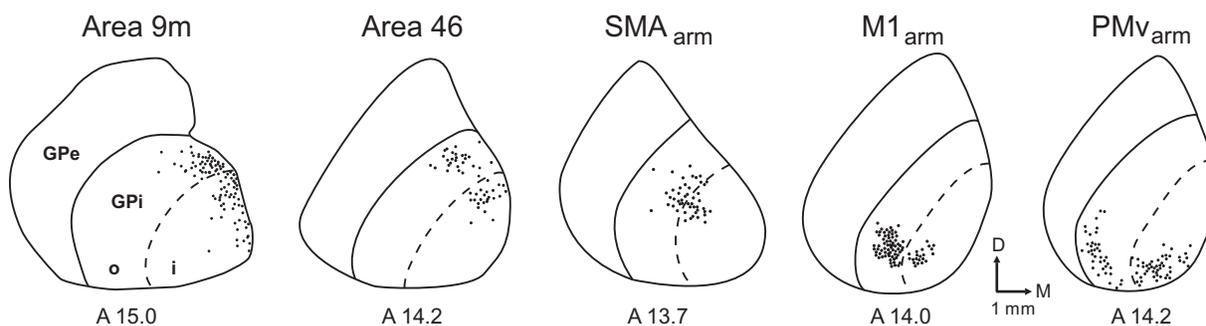

FIGURE 38.2 Origin of pallidal projections to M1, PMv, SMA, area 46, area 9. Representative coronal sections through the GPi of animals that received virus injections into different cortical areas (see figure 38.1). The *dots* indicate the positions of neurons labeled by retrograde transneuronal transport of virus. The maps display labeled neurons found on two or three adjacent sections whose

approximate anterior-posterior location is indicated at the bottom of each section outline. Abbreviations: GPe, external segment of globus pallidus; GPi, internal segment of the globus pallidus; o, outer portion of the internal segment of globus pallidus; i, inner portion of the internal segment of globus pallidus. (Adapted from Middleton & Strick, 1996b.)

ronal transport of virus to label “second-order” neurons that are the origin of basal ganglia and cerebellothalamocortical inputs to M1. The brain of each animal was processed by using immunohistochemical procedures to demonstrate the location of virus-specific antigen in infected neurons (Strick & Card, 1992; Kelly & Strick, 2000).

Three major results came from these experiments. First, we found that M1 is richly innervated by the output nuclei of the basal ganglia and cerebellum. The densest projections originate from GPi (figures 38.2 and 38.3, M1 arm) and the dentate (figures 38.4 and 38.5, M1 arm). Less dense projections originate from portions of the SNpr

and interpositus. Second, we found that both the GPi and the dentate are somatotopically organized with separate face, arm, and leg areas that project via the thalamus to the face, arm, and leg areas of M1. Third, and perhaps most surprising, we discovered that projections to M1 originate from only 15% of the volume of the GPi and about 30% of the volume of the dentate. Thus, the output to M1 originates from restricted portions of each subcortical nucleus. This result implies that the majority of the output from the basal ganglia and cerebellum is directed to other cortical areas.

Premotor areas

Our next experiments used virus tracing to examine basal ganglia and cerebellar projections to the arm representations of premotor areas in the frontal lobe (figure 38.1) (Hoover & Strick, 1993; Akkal, Dum, & Strick, 2007). Injections of virus into either the ventral premotor area (PMv) or the supplementary motor area (SMA) consistently labeled neurons in the middle of the GPi rostrocaudally. Within this region, neurons labeled after injections into the SMA, M1, or PMv formed separate clusters in a dorsal-to-ventral arrangement (figures 38.2 and 38.3). These observations indicate that pallidal output is not confined to M1 but projects via the thalamus to multiple premotor areas in the frontal lobe (see also Jinnai, Nambu, Tanibuchi, & Yoshida, 1993; Inase & Tanji, 1995; Sakai, Inase, & Tanji, 1999). Furthermore, the arm representation of each motor area receives input from a topographically distinct set of GPi neurons. We have proposed that this arrangement creates distinct “output channels” in the sensorimotor portion of GPi (Hoover & Strick, 1993; Akkal et al., 2007).

We found a similar topographic organization of output neurons in the dentate. Injections of virus into the arm representations of M1, PMv, and SMA labeled clusters of neurons in the middle of the dentate rostrocaudally (figures 38.4 and 38.5) (Middleton & Strick, 1997; Akkal et al., 2007). However, the “hotspot” of each cluster appeared to be centered in a slightly different region of the dentate. The hotspots for the different motor areas are shown on a single unfolded map of the dentate (figure 38.5). This diagram emphasizes two important observations. First, the arm representations of the PMv and SMA are the target of output from the dentate. Second, the output channels to the different arm representations are clustered together in a common region of the dorsal dentate. This observation raises the possibility that the dorsal dentate contains a single integrated map of the body in which the maps for output channels to different cortical areas are in register within the nucleus. In any event, the dentate, like the GPi, contains distinct output channels that innervate different cortical motor areas.

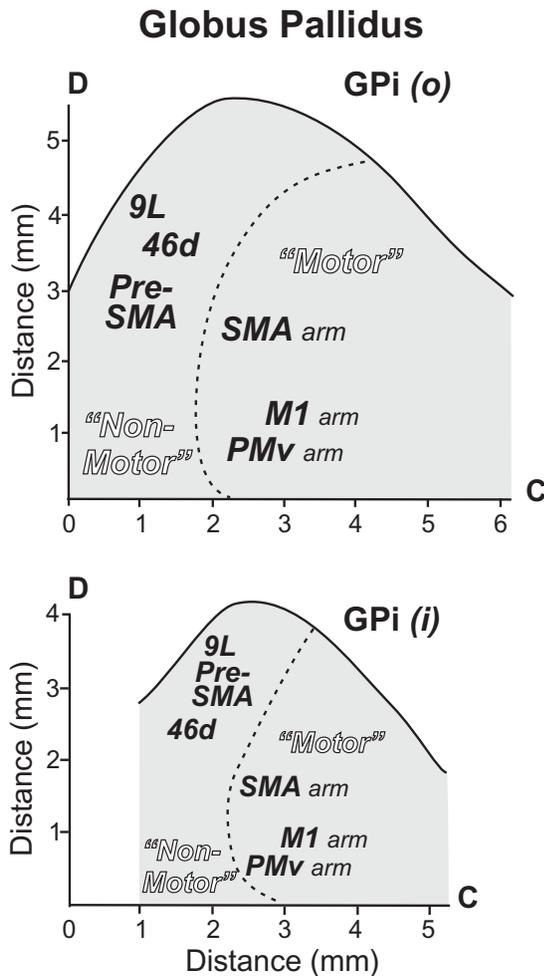

FIGURE 38.3 Summary map of the basal ganglia output channels. The outer and inner segments of the GPi are shown as separate unfolded maps (for details of unfolding, see Akkal et al., 2007). This map provides a planar view of the rostrocaudal and dorsoventral location of output channels in each segment of the GPi. The cortical target of each output channel is placed at the site of the peak labeling following retrograde transneuronal transport of virus from that cortical area. Note that the GPi can be divided into “motor” and “nonmotor” domains based on the grouping of the cortical targets of its output channels. Abbreviations: D, dorsal; C, caudal; see also figures 38.1 and 38.2. (Adapted from Akkal et al., 2007.)

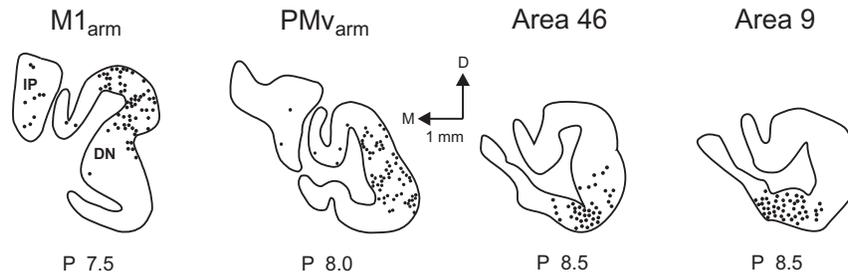

FIGURE 38.4 Origin of cerebellar projections to M1, PMv, area 46, and area 9. Representative coronal sections through the dentate and interpositus nuclei of animals that received virus injections into different cortical areas (see figure 38.1). Conventions are according

to figure 38.2. Abbreviations: D, dorsal; DN, dentate nucleus; IP, interpositus nucleus; M, medial. (Adapted from Middleton & Strick, 1996b.)

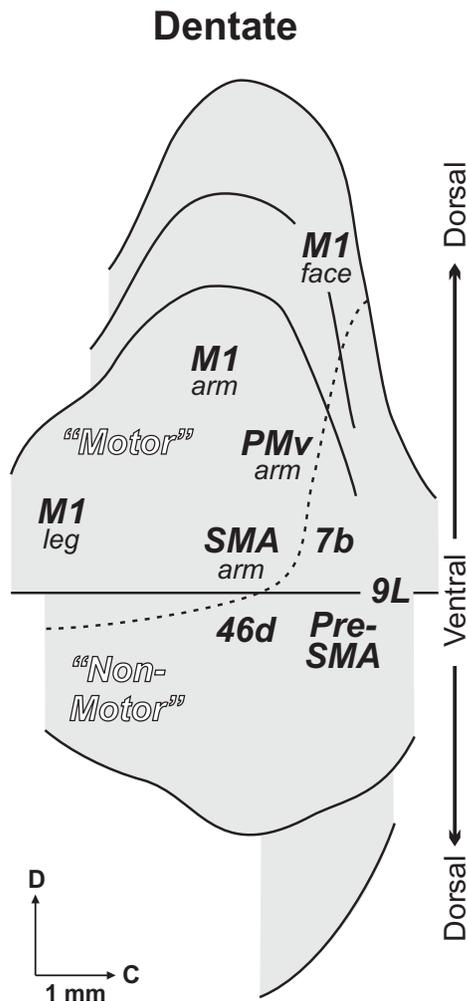

FIGURE 38.5 Summary map of dentate output channels. The dentate is displayed as an unfolded map (for details of unfolding, see Dum & Strick, 2003). The cortical target of each output channel is placed at the site of the peak labeling following retrograde transneuronal transport of virus from that cortical area. Note that the dentate can be divided into “motor” and “nonmotor” domains based on the grouping of the cortical targets of its output channels. Abbreviations as in figure 38.1. (Adapted from Dum & Strick, 2003; Akkal et al., 2007.)

Results from single-neuron recording experiments in awake trained monkeys provide physiological support for the existence of distinct output channels in the GPi and dentate (Mushiaki & Strick, 1993, 1995; Strick, Dum, & Picard, 1995). These studies suggest that individual output channels are involved in different aspects of motor behavior. Specifically, some output channels appear to be especially concerned with movements that are internally generated, whereas others appear to be devoted to movements guided by exteroceptive cues. Taken together, these observations indicate that the basal ganglia and cerebellum have the capacity to influence a broad range of motor behavior using output channels that project to the premotor areas in the frontal lobe as well as to M1. Thus, the skeletomotor circuit of Alexander and colleagues (1986) is more accurately viewed as multiple discrete channels to each of the cortical motor areas (figure 38.6). A similar arrangement of output channels characterizes skeletomotor output from the dentate.

Frontal eye field

We have also used transneuronal transport of virus to examine subcortical inputs to the frontal eye field (FEF) (figure 38.1) (Lynch, Hoover, & Strick, 1994). The results of prior studies with conventional tracers led to the proposal that the FEF receives input via the thalamus from three major subcortical nuclei: SNpr, the superior colliculus (SC), and the deep cerebellar nuclei. To test this proposal, we injected virus into physiologically identified portions of the FEF (i.e., regions where eye movements were evoked by intracortical stimulation with currents $< 50 \mu\text{A}$). Neurons labeled by retrograde transneuronal transport were found in lateral portions of SNpr, the optic and intermediate gray layers of the SC, and ventrally in the caudal third of the dentate nucleus. Within the dentate, labeled neurons were confined to its posterior pole, where some neurons exhibit activity correlated with saccadic eye movements (van Kan, Houk, & Gibson, 1993). Within the basal ganglia, FEF injections labeled neurons in a posterior and lateral region of

“SKELETOMOTOR” CIRCUIT

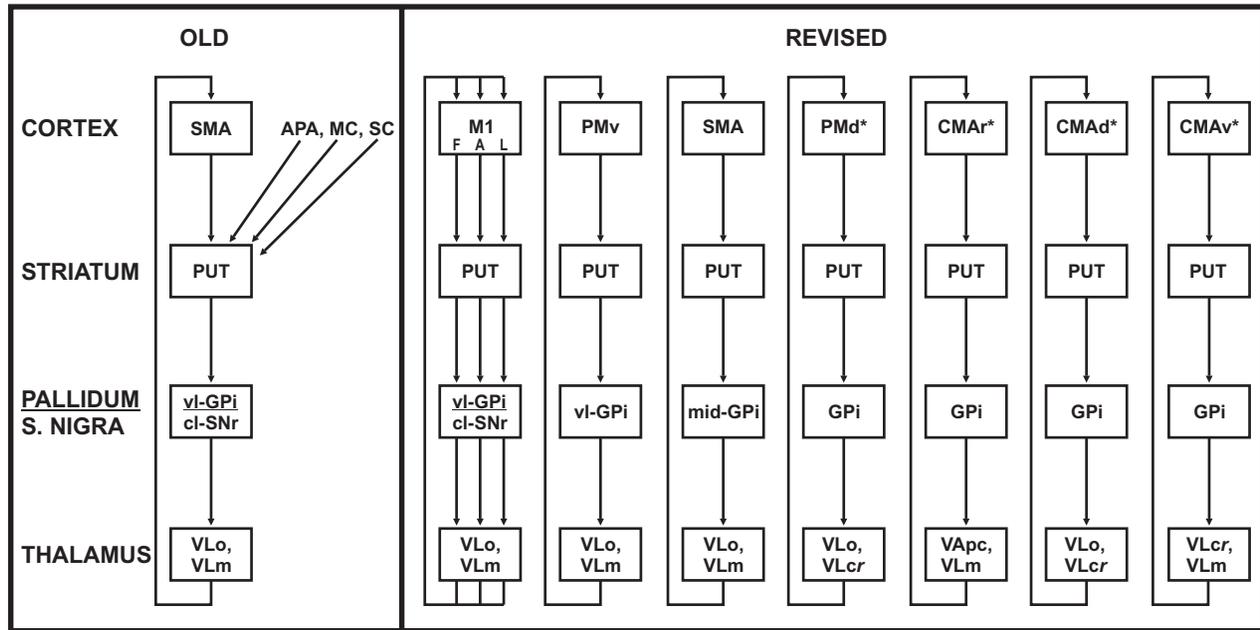

FIGURE 38.6 The original skeletomotor circuit proposed by Alexander, DeLong, and Strick (1986) and our revised scheme. *Asterisks* indicate loops whose existence is suspected but not specifically tested using virus transport. Cortical abbreviations: CMAAd, dorsal cingulate motor area; CMAR, rostral cingulate motor area; CMAv, ventral cingulate motor area; M1, primary motor cortex; PMd, dorsal premotor area; PMv, ventral premotor area; SMA, supplementary motor area. Basal ganglia abbreviations:

GPi, internal segment of globus pallidus; PUT, putamen; SNr, substantia nigra pars reticulata; cl, caudolateral; mid, middle; vl, ventrolateral. Thalamic abbreviations: VApC, nucleus ventralis anterior, parvocellular portion; VLcc, nucleus ventralis lateralis pars caudalis, caudal division; VLcr, nucleus ventralis lateralis pars caudalis, rostral division; VLm, nucleus ventralis lateralis pars medialis; VLo, nucleus ventralis lateralis pars oralis. (Adapted from Middleton & Strick, 2000.)

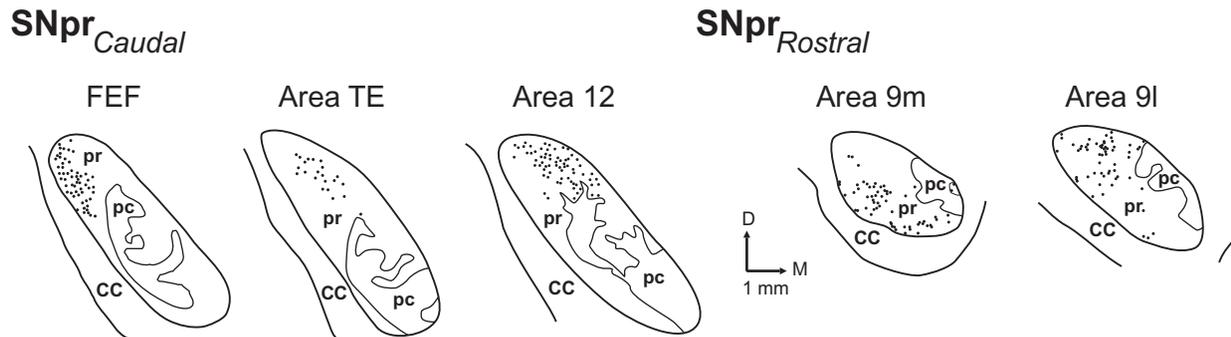

FIGURE 38.7 Origin of nigral projections to the FEF, area TE, area 12, area 9m, and area 9l. Coronal sections indicating the location of labeled neurons in the caudal and rostral regions of the

SNpr following virus injections into the different cortical areas (see figure 38.1). Abbreviations: CC, crus cerebri; pc, pars compacta; pr, pars reticulata. (Adapted from Middleton & Strick, 1996b.)

SNpr (figure 38.7, FEF) where neurons also display changes in activity related to saccadic eye movements (Hikosaka & Wurtz, 1983a, 1983b). Overall, the regions of the basal ganglia and cerebellum that were labeled after FEF injections of virus were strikingly different from those labeled after injections into any of the skeletomotor areas of the frontal lobe. Thus the output channels in the basal ganglia and cerebellum that are concerned with oculomotor func-

tion are distinct from those concerned with skeletomotor function.

Prefrontal cortex

It is clear from the studies reviewed above that the output nuclei of the basal ganglia and cerebellum have well-organized projections to skeletomotor and oculomotor areas

of cortex. Nevertheless, substantial portions of these output nuclei do not project to cortical motor areas. This observation raises the possibility that the remaining portions of these output nuclei target nonmotor areas of cortex. Because of prior suggestions that the basal ganglia and cerebellum influence some of the cognitive operations that are normally thought to be subserved by the frontal lobe (Alexander et al., 1986; Leiner et al., 1986, 1991, 1993), we used virus tracing to test whether basal ganglia and cerebellar projections to prefrontal cortex provide an anatomical substrate for this influence.

Our experiments focused on subfields within areas 9, 12, and 46 of the prefrontal cortex (Middleton & Strick, 1994, 2001, 2002). Each of these areas appears to be involved in aspects of “working memory” and is thought to guide behavior based on transiently stored information rather than immediate external cues (for reviews, see Passingham, 1993; Goldman-Rakic, 1996; Fuster, 1997). Virus injections into area 9, 12, or 46 labeled many neurons in the output nuclei of the basal ganglia (figures 38.2, 38.3, and 38.7). Injections into area 12 labeled neurons in a localized portion of SNpr. In contrast, injections into area 46 labeled neurons largely in GPi. Area 9 injections labeled neurons in both the SNpr and GPi. The topographic nature of basal ganglia projections to prefrontal cortex is further emphasized by the finding that different regions within the rostral SNpr project to medial and lateral portions of area 9 (figure 38.7, areas 9m and 9l). In all cases, the locations of the neurons labeled in the GPi and SNpr after injections into prefrontal areas of cortex are different from the locations of neurons labeled after injections into motor areas of cortex.

Virus injections into areas 9 and 46 (but not area 12) labeled neurons in ventral regions of the dentate nucleus (figures 38.4 and 38.5). The neurons that were labeled after injections into area 9 were found largely medial and caudal to those labeled by injections into area 46. The ventral regions of the dentate that project to these nonmotor areas in the frontal lobe clearly differ from the more dorsal regions of this nucleus that innervate motor areas of the cortex (figures 38.4 and 38.5). Thus, both the basal ganglia and the cerebellum project via the thalamus to multiple areas of prefrontal cortex. Moreover, the output channels in the basal ganglia and cerebellum that influence prefrontal areas of cortex are separate from those that influence motor areas of cortex. This observation suggests that GPi and the dentate can be divided into motor and nonmotor domains (figures 38.3 and 38.5) (Dum & Strick, 2003; Akkal et al., 2007).

Although the presupplementary motor area (PreSMA) has traditionally been included with the motor areas of the frontal lobe, a number of recent observations emphasize the nonmotor nature of this cortical area (for a review, see Picard & Strick, 2001). For example, unlike the cortical motor areas, the PreSMA does not project directly to M1 or to the

spinal cord. Instead, the PreSMA is densely interconnected with regions of prefrontal cortex. We used virus tracing to test whether basal ganglia and cerebellar projections to the PreSMA originate from the motor or nonmotor domains of the GPi and the dentate (Akkal et al., 2007). We found that the output channel in the GPi that projects to the PreSMA is located dorsally in a rostral portion of the nucleus (figure 38.3). The output channel in the dentate that projects to the PreSMA is located in a ventral part of the nucleus (figure 38.5). Thus the output channels to the PreSMA in both the GPi and the dentate are adjacent to output channels that project to regions of prefrontal cortex rather than near output channels to the cortical motor areas (figures 38.3 and 38.5). These observations provide further support for the proposal that the PreSMA is more similar to regions of prefrontal cortex than it is to a cortical motor area (Picard & Strick, 2001; Akkal et al., 2007).

Posterior parietal cortex

Areas 5 and 7 in the posterior parietal cortex are known to project to the input stage of basal ganglia and cerebellar processing (e.g., Kemp & Powell, 1971; Glickstein, May, & Mercier, 1985; Cavada & Goldman-Rakic, 1991; Yeterian & Pandya, 1993; Schmammann & Pandya, 1997). These connections led us to ask whether the posterior parietal cortex is a target of basal ganglia and cerebellar output (Clower, West, Lynch, & Strick, 2001; Clower, Dum, & Strick, 2005). Our results demonstrate that a portion of area 7b in the intraparietal sulcus is the target of output from the dentate nucleus, whereas a portion of area 7b on the cortical surface is the target of output from the SNpr as well as from the dentate nucleus. These results clearly indicate that the sphere of influence of basal ganglia and cerebellar output extends to include portions of the posterior parietal cortex. Space limitations do not allow us to describe the full implications of basal ganglia and cerebellar projections to posterior parietal cortex. Instead, we will highlight two specific proposals about these circuits. We have suggested that the cerebellar projection to the posterior parietal cortex may provide signals that contribute to the sensory recalibration that occurs during some adaptation paradigms (Clower et al., 2001). On the other hand, we have suggested (Clower et al., 2005) that abnormal signals in the basal ganglia projection to the posterior parietal cortex may contribute to the visuospatial deficits that are observed in some patients with basal ganglia lesions (Karnath, Himmelbach, & Rorden, 2002).

Inferotemporal cortex

In general, each of the cortical areas found to receive input from the basal ganglia or cerebellum is known to send pro-

jections back to these subcortical nuclei. This anatomical arrangement suggests that many cortical areas in the frontal lobe participate in “closed loop” circuits with the basal ganglia and cerebellum. To test whether this arrangement extends to areas outside the frontal lobe, we examined subcortical inputs to a region of inferotemporal cortex, area TE (Middleton & Strick, 1996a) (figure 38.1, area TE). Area TE is known to project to the input stage of basal ganglia processing (i.e., the tail of the caudate and ventral portions of the putamen) (Saint-Cyr, Ungerleider, & Desimone, 1990) but not to the input stage of cerebellar processing (Glickstein et al., 1985; Schmahmann & Pandya, 1997).

Virus injections into area TE did not result in any labeled neurons in the deep cerebellar nuclei. This suggests that TE neither projects to nor receives from the cerebellum. On the other hand, the same virus injections into TE did result in a distinct cluster of labeled neurons in SNpr (figure 38.7, area TE). Most of these neurons were located dorsally in a caudal region of the SNpr that appears to be separate from the regions that influence the FEF or subdivisions of prefrontal cortex. Thus TE is both a source of input to and a target of output from a distinct portion of the basal ganglia.

TE is known to play a critical role in the visual recognition and discrimination of objects (e.g., Gross, 1972; Tanaka, Saito, Fukuda, & Moriya, 1991; Miyashita, 1993). Physiological studies have shown that the region of the SNpr that influences TE contains some neurons that are responsive to the presentation of visual stimuli (e.g., Hikosaka & Wurtz, 1983a). These observations, together with our anatomical results, provide evidence that basal ganglia output is involved in higher-order aspects of visual processing, as well as in motor and cognitive function.

Macroarchitecture of subcortical loops with the cerebral cortex

Our observation that cortical areas that receive output from the basal ganglia and cerebellum also project to the input stage of these subcortical structures suggests that closed loop circuits represent a fundamental architectural feature of basal ganglia and cerebellar connections with the cerebral cortex. We used retrograde transneuronal transport of rabies virus to define the region of cerebellar cortex that projects to a specific region of the cerebral cortex. Then we used anterograde transneuronal transport of the H129 strain of HSV1 to define the region of the cerebellar cortex that receives input from a specific region of the cerebral cortex (Kelly & Strick, 2003). Our first experiments using this approach examined the topographic organization of circuits linking the cerebellar cortex with the arm area of M1 and with area 46 in dorsolateral prefrontal cortex. In short, we found that the arm area of M1 receives input from Purkinje cells located mainly in lobules IV–VI of cerebellar

cortex (figure 38.8, left). In contrast, area 46 receives input from Purkinje cells located mainly in crus II of the ansiform lobule (figure 38.8, right). Thus M1 and area 46 are the target of output from separate regions of the cerebellar cortex.

Anterograde transneuronal transport of the H129 strain HSV1 revealed that granule cells in lobules IV–VI of cerebellar cortex receive input from the arm area of M1. This is the same region of the cerebellar cortex that projects to M1 (figure 38.8, left). Similarly, granule cells in crus II of the cerebellar cortex receive input from area 46. This is the same region of the cerebellar cortex that projects to area 46 (figure 38.8, right). These observations provide strong support for our proposal that multiple closed loop circuits represent a fundamental architectural feature of cerebrocerebellar interactions. Similar closed loop circuits are also likely to be a fundamental feature of cerebrobasal ganglia interactions (Kelly & Strick, 2004).

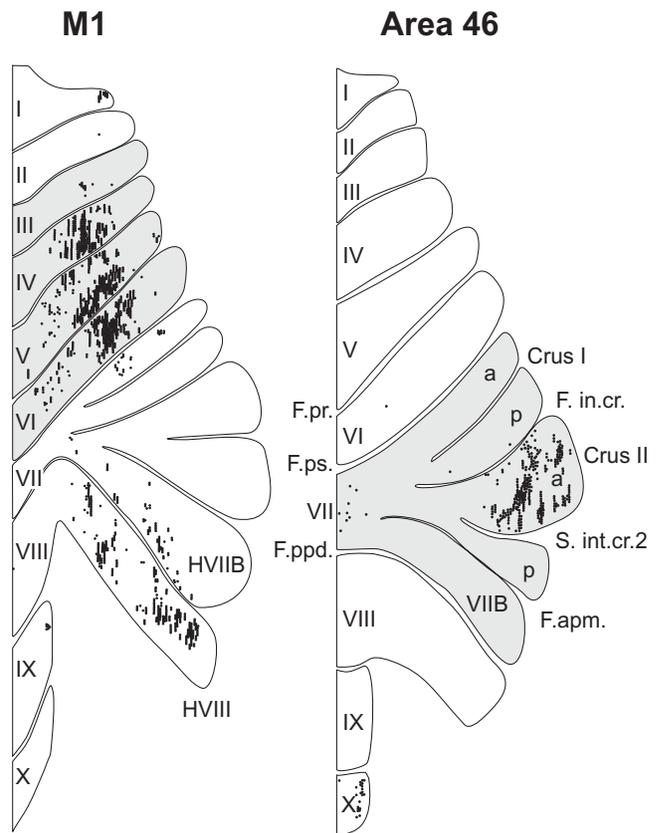

FIGURE 38.8 Origin of cerebellar cortical projections to M1 and area 46. The black dots on the flattened surface maps of the cerebellar cortex represent Purkinje cells that were labeled by retrograde transneuronal transport of rabies virus from the arm area of M1 (left panel) or from area 46 (right panel). Note that the Purkinje cells that project to M1 are located in separate lobules from those that project to area 46. Nomenclature and abbreviations are according to Larsell (1970). (Adapted from Kelly & Strick, 2003.)

Functional implications

Clearly, the outputs from the basal ganglia and cerebellum gain access to more widespread and diverse areas of cortex than was previously imagined. To date, our studies have shown that the output nuclei of the basal ganglia and cerebellum project (via the thalamus) to skeletomotor, oculomotor, prefrontal, and posterior parietal areas of cortex. In addition, a portion of SNpr projects to inferotemporal cortex. Thus, the anatomical substrate exists for the basal ganglia and cerebellum to influence higher-order aspects of cognition such as planning, working memory, sequential behavior, visuospatial perception, and attention as well as skeletomotor and oculomotor function. As a consequence, a sizable component of basal ganglia and cerebellar output operates outside of the domain of motor control.

Some support for this conclusion comes from recent analyses of the consequences of cerebellar pathology in human subjects. In addition to the classical motor deficits, there is considerable evidence that cerebellar damage can lead to deficits in the performance of cognitive tasks that require rule-based learning, judgment of temporal intervals, visuospatial analysis, shifting attention between sensory modalities, and working memory and planning (see reviews by Leiner et al., 1986, 1991, 1993; Botez, Botez, Elie, & Attig, 1989; Ivry & Keele, 1989; Fiez, Petersen, Cheney, & Raichle, 1992; Akshoomoff & Courchesne, 1992; Grafman et al., 1992; Schmahmann, 1991, 1997; Schmahmann & Sherman, 1998). Many of these deficits reflect functions that are normally thought to be subserved by areas of prefrontal cortex.

On the basis of our results, one interpretation of the origin of these deficits is that they result from an interruption of input to prefrontal cortex from the cerebellum. A study by Fiez and colleagues (1992) provides some support for this interpretation. They described a patient, designated RC1, who had circumscribed damage to the lateral portion of his right cerebellar cortex. This patient exhibited few classical signs of cerebellar damage but was impaired on the performance of specific types of rule-based language and memory tasks. The deficits appeared on tasks that in normal subjects activate lateral portions of the cerebellar hemispheres and areas 9 and 46 (Petersen, Fox, Posner, Mintun, & Raichle, 1988; Raichle et al., 1994; Fiez et al., 1996). Our anatomical studies suggest that the portions of the cerebellum that are damaged in RC1 are part of the cerebellar loop with the prefrontal cortex (Kelly & Strick, 2003). Thus the cognitive deficits in RC1 may have been a consequence of interrupting this circuit.

In general, we found that basal ganglia and cerebellar projections to a cortical area originate from a localized cluster of neurons that we have termed an output channel. The output channels to different cortical areas display a surprising degree of topographic organization. For example,

the output channels that influence dorsomedial regions of prefrontal cortex are located largely in the GPi, whereas the output channels that influence ventrolateral regions of prefrontal cortex are located largely in the SNpr (Middleton & Strick, 2002; Akkal et al., 2007). Both sets of output channels are separate from those that influence skeletomotor and oculomotor areas of cortex. Output channels within the dentate are as topographically organized as those in the basal ganglia, if not more so (Dum & Strick, 2003; Akkal et al., 2007).

Evidence for a segregation of function in the human GPi comes from the observation that the cognitive and motor effects of pallidotomies, performed to ameliorate the symptoms of Parkinson's disease, depend significantly on the location of the lesion (Lombardi et al., 2000). Lesions located in the most anteromedial region of the GPi, the likely origin of output channels to prefrontal cortex, produced the greatest degree of cognitive impairment. In contrast, lesions in the intermediate region of the GPi, the likely origin of output channels to motor areas of cortex, led to maximal effects on motor performance but produced little effect on cognition. Thus the human GPi appears to have spatially separate motor and cognitive output channels.

To date, we have identified the output channels in the basal ganglia and cerebellum to skeletomotor, oculomotor, prefrontal, and some posterior parietal areas of cortex. All together, these output channels occupy approximately 70% of the volume of these subcortical nuclei. This means that the cortical targets for approximately 30% of the output from the basal ganglia and cerebellum remain to be identified. The architecture of basal ganglia and cerebellar loops with the cerebral cortex allows us to make some predictions about the identity of these targets. Cingulate, orbital frontal, and medial posterior parietal cortex are known to be major sources of input to the basal ganglia and cerebellum. Our results suggest that cortical areas that project to the input stage of the basal ganglia and cerebellum processing are the targets of the output stage of processing in these circuits. If this proposal is correct, then the remaining 30% of the basal ganglia and cerebellar output is directed at cingulate, orbital frontal, and medial posterior parietal areas of cortex. This prediction will be tested in future experiments.

The new insights gained from virus tracing have important implications for hypotheses about basal ganglia and cerebellar contributions to normal and abnormal behavior. Detailed discussions of this issue have been presented in our recent papers (Middleton & Strick, 1996a, 2001, 2002; Clower et al., 2001, 2005; Akkal et al., 2007); therefore only some examples will be presented here. It is known that abnormal activity in basal ganglia and cerebellar loops with motor areas of cortex results in striking disorders of movement. Likewise, abnormal activity in basal ganglia and cerebellar loops with nonmotor areas of the cerebral

cortex could lead to a broad range of psychiatric and neurological symptoms such as those associated with depression, obsessive-compulsive disorder, Parkinson's disease, and Huntington's disease (for a review, see Lichter & Cummings, 2000). For example, Courchesne and colleagues (1988, 1994, 1997) have suggested that alterations in the cerebellum and its projections to posterior parietal cortex may underlie some of the deficits seen in autistic patients. Rapoport and Wise (1988) have proposed that dysfunction in basal ganglia circuits with anterior cingulate and orbital frontal cortex may explain some of the features of obsessive-compulsive disorder. We have suggested that abnormal signals in the basal ganglia loop with area TE in inferotemporal cortex are responsible for the visual hallucinations that are seen in L-dopa toxicity (Middleton & Strick, 1996a). It is clear that additional studies aimed at unraveling these loops could lead to new insights into the pathophysiological basis of basal ganglia and cerebellar disorders.

In summary, virus tracing has revealed that the output of the basal ganglia and cerebellum targets motor, premotor, prefrontal, posterior parietal, and inferotemporal areas of cortex. These connections provide the basal ganglia and cerebellum with the anatomical substrate to influence not only the control of movement, but also many aspects of cognitive behavior such as planning, working memory, sequential behavior, visuospatial perception, and attention. Similarly, there is growing evidence that disorders such as schizophrenia, autism, attention-deficit disorder, and obsessive-compulsive disorder are associated with alterations in basal ganglia or cerebellar function. Thus, it is possible that abnormal activity in specific basal ganglia and cerebellar loops with the cerebral cortex results in identifiable sets of neuropsychiatric symptoms. Taken together, the recent findings about basal ganglia and cerebellar circuitry provide a new anatomical framework for understanding the contributions of these structures to diverse aspects of motor and nonmotor behavior.

39 The Basal Ganglia and Cognition

ANN M. GRAYBIEL AND JONATHAN W. MINK

ABSTRACT Clinical evidence, experimental studies in animals, and anatomical findings suggest that the basal ganglia act to influence not only motor behavior but also cognitive functions. We discuss the functions of the basal ganglia in relation to four categories: (1) movement release and inhibition, (2) response selection, (3) attention and assignment of salience, and (4) learning and adaptive control of behavior. In establishing these functions, striatal output neurons lead into different output pathways: the direct, indirect, hyperdirect, and striosomal pathways. Divergence of cortical inputs to the striatum and reconvergence of these motor and cognitive signals in cortico-basal ganglia pathways is seen as essential in remapping forebrain representations of action and intrastriatal networks in the binding process. We propose that a crucial feature of this remapping is a learning-related recoding of sequential motor and cognitive action representations so that they can be expressed as units. This chunking function of the striatum and associated cortico-basal ganglia loops may be a key mechanism operative across each of the functional categories of behavioral control attributed to the basal ganglia.

The basal ganglia make up a group of interconnected subcortical nuclei that are organized into circuits involved in the control of behavior. The basal ganglia have long been recognized as important for motor control, because prominent movement disorders such as Parkinson's disease result from basal ganglia dysfunction. However, it is now widely recognized that the basal ganglia are parts of cortico-thalamo-basal ganglia loops, and that they function not only in sensorimotor control, but also in a wide range of cognitive processes ranging from attention to emotion, from response release and inhibition to response selection, and from on-line control to a primary function in learning and memory. Accordingly, the basal ganglia have now been implicated in an equally broad range of clinical disorders, ranging from the classical extrapyramidal disorders (Parkinson's disease, Huntington's disease, and dystonia) to neuropsychiatric disorders including obsessive-compulsive disorder, Tourette syndrome, attention-deficit disorder, and even schizophrenia. The basal ganglia themselves contain highly organized

neuronal circuitry, but they do not function in isolation. The basal ganglia are intimately connected with the cerebral cortex and are perhaps best viewed as parts of cortico-basal ganglia circuits.

How could this system have such broad functions? A clue that the basal ganglia might contribute to cognitive processing is that the basal ganglia attain a very large size in the human brain. But an even more telling clue is that a large part of the outflow of the basal ganglia in primates is directed via the thalamus toward executive areas of the frontal cortex—areas that are themselves associated with attention, planning, volitional decision, and selection among potential responses to external or internal cues (Fuster, 1997; Paus, 2001). Yet more evidence comes from brain imaging studies of subjects engaged in cognitive tasks (Klein, Zatorre, Milner, Meyer, & Evans, 1994; Grafton, Hazeltine, & Ivry, 1995; Braver et al., 1997; Rao et al., 1997; Desmond, Gabrieli, & Glover, 1998; Poldrack, Prabhakaran, Seger, & Gabrieli, 1999; Peigneux et al., 2000; Poldrack & Gabrieli, 2001; Small, Zatorre, Dagher, Evans, & Jones-Gotman, 2001; van den Heuvel et al., 2003; Cools, Ivry, & Esposito, 2006; Chang, Crottaz-Herbette, & Menon, 2007; Cools, Gibbs, Miyakawa, Jagust, & D'Esposito, 2008; Dahlin, Neely, Larson, Backman, & Nyberg, 2008; McNab & Klingberg, 2008) and from findings in patients with brain dysfunction due to disease or injury (Mendez, Adams, & Lewandowski, 1989; Bhatia & Marsden, 1994; Sawamoto et al., 2007). Experiments on animals have also generated working hypotheses about the neurobiology underlying basal ganglia function (Oberg & Divac, 1979; Graybiel, 1995, 1998, 2005, 2008; Miyashita, Hikosaka, & Kato, 1995; Bergman et al., 1998; Hikosaka et al., 1999; Jog, Kubota, Connolly, Hillegart, & Graybiel, 1999; Brainard & Doupe, 2000; Mink, 2001; Packard & Knowlton, 2002; Barnes, Kubota, Hu, Jin, & Graybiel, 2005; Apicella, 2007). Together, these findings have brought the basal ganglia to the forefront of work on how the brain engages in interactions with the sensory and internal environment to form structured predictions about the world and, on this basis, to make and execute action plans (figures 39.1 and 39.2).

Perspectives from anatomy

The basal ganglia receive a massive input from the neocortex. Most of these cortical inputs are directed toward

Planner circuits of the forebrain are influenced by motivation-related inputs (A) and sensory-motor stimuli (B). Abbreviations: 5-HT, serotonin; NE, norepinephrine. (Adapted from Graybiel, 1997.)

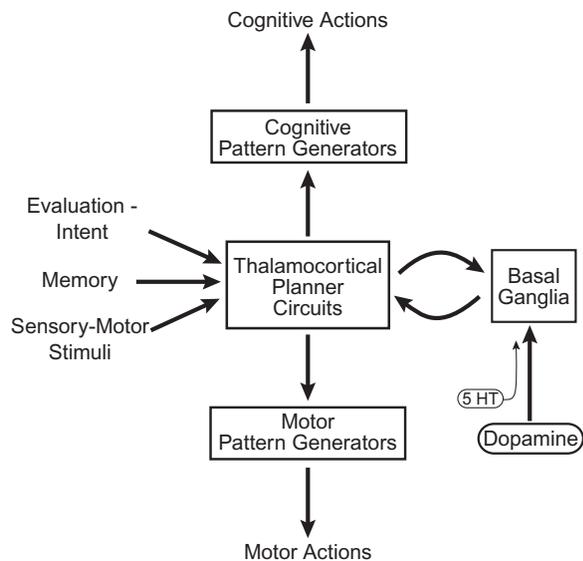

FIGURE 39.2 Schematic diagram illustrating potential influences of the basal ganglia not only on motor pattern generators but also on cognitive pattern generators. (Adapted from Graybiel, 1997.)

the striatum (caudate nucleus and putamen). The range of these corticostriatal inputs is impressive. They come not only from primary and higher-order sensory areas and from motor and premotor areas, but also from the large areas of association cortex in the parietal, temporal, medial, and frontal association cortex (Webster, Bachevalier, & Ungerleider, 1993; Eblen & Graybiel, 1995; Yeterian & Pandya, 1998; Ferry, Ongur, An, & Price, 2000; Leichnetz, 2001; Haber, Kim, Maily, & Calzavara, 2006; Calzavara, Maily, & Haber, 2007). There are other very large inputs to the striatum from thalamic nuclei, especially the intralaminar nuclei (Parent, Mackey, & De Bellefeuille, 1983; Ragsdale & Graybiel, 1991; Haber & McFarland,

2001). Further inputs come to other nuclei in basal ganglia circuits, as we will see below. If one includes, as should be done, the ventral striatum/ventral pallidum in the basal ganglia, cortical inputs to the system also come from the hippocampal formation and amygdala (Groenewegen, Wright, & Uylings, 1997; Fudge, Kunishio, Walsh, Richard, & Haber, 2002). When we add inputs from neuromodulatory systems, including the dopamine-containing nigrostriatal tract and serotonergic inputs, and inputs from the neocortex and elsewhere to other nuclei of the basal ganglia, the inputs to the basal ganglia system as a whole are rich and diverse and by no means restricted to one functional domain.

It is also important to keep in mind that different regions within each nucleus of the basal ganglia are probably as different from one another functionally as different parts of the neocortex are from one another. When we think of behavior-related functions of the neocortex, we naturally think of the functions of individual cortical areas, for example, the middle temporal area for visual motion, parietal areas for reach and grasp, or prefrontal areas for working memory. We do not know as much about the regionally specialized subdivisions of the basal ganglia, but it is clear that there are different “families” of cortico-basal ganglia circuits related to motor, associative, and limbic functions (Graybiel, 1984; Alexander, DeLong, & Strick, 1986). The behavioral evidence leading to this idea is important: Lesion studies have shown that localized lesions of the striatum produce symptoms similar to those induced by lesions in the cortical areas projecting strongly to the particular parts of the damaged striatum (Divac, Rosvold, & Szwarcbart, 1967; Goldman & Rosvold, 1972). Somehow, the functional domain of specific basal ganglia circuits seems to relate to the function of their cortical input sources.

What the basal ganglia do, of course, depends not only on their inputs but also on their outputs. Here, the story is interesting. Most current anatomical tract-tracing studies indicate that the largest ascending outflow of the basal ganglia is directed toward the frontal cortex via synaptic links in the thalamus. This puts the basal ganglia squarely in the “executive” realm of function. This view is consistent with the undoubted participation of these structures in motor control. But the frontal areas that receive basal ganglia outflow extend from the classical motor and premotor areas into the prefrontal cortex (Middleton & Strick, 2002). In fact, a large part of the neocortex in front of the central sulcus—including medial and lateral prefrontal, cingulate, and lateral and orbitofrontal cortex—is now thought to receive inputs (via thalamically processed routes) from the basal ganglia proper. Thus the outflow from the basal ganglia reaches regions that function in cognitive and emotional control. Anatomical work by Strick and colleagues with viral transport methods demonstrates that also part of the inferotemporal cortex and part of the parietal cortex also receive inputs via basal ganglia–thalamocortical pathways (see chapter 39). These temporal and parietal areas are themselves linked to the executive and cognitive networks of the frontal lobes. Conceptually, then, the anatomy overwhelmingly favors the basal ganglia as poised to influence high-level functions associated with activity in the frontal neocortex (figure 39.3).

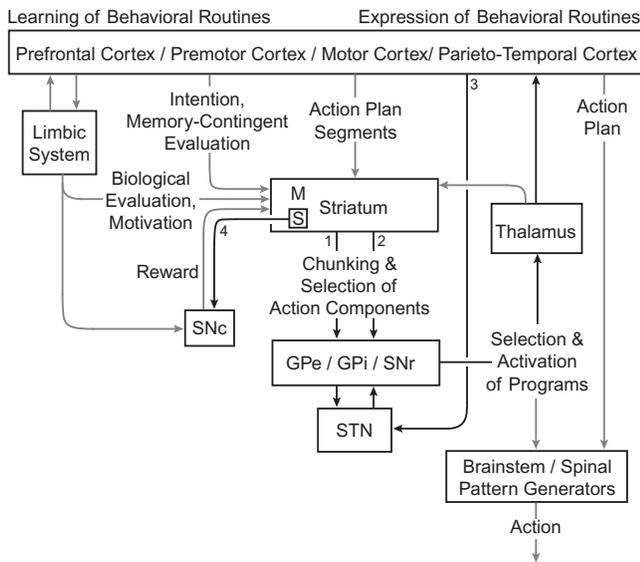

FIGURE 39.3 Schematic diagram of major basal ganglia circuits with highly schematized indications of component functions. The striatum with its matrix (M) and striosomal (S) compartments is centered in the diagram. Four major pathways are emphasized: the direct (1) and indirect (2) pathways, the hyperdirect pathway (3), and the striosomal pathway (4). Abbreviations: GPe, GPI, globus pallidus external and internal subdivisions; STN, subthalamic nucleus; SNc, dopamine-containing substantia nigra pars compacta. (Adapted from Graybiel, 1997.)

This emphasis on the cortically directed pathways leading out from the basal ganglia is natural enough when thinking about the possible cognitive functions of the basal ganglia, but it is equally important to keep in mind that there are other robust outputs of the basal ganglia (Graybiel & Ragsdale, 1979; Parent & Hazrati, 1995a, 1995b). These may also, directly or indirectly, influence potential cognitive functions of the basal ganglia. Such connections include projections to the reticular nucleus of the thalamus, a major controller of thalamocortical and corticothalamic state-dependent activity (McAlonan & Brown, 2002), and descending projections from the basal ganglia, among which are connections leading to the superior colliculus and brain stem reticular formation, and to the nuclei that are recurrently connected with the basal ganglia (Parent & Hazrati, 1995a, 1995b). The largest of these are the descending projections to the superior colliculus (Rinvik, Grofova, & Ottersen, 1976; Graybiel, 1978) and to the pedunculopontine area of the brain stem reticular formation (Parent & Hazrati, 1995a, 1995b).

The most intensively studied of the recurrent-pathway nuclei is the substantia nigra, and this is for a good reason. The dopamine-containing subdivision of the substantia nigra degenerates in Parkinson’s disease and in related parkinsonian disorders. It is now known that dopamine-containing neurons respond phasically to predictors of reward or to primary rewards themselves and have tonic activity that appears to reflect probability of reward (Schultz, 2002; Fiorillo, Tobler, & Schultz, 2003). A second key nucleus is the subthalamic nucleus. The subthalamic nucleus, like the striatum, receives input from cerebral cortex, and as we will see, this nucleus is a pivotal control nucleus of the basal ganglia circuitry. It functions both as a direct cortical input node and as part of recurrent loops within basal ganglia circuits. Cortical inputs arise largely from the frontal lobes (Monakow, Akert, & Kunzle, 1978; Nambu, Yoshida, & Jinnai, 1990; Nambu, Takada, Inase, & Tokuno, 1996; Kolomiets et al., 2001). Lesions of this nucleus result in the hyperkinetic syndrome called ballism. Remarkably, it is now recognized that lesions or deep-brain stimulation in the subthalamic nucleus can relieve symptoms of Parkinson’s disease (Bergman, Wichman, & DeLong, 1990; Lang, 2000; Obeso et al., 2000; Benabid et al., 2003). The input from the motor cortex (and related cortical areas) to the subthalamic nucleus is now recognized as the hyperdirect pathway (Nambu, Tokuno, & Takada, 2002), and this pathway is now considered to be key to the control of the motor functions—and also probably the cognitive and emotion-related functions—of the basal ganglia (Feger, Bevan, & Crossman, 1994; Deschenes, Bourassa, Doan, & Parent, 1996; Nambu et al., 2002; Schupbach & Agid, 2008) pathway. The third nucleus that we consider is the pedunculopontine nucleus, embedded in the reticular formation. The pedunculopontine

nucleus sends outputs to motor control centers of the lower brain stem and also is modulator of basal ganglia function by way of its recurrent upstream connections (Lavoie & Parent, 1994; Pahapill & Lozano, 2000). This nucleus is now also considered to be a key controller of basal ganglia output functions. Put together, then, we can see that the basal ganglia can influence a wide range of behavior through both their ascending projections toward the neocortex and by way of key descending connections to an influential set of brain stem nuclei.

Perspectives from the clinic

In Parkinson's disease and Huntington's disease, classical basal ganglia disorders that are accompanied by motor abnormalities, patients frequently experience cognitive dysfunction, including memory deficiency, depression, and, most important, disordered executive functions (R. G. Brown & Marsden, 1990; Dubois, Pillon, & Agid, 1992; Bédard et al., 1998, 2003; Joel, 2001; Saint-Cyr, 2003). Moreover, dementia is frequent in these diseases and mostly exhibits the features of frontal dementia syndromes (Pillon et al., 1994; Saint-Cyr, 2003). These "additional" (i.e., non-motor) symptoms are often taken to suggest that the basal ganglia proper have cognitive functions, but this view is now being modified by the realization that both Parkinson's disease and Huntington's disease are neurodegenerative diseases with neuronal damage extending—and even starting—outside the basal ganglia (Sieradzan & Mann, 2001; Braak et al., 2003). It is therefore not possible to attribute cognitive signs and symptoms of these disorders to dysfunction of the basal ganglia alone. However, there are other reasons to place the basal ganglia firmly within the cognitive domain.

First, there are other neurological disorders involving cognitive dysfunction that at least appear to affect more selectively specific basal ganglia nuclei (e.g., certain cerebrovascular disorders). Dysfunction in multiple cognitive domains is reported with infarctions or hemorrhages that are apparently limited to the caudate nucleus (e.g., abulia, restlessness, disinhibition and impulsivity, executive dysfunction) or to the putamen (e.g., contralateral neglect, language abnormalities) (Mendez et al., 1989; Caplan et al., 1990; Bhatia & Marsden, 1994). The single most prominent symptom associated with lesions of the caudate nucleus is abulia, a lack of drive. Lesions in the ventromedial caudate nucleus are associated with disinhibition and impulsivity. Work in the behaving primates supports such clinical findings and suggests some topographic differences of behavioral mechanisms within the basal ganglia (Francois et al., 2002; Tremblay et al., 2003).

Finally, imaging studies have demonstrated alterations of basal ganglia activity in disorders in which cognitive deficits are evident, including obsessive-compulsive (OC)

spectrum disorders such as Tourette syndrome and obsessive-compulsive disorder (OCD), and attention-deficit/hyperactivity disorder (ADHD) (Graybiel & Rauch, 2000; Teicher et al., 2000; Rauch et al., 2001; Leckman, 2002; Albin & Mink, 2006). We will refer to these disorders again in what follows.

Hypotheses of basal ganglia function

We have grouped hypotheses about the functions of the basal ganglia into categories related to (1) movement release and inhibition, (2) response selection, (3) attention and assignment of salience, and (4) learning and adaptive control of behavior.

MOVEMENT RELEASE AND INHIBITION We will in this chapter use the "motor circuits" of the basal ganglia as templates to understand the organization of basal ganglia circuits. Increasing evidence suggests that this same organization underlies the cognitive functions of the basal ganglia.

The main pathways that lead out from the basal ganglia are known as the direct and indirect pathways, the hyperdirect pathway, and the striosomal pathway (figures 39.3 and 39.4). These pathways are thought to influence motor control by release (direct pathway) or inhibition (indirect pathway and hyperdirect pathway) of motor behaviors (Albin, Young, & Penney, 1989; DeLong, 1990) and by control of the repetitiveness of behaviors for the striosomal pathway (Graybiel, Canales, & Capper-Loup, 2000; Saka & Graybiel, 2004). The release-inhibit model suggests, in simplest form, that the neocortex excites the striatum, which inhibits the internal pallidum, which in turn inhibits the motor thalamus. The double inhibition suggests that cortical activation phasically "releases" the thalamus, which then can excite the neocortex. This movement-releasing pathway is, according to the release-inhibit model, in direct competition with the *indirect pathway*, which, due to its connecting link in the subthalamic nucleus, is thought to depress movement. The subthalamic nucleus is released by striatal excitation of its inhibitory input nucleus (the external pallidum), and the subthalamic nucleus then excites the internal pallidum, leading to less movement. Many current models of the basal ganglia focus on this winner-take-all model (Dominey, Arbib, & Joseph, 1995; Beiser & Houk, 1998; J. E. Brown, Bullock, & Grossberg, 1999; Gillies & Arbuthnott, 2000; Frank, Loughry, & O'Reilly, 2001a; Kitano, Aoyagi, & Fukai, 2001). Current evidence suggests that this release-inhibit model may need revision (see Graybiel, 2005), but it has spurred major clinical advances and has been applied to the cognitive side of basal ganglia function as well.

The *hyperdirect pathway* (figure 39.3) consists of a fast, direct excitatory pathway from the motor cortex (and some other

cortical areas) to the subthalamic nucleus, which can therefore rapidly excite the pallidum (Nambu et al., 2002). This pathway bypasses the striatum and could help to account for the efficacy of deep brain stimulation of the subthalamic nucleus to relieve symptoms of Parkinson's disease (Lang, 2000; Obeso et al., 2000; Benabid et al., 2003).

We emphasize that if we extend the release-inhibit idea to the cognitive level, we can think of other actions—even thoughts or emotions—as being released through this mechanism (Swerdlow & Koob, 1987; Graybiel, 1997). This possibility is receiving potential support from the results of deep brain stimulation used as a therapeutic intervention for Parkinson's disease (Bejjani et al., 1999; Krack et al., 2001).

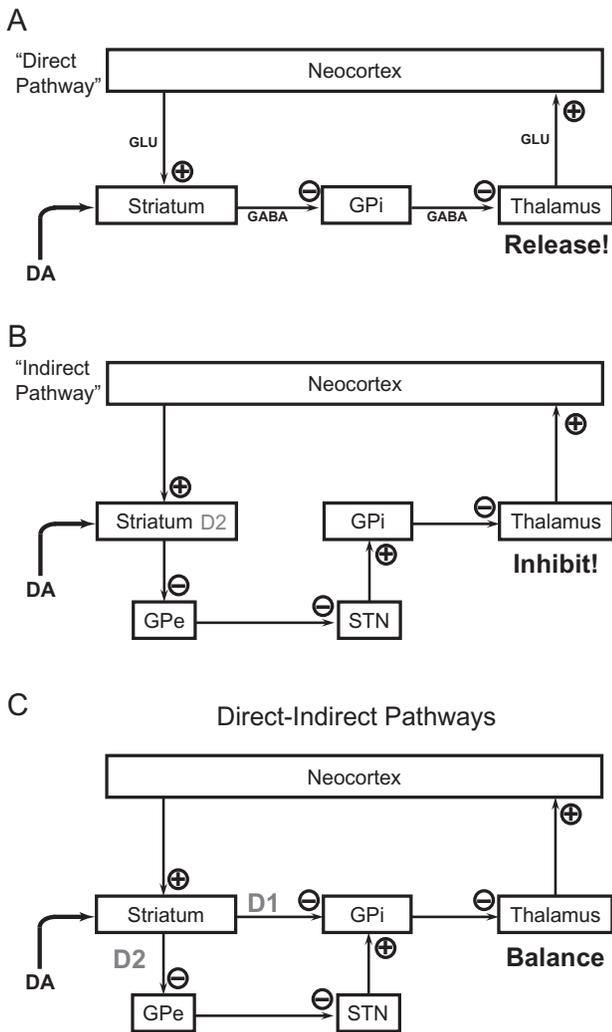

FIGURE 39.4 Highly schematic diagrams of the direct and indirect pathways identified in basal ganglia circuitry. *A* and *B* separate out these two pathways to emphasize their proposed “release” and “inhibit” functions. The diagrams in *C* puts them together to show the balance between them that is thought to underlie normal behavioral control. The hyperdirect and striosomal pathways are not shown here (see figures 39.3, 39.5, and 39.6).

The *striosomal pathway* (figure 39.3) is thought to lead from the anterior cingulate cortex and caudal orbitofrontal cortex to neurochemically defined compartments in the striatum that are called striosomes (striatal bodies). These in turn are interconnected with the dopamine-containing substantia nigra (Eblen & Graybiel, 1995; Prensa & Parent, 2001). These connections may serve to regulate the functions of the substantia nigra, and this striosomal system has been implicated regulating the frequency and repetitiveness of behavior of actions (Graybiel et al., 2000; Graybiel & Canales, 2001).

SELECTION AND INHIBITION OF COMPETING BEHAVIORS If we now think of these control pathways again, we can note that there are two primary disynaptic pathways of information flow from the cerebral cortex to the basal ganglia output nuclei, the internal pallidum (GPi), and the substantia nigra, pars reticulata (SNpr): (1) the disynaptic direct pathway from the neocortex to striatum to the output nuclei and (2) the hyperdirect pathway from the neocortex to the subthalamic nucleus (STN) and then to the basal ganglia output nuclei (figures 39.5 and 39.6). The contrasts between these two are important. First, the cortical input to the STN comes only from the frontal cortex, whereas the input to the striatum arises from all or nearly all areas of the cerebral cortex.

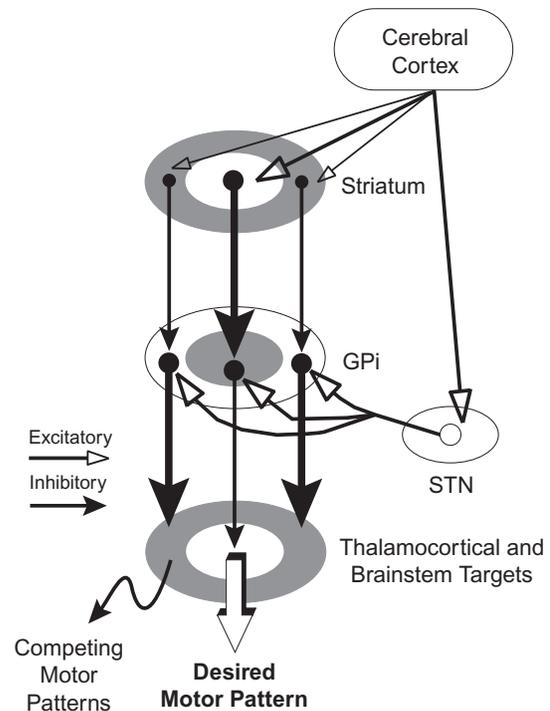

FIGURE 39.5 Schematic diagram of functional organization of the basal ganglia output. Excitatory projections are indicated with open arrows; inhibitory projections are indicated with filled arrows. Relative magnitude of activity is represented by line thickness. (Modified from Mink, 2001.)

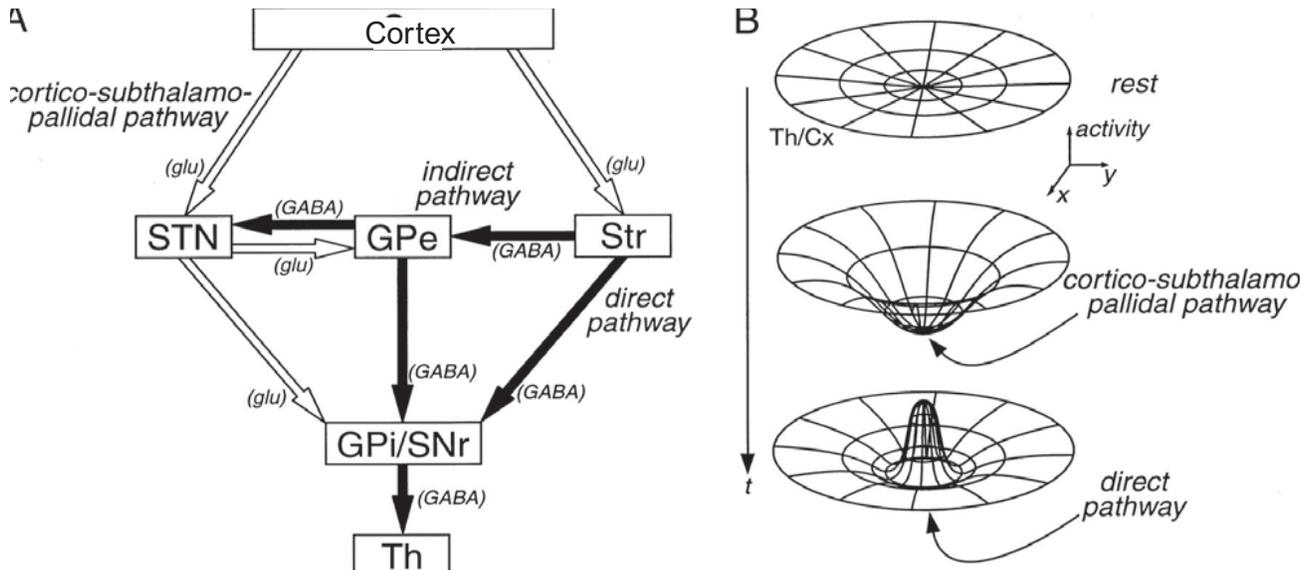

FIGURE 39.6 (A) Schematic diagram of the hyperdirect cortico-subthalamo-pallidal, the direct cortico-striato-pallidal, and the indirect corticostriato-GPe-subthalamo-GPi pathways. *White and black arrows* represent excitatory glutamatergic (*glu*) and inhibitory GABAergic (*GABA*) projections, respectively. Abbreviations: GPe, external segment of the globus pallidus; GPi, internal segment of the globus pallidus; SNr, substantia nigra, pars reticulata; STN,

subthalamic nucleus; Str, striatum; Th, thalamus. (B) Schematic diagram depicting the hypothesized activity change over time (*t*) in the thalamocortical projection (Th/Cx) following the sequential inputs through the hyperdirect cortico-subthalamo-pallidal (*middle*) and direct cortico-striato-pallidal (*bottom*) pathways. (Modified from Nambu et al., 2002.)

Second, the output from the STN is excitatory, whereas the output from the striatum is inhibitory. Third, the excitatory route through the STN is faster than the inhibitory route through the striatum (Nambu et al., 2000). Finally, the STN projection to the GPi is divergent, and the striatal projection is more focused (Parent & Hazrati, 1993). Thus, the two disynaptic pathways from cerebral cortex to the basal ganglia output nuclei, the GPi and SNpr, provide fast, widespread, divergent excitation through the STN, and slower, focused, inhibition through the striatum. Because the outputs of the GPi and the SNpr are thought to be inhibitory (but see potential evidence for the contrary reviewed in Graybiel, 2005), this arrangement would result in focused facilitation and surround inhibition of basal ganglia thalamocortical targets.

In this scheme, the tonically active inhibitory output of the basal ganglia acts as a “brake” on motor control circuits of the cerebral cortex and brain stem. When a movement is initiated by a particular motor pattern generator, basal ganglia output neurons projecting to competing generators increase their firing rate, thereby increasing inhibition and applying a “brake” on these generators. Other basal ganglia output neurons projecting to the generators that are involved in the desired movement decrease their discharge, thereby removing tonic inhibition and releasing the “brake” from the desired motor patterns. Thus, the intended movement is enabled, and competing movements are prevented from interfering with the desired one.

The anatomical arrangement of STN and striatal inputs to the GPi and SNpr form the basis for a functional center-surround organization as shown in figure 39.5. When a voluntary movement is initiated by cortical mechanisms, a separate signal is sent to the STN, exciting it. The STN projects in a widespread pattern and excites the GPi. The increased GPi activity produces inhibition of thalamocortical motor mechanisms. In parallel to these pathways through the STN, signals are sent from all areas of the cerebral cortex to the striatum. The cortical inputs are transformed by integrative circuitry in the striatum to a focused, context-dependent output that inhibits specific neurons in the GPi. The inhibitory striatal input to the GPi is slower than the excitatory STN input, but it is more powerful. The resulting focally decreased activity in the GPi selectively disinhibits the desired thalamocortical motor circuits. Indirect pathways from the striatum to the GPi (striatum → external pallidum (GPe) → GPi and striatum → GPe → STN → GPi) result in further focusing of the output. The net result of basal ganglia activity during a voluntary movement is the inhibition (“braking”) of competing motor patterns and focused facilitation (releasing the “brake”) from the selected voluntary movement pattern generators.

This scheme provides a framework for understanding both the pathophysiology of parkinsonism and involuntary movements (Young, Albin, & Penney, 1989; Mink, 1996, 2003; Goldberg et al., 2002). Different involuntary movement disorders such as parkinsonism, chorea, dystonia, and

tic disorders result from different abnormalities in these basal ganglia circuits. Loss of the dopamine-containing nigrostriatal input to the striatum results in a loss of normal pauses of GPi discharge during voluntary movement. Hence, there is excessive inhibition of motor pattern generators and ultimately bradykinesia (Goldberg et al., 2002). Furthermore, loss of dopamine results in abnormal synchrony of GPi neuronal discharge and loss of the normal spatial and temporal focus of GPi activity (Filion, Tremblay, & Bedard, 1989; Raz, Vaadia, & Bergman, 2000; Goldberg et al., 2002). Large lesions of the GPi or the SNpr disinhibit both desired and unwanted motor patterns, leading to inappropriate activation of competing motor patterns, but normal generation of the wanted movement. Thus, lesions of GPi lead to cocontraction of multiple muscle groups and difficulty turning off unwanted motor patterns, similar to what is seen in dystonia, but they do not affect movement initiation (Mink & Thach, 1991).

Lesions of SNpr produce unwanted saccadic eye movements that interfere with the ability to maintain visual fixation but do not impair the initiation of voluntary saccades (Hikosaka & Wurtz, 1985). Lesions of putamen may result in dystonia due to the loss of focused inhibition in GPi (Mink, 2003). Lesions of the STN produce continuous involuntary movements of the contralateral limbs (hemiballism or hemichorea) (Mink, 2003). Despite the involuntary movements, voluntary movements can still be performed. Although structural lesions of putamen, GPi, SNpr, or STN produce certain types of unwanted movements or behaviors, they do not produce tics. Tics are more likely to arise from abnormal activity patterns, most likely in focal zones in the striatum (Flaherty & Graybiel, 1994; Canales & Graybiel, 2000; Mink, 2003).

The notion that the basal ganglia affect motor pattern generators helps to account for these motor disorders. But as we noted, the basal ganglia, via the thalamus, also project to a large part of the prefrontal cortex and to limbic structures. It has been proposed that these circuits act as “cognitive pattern generators” (Graybiel, 1997). Through these circuits, with similar functional structures as those considered to be motor circuits, the basal ganglia can affect cognition, planning, executive function, and our emotional lives. Some neuropsychiatric disorders, such as OCD, Tourette syndrome, and even schizophrenia, may have their origin in such cortico-basal ganglia circuits (Swerdlow & Koob, 1987; Graybiel, 1997, 2008). Possibly related to these findings is evidence that emotional distress and anguish, or irrepressible laughter and hilarity, can be evoked by deep-brain stimulation in or near the substantia nigra and the subthalamic nucleus (Bejjani et al., 1999; Krack et al., 2001; Schupbach & Agid, 2008).

The selection of which response to make is a huge job, probably engaging much of the neocortex and other brain

regions, but the basal ganglia may strongly influence such selections on the basis of recognition of context, assignment of salience, and expectancy of outcome, which are discussed below. Specifically, which behaviors are selected for facilitation and which are inhibited may be based on a winner-take-all model that is established in the striatum (Dominey et al., 1995; Beiser & Houk, 1998; J. E. Brown et al., 1999; Redgrave, Prescott, & Gurney, 1999; Gillies & Arbuthnott, 2000; Frank, Loughry, & O’Reilly, 2001b; Kitano et al., 2001; Doya, 2002).

Selection is likely to take place via the compartmentally organized input-output organization of the striatum and the interaction of these compartmentalized circuits with neuromodulatory circuits (Graybiel & Ragsdale, 1978; Malach & Graybiel, 1986; Flaherty & Graybiel, 1994). If there is sufficient simultaneous activity of convergent inputs to a subgroup of striatal medium spinal neurons (Schneider & Lidsky, 1981; Flaherty & Graybiel, 1991; Kincaid, Zheng, & Wilson, 1998), they will “win,” and if they are striatal neurons leading into indirect pathway, they can inhibit output neurons in the GPi and the SNpr, leading to facilitation of thalamocortical neurons. Simultaneous suppression of competing responses in this scenario would be mediated by the hyperdirect and indirect pathways. Thus, competition occurs at both the input (striatal) and output (GPi/SNpr) levels of basal ganglia circuits (Filion, Tremblay, & Bédard, 1988; Flaherty & Graybiel, 1994; Mink, 2001). This view has been adapted to account for imaging data in OCD patients (Rauch et al., 2001) and some basal ganglia models (Beiser & Houk, 1998; J. E. Brown et al., 1999; Gillies & Arbuthnott, 2000), but remains controversial.

There is substantial evidence that selection at the striatal level depends on learning mechanisms (Graybiel, 1995, 2005, 2008). Thus behavioral selections can be influenced by experience, and the striatum—and therefore the rest of the basal ganglia—participate strongly in the adaptive control of motor and cognitive behaviors. This idea originated with the recognition that corticostriatal inputs (and other inputs to the striatum) are modular, as was noted above, and that the cortical inputs show modular divergence but then can show reconvergence at the next stage of the basal ganglia circuit, within the pallidum (figure 39.7a) (Flaherty & Graybiel, 1994; Graybiel, Aosaki, Flaherty, & Kimura, 1994; Parthasarathy & Graybiel, 1997). This pattern resembles a mixture of experts learning architectures (e.g., Jacobs, Jordan, Nowlan, & Hinton, 1991), whereby information can be distributed divergently to an intermediate layer of the network, and then be gated and recombined at an output layer (figure 39.7b) (Graybiel, 1998). The dopaminergic input to the striatum could be one strong gating mechanism. Dopamine-containing inputs carry signals related to predicted reward and saliency to striatal neurons, and they are arranged anatomically to maximize their ability to gate

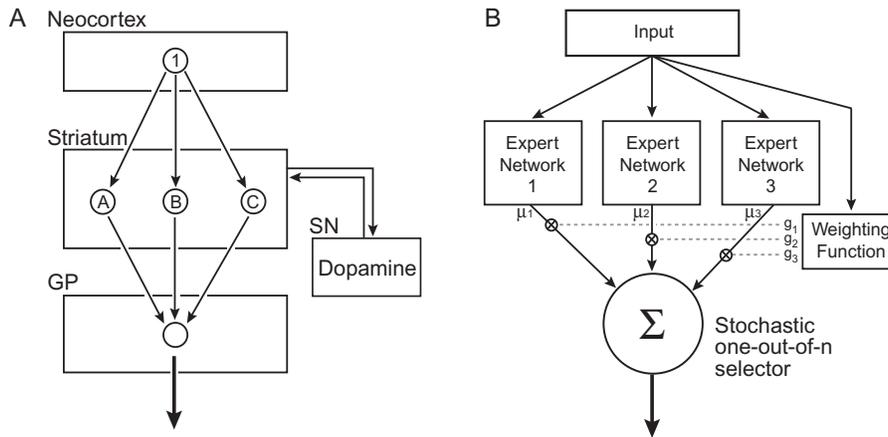

FIGURE 39.7 (A) Divergent-reconvergent processing of signals through cortico-basal ganglia pathways. Divergence of cortical input to modules (matrisomes A, B, C) occurs at the level of the striatum. In the globus pallidus (GP), information is reconverged, resulting in the remapping of the cortical output. The network is

corticostriatal information flow (A. D. Smith & Bolam, 1990; Bolam, Hanley, Booth, & Bevan, 2000). In addition, dopamine is critically involved in long-term potentiation and depression in the striatum (Reynolds, Hyland, & Wickens, 2001; Wise, 2004; Calabresi, Piconi, Tozzi, & Di Filippo, 2007; Tang, Pawlak, Prokopenko, & West, 2007).

Many movement disorders resulting from diseases that affect the basal ganglia can be understood as disorders of response selection and inhibition. These include disorders characterized by paucity of movement, such as Parkinson's disease (Mink, 1996; Goldberg et al., 2002), and disorders characterized by excessive involuntary movements, such as chorea, dystonia, or tics (Mink, 1996, 2003; Sato et al., 2008). Notably, the treatment of Parkinson's disease by STN deep brain stimulation can improve both response selection and inhibition (Nieuwenhuis, Yeung, van den Wildenberg, & Ridderinkhof, 2003).

In parallel with these movement disorders, neuropsychiatric disorders can also result from impaired response selection or inhibition. Inappropriate facilitation or impaired inhibition may lead to the cognitive and motor intrusions, inflexibility, repetitiveness, and overt cognitive and motor stereotypic responses that occur in OC-spectrum disorders (Graybiel & Rauch, 2000; Leckman, 2002; Graybiel, 2008). Functional imaging studies of individuals with OC-spectrum disorders indicate increased activity in the caudate nucleus combined with increased activity in the cingulate and orbitofrontal cortices (see Rauch et al., 2001). Moreover, symptom provocation in OCD patients further increases the activity of these regions (Breiter et al., 1996), and the increased activation can be lessened by treatment of the symptoms (Baxter et al., 1992; Schwartz, Stoessel, Baxter, Martin, & Phelps, 1996; Lazaro et al., 2008). This dynamic modulation supports the idea that the basal ganglia and

modulated by dopamine-containing inputs from the substantia nigra (SN). (Modified from Graybiel et al., 1994.) (B) Mixture-of-experts learning network model. (Modified from Jacobs et al. 1991.) Note the similarity of the models in A and B.

anterior cingulate/orbitofrontal cortical regions are important in response selection and attentional shifting.

Selecting which action to perform is critical for normal behavior. But when particular actions (or thoughts) are selected over and over again, the repetitiveness can signal the occurrence of syndromes such as OC-spectrum disorders or other disorders in which behavioral stereotypies occur. There is some evidence that the repetitiveness of action selection can be controlled independently of which action is selected. That is, different actions can be selected but, when selected, each is repetitively selected. In both rodents and primates, a specific modular pattern of neuronal activation in the striatum is highly predictive of the stereotypies induced by psychomotor stimulants: Activity in striosomes is greater than activity in the surrounding matrix regardless of which particular actions are being repeated—that is, regardless of which have been selected (figure 39.8) (see Canales & Graybiel, 2000; Saka, Goodrich, Harlan, Madras, & Graybiel, 2004). This is interesting, because anatomical work in the primate suggests that striosomes receive differentially strong input from parts of the anterior cingulate and orbitofrontal cortex. In the human, as was noted above, these are cortical regions that are abnormal in OCD patients and in addictive states (for a review, see Graybiel, 2008). Modular patterns of striatal activation have also been invoked to account for focal tics and repetitive actions in Tourette syndrome (Mink, 2001). In this case, overactivity in particular modules (matrisomes) is thought to be involved in the “selection” of the repeated behavior (figure 39.7a). Thus both striosomes and matrisomes could contribute to disorders of action selection and behavioral switching and could be important for the normal discharge of these complex functions.

Impulse-control disorders may relate to impaired response inhibition. This has become an area of substantial

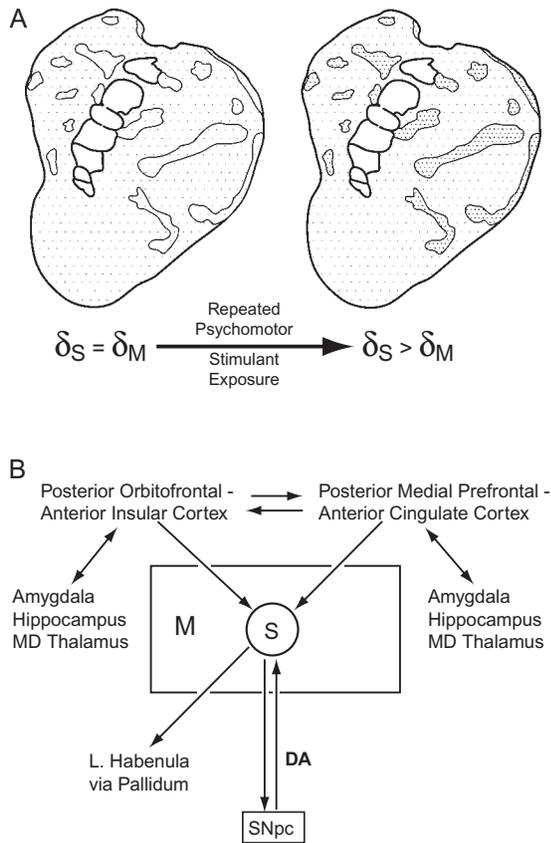

FIGURE 39.8 (A) Schematization of neuronal activity mapped in the caudate nucleus and putamen of the squirrel monkey in response to either single (*left*) or repeated (*right*) exposure of the monkey to psychomotor stimulants. The activity measure is the average density of striatal neurons expressing early-genes in response to the drug treatment, calculated separately for the striosome (δ_S) and matrix (δ_M) compartments. The single dose of the psychomotor stimulant induces only low levels of behavioral stereotypy and little predominance of striosomal activation. By contrast, repeated exposure to the psychomotor stimulant induces high levels of behavioral stereotypy and sharply increased striosome predominance. (B) Schematization of the major connections of the striosomes. The central rectangle represents the striatum with its matrix (M) and striosomal (S) compartments. Abbreviations: MD, mediodorsal nucleus; SNpc, substantia nigra, pars compacta; DA, dopamine. (Modified from Graybiel, 1997.)

interest recently in relation to Parkinson's disease. Patients with Parkinson's disease are commonly treated with dopamine replacement therapy (levodopa) or with direct dopamine receptor agonists. A variety of impulse control disorders, including compulsive gambling and excessive risk taking ("punding"), have been described in patients with Parkinson's disease who are treated with these dopaminergic medications (Dodd et al., 2005; Pontone, Williams, Bassett, & Marsh, 2006; Weintraub et al., 2006). As was discussed above, the STN is thought to play a central role in response inhibition (Aron & Poldrack, 2006; Eagle et al., 2008), and it is thought that impulse control disorders in Parkinson's

disease may relate to impairment of STN-mediated response inhibition. Indeed, STN deep brain stimulation may cause impaired impulse control despite improvement of other aspects of movement (Frank, 2006; Winstanley, Eagle, & Robbins, 2006).

ATTENTION AND ASSIGNMENT OF SALIENCE The attention-salience assignment model of the basal ganglia suggests that the outputs of the basal ganglia are influential in modulating movement because they can influence attention to stimuli and because they have the capacity to assign salience to stimuli. This idea is strongly supported by work on the dopamine-containing inputs to the basal ganglia, which carry signals related to reinforcement probability, salience, and expectation of reinforcement (Schultz, Dayan, & Montague, 1997; Berridge & Robinson, 1998; Doya, 2002; Glimcher, 2003; Daw, Niv, & Dayan, 2005; Niv, Duff, & Dayan, 2005; Niv, Joel, & Dayan, 2006; Schultz, 2007; Graybiel, 2008). We note, however, that several other systems that could have this function also project to the basal ganglia. These include the locus coeruleus/norepinephrine system (projecting especially strongly to the ventral striatum), the serotonergic raphe system, the intralaminar thalamic nuclei, and other structures such as the amygdala.

Clinical studies also have repeatedly implicated the basal ganglia in attentional control (Mesulam, 2000), and, in modern formulations of this idea, the basal ganglia are particularly singled out as being important for "attention to action" (Jueptner, Stephan, et al., 1997). Imaging studies indicate that cortico-basal ganglia circuit dysfunction in Parkinson's disease may account for the marked attentional problems suffered by Parkinson's disease patients (see Saint-Cyr, 2003). There is, in addition, evidence for dysfunction of corticocortical connections linking the supplementary motor area and premotor areas (Rowe et al., 2002). This dysfunction at the cortical level could itself be related to abnormal basal ganglia influences on these cortical areas (Brooks, 1997; Samuel et al., 1997). It should be clear, however, that "attention" is a broad concept and, in the context of cortico-basal ganglia loops, includes functions ranging from saliency signals modulating signal-to-noise ratios to motor readiness (Denny-Brown & Yanagisawa, 1976; Robbins & Everitt, 1992; Aosaki, Graybiel, & Kimura, 1994; L. L. Brown, Schneider, & Lidsky, 1997; Jog et al., 1999; Barnes et al., 2005). Considered in this way, attentional deficits in Parkinson's disease could lead to bradykinesia (slowness of movement), bradyphrenia (slowness of thought), and abulia (a cardinal sign of anterior striatal dysfunction in which a profound inertia of psychomotor response initiation occurs).

Patients with Parkinson's disease and Huntington's disease exhibit deficits in shifting of attention, termed set-shifting (Owen et al., 1993; Georgiou, Bradshaw, Phillips, & Chiu,

1996; Bédard et al., 1998). Again, these are disorders with widespread neurodegeneration not confined to the basal ganglia proper, but in normal individuals, there are significant and selective increases in blood flow in the striatum for tasks that measure attention shifts in response to visual cues (Koski, Paus, Hofle, & Petrides, 1999).

A dramatic deficiency in attentional control is present in ADHD, in which individuals exhibit hyperactive behavior, a lack of focusing ability, and impulsivity. Functional imaging studies addressing the possible involvement of the basal ganglia in this disorder suggest that the capacity to inhibit motor activity and the capacity to sustain attention may be linked in ADHD individuals, and that these clinical measures of abnormal function are correlated with altered activity in the putamen (Teicher et al., 2000).

There now is direct evidence that activity in the striatum is important as an attentional filter in humans (McNab & Klingberg, 2008), and there is direct electrophysiological

evidence in animals for striatal representations that emphasize salient events and deemphasize others (Jog et al., 1999; Barnes et al., 2005). Electrophysiological studies in primates also support the idea that the basal ganglia are part of forebrain attentional systems. Explicit tests of attentional shifting suggest that many striatal projection neurons fire for shifts in attention that are unaccompanied by overt movements (Kermadi & Boussaoud, 1995; Boussaoud & Kermadi, 1997). An instructive example comes from studies of striatal interneurons called tonically active neurons (TANs), which are broadly distributed through the caudate nucleus and putamen (figure 39.9). These neurons modify their responses to sensory stimuli depending on the saliency of the sensory stimuli. The saliency can be unconditional (e.g., a loud, unexpected sound makes them respond) or can be built up through conditioning by pairing the sensory cues with positive or negative reinforcements (Aosaki, Tsubokawa, et al., 1994; Apicella, 2002; Blazquez et al.,

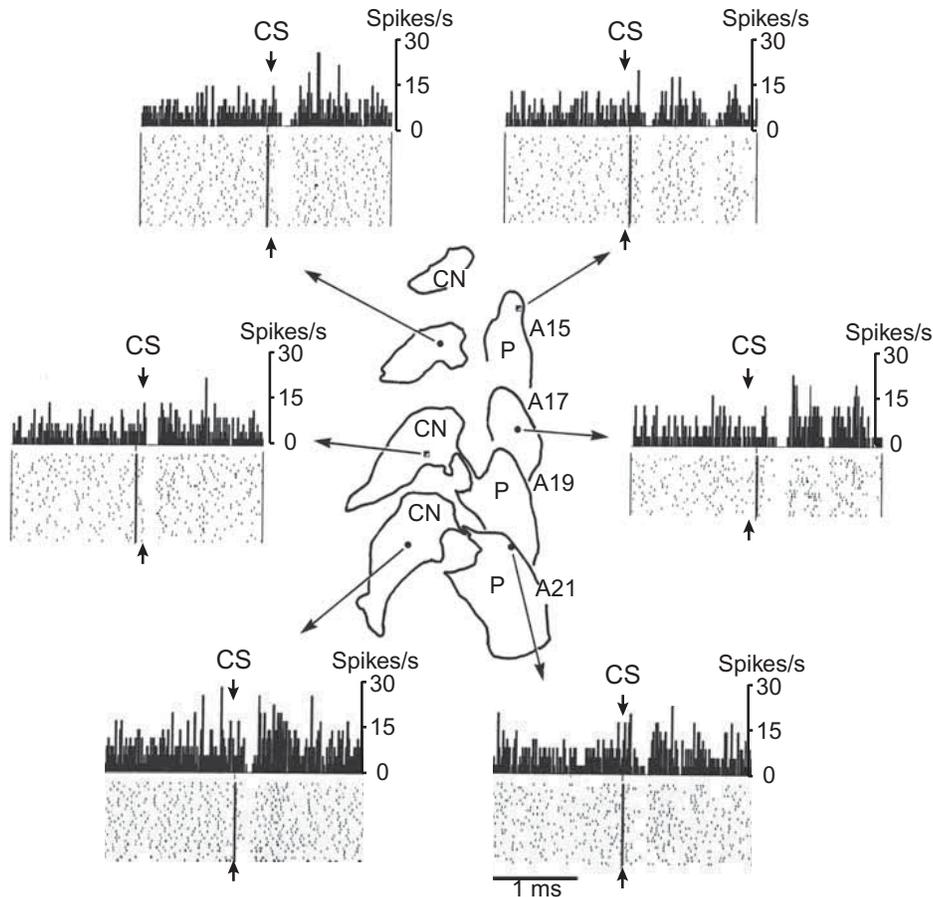

FIGURE 39.9 The responses of tonically active neurons (TANs) of the macaque monkey striatum in response to conditioned stimuli (CS: clicks or light-emitting diodes) in a simple behavioral conditioning paradigm in which the monkey receives liquid rewards following delivery of the CS. The neurons acquire responses to the cues associated with the rewards (see pauses in activity). The responses of six representative TANs recorded at the illustrated

sites (black dots or squares) are shown in raster plots and spike histograms, and the anteroposterior (AP) sites at which they were recorded are shown in diagrams. Note the widespread, coherent appearance of the response, suggesting that these interneurons might serve as a temporal binding mechanism across cortico-basal ganglia loops. (Adapted from Graybiel et al., 1994.)

2002). The reward/saliency signals are partly dependent on inputs from the dopamine-containing neurons of the substantia nigra (Aosaki et al., 1994). But they depend also on inputs from the intralaminar nuclei of the thalamus (Matsumoto, Minamimoto, Graybiel, & Kimura, 2001) and probably the neocortex as well. Because the TANs are widely distributed local network neurons, and tend to have synchronous responses (Graybiel, Aosaki, Flaherty, & Kimura, 1994; Raz, Feingold, Zelanskaya, Vaadia, & Bergman, 1996; Blazquez, Fuji, Kojima, & Graybiel, 2002), they could coordinate together activity in functionally distinct cortico-basal ganglia loops to achieve sensorimotor and cognitive binding (figure 39.10) (see Graybiel et al., 1994; see Graybiel, 1997).

This example gives an idea of how signals from many different brain regions could ultimately lead to salience signaling in basal ganglia networks and contribute to motor and cognitive attention. Remarkably, it has been estimated that the population activity of even a small number of these interneurons can accurately predict ongoing behavioral events (Blazquez et al., 2002). This means that the intrinsic circuitry of the striatum has within it a signal that is proportional to behavioral outcome—exactly what is needed to develop a forward model for behavioral control (Blazquez et al., 2002).

LEARNING AND ADAPTIVE CONTROL OF BEHAVIOR The idea that the basal ganglia are sites for learning has strong support from experimental work in animals and increasing support from imaging and other work in humans. Commonly, attempts to formulate how the basal ganglia could contribute to learning involve comparing the basal ganglia to the hippocampus, or comparing them to the cerebellum (Packard & Knowlton, 2002; Doyon, Penhune, & Ungerleider, 2003). Helpful as such comparisons may be, they are not enough to define the type of neural processing that occurs in basal

ganglia networks and cortico-basal ganglia circuits during behavioral learning. As noted below, new techniques are now beginning to let investigators approach this issue directly.

Studies in rat, monkey, and human suggest that the basal ganglia mediate a particular type of learning and memory: stimulus-response (S-R) learning, in which learning proceeds by trial and error and performance improves according to the sensory feedback obtained as a result of the response (Packard & McGaugh, 1992; McDonald & White, 1994). Evidence for this has led to the notion that the basal ganglia are important for habit or skill learning (Graybiel, 1995, 2005, 2008; Packard & Knowlton, 2002). The function of the basal ganglia in feedback (S-R) learning appears to be highly conserved. In birds, the anterior forebrain pathway (AFP) is thought to be analogous to certain cortico-basal ganglia circuits in mammals, and it has been shown that this AFP pathway is critical to bird song learning (Brainard & Doupe, 2000; Amin, Doupe, & Theunissen, 2007; Calaminus & Hauber, 2007; Aronov, Andalman, & Fee, 2008).

Experimental psychologists working with rats have amassed strong evidence that the caudoputamen (dorsal striatum) is necessary for both the acquisition and the expression of S-R associations and memory and for “win-stay” learning in which the animal repeats the behavior that led to reward (Packard, Hirsh, & White, 1989; Packard & McGaugh, 1992, 1996; McDonald & White, 1994). This behavior is contrasted with “win-shift” behavior involving explicit memory of the context of the behavior. However, the situation may be more than one of different basal ganglia loops participating in different aspects of learning. For example, performance on S-R learning tasks suffers in rats with lateral (sensorimotor) striatal lesions; but in rats with medial striatal lesions, performance suffers on tasks similar to those requiring hippocampal function, for example, spatial navigation (Devan, McDonald, & White, 1999; Devan & White, 1999; Packard & Knowlton, 2002; Yin & Knowlton, 2006). Moreover, there is good reason to think that in most of the tasks that are used in such rodent experiments, explicit awareness of the associations (e.g., place learning) could occur, engaging the hippocampus. Some studies suggest that in such contexts, the hippocampus may operate during an early, explicit stage of learning and that the striatum may then take over (or at least be more critical) when the task is repeated to the point at which the animal can perform the task without explicit knowledge (McDonald & White, 1994; Packard & McGaugh, 1996). Thus even with damage to the striatum, habit learning could be partly intact because learning strategies based on hippocampal function can partly compensate for the deficient recruitment of the basal ganglia (Packard & Knowlton, 2002). Interestingly, evidence in these rodent studies suggests that the striatum and hippocampus can compete with each other, so that a lesion of one system

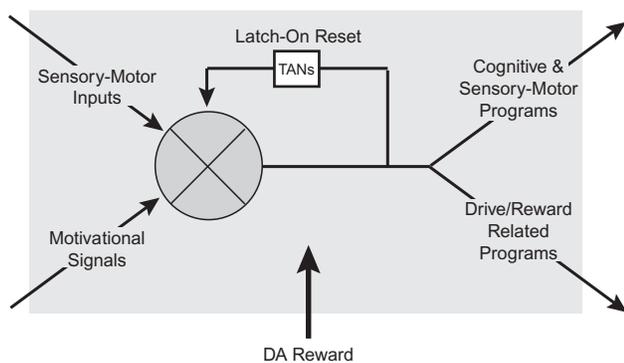

FIGURE 39.10 Diagram illustrating the hypothesis that the striatum acts as a dynamic modulator of cognitive and motor programs and that striatal interneurons, including TANs, function as part of the plastic neural mechanism underlying this dynamic modulation. (Adapted from Graybiel et al., 1994.)

may actually facilitate learning mediated by the other system. For example, a deficit in spatial learning strategy following hippocampal damage can improve performance of S-R learning (Packard et al., 1989; McDonald & White, 1993; Schroeder, Wingard, & Packard, 2002).

The electrophysiological recordings that are made as animals learn association tasks demonstrate remarkable plasticity in the responses of striatal neurons as the animals learn (Jog et al., 1999; Barnes et al., 2005; for reviews, see Graybiel, 2005, 2008; Pasupathy & Miller, 2005). If monkeys learn a task and then the task requirements are reversed, striatal neurons are quick to acquire the new (reversed) association (Pasupathy & Miller, 2005). In association maze-learning tasks, there are dramatic changes in the patterns of task-related activity of striatal neurons in the sensorimotor striatum (Jog et al., 1999; Barnes et al., 2005). These changes at the neuronal level have been likened to the explore-exploit behaviors that are delineated in reinforcement learning models (Sutton & Barto, 1998; Barnes et al., 2005). Remarkably, just such models have been invoked to account for the acquisition of song in avian species that learn their songs (Doya & Sejnowski, 1995). Interestingly, as the task-related neurons change their firing patterns, other neurons that do not exhibit phasic spike activity in relation to the task gradually become nearly silent.

In imaging studies of human performance, activation of the basal ganglia has been repeatedly found to accompany motor skill learning. Skill learning can be broken down into a number of phases but, as in learning a sport, requires practice, S-R (feedback) learning, and consolidation (Brashers-Krug, Shadmehr, & Bizzi, 1996; Karni et al., 1998; Hikosaka et al., 1999; Ungerleider, Doyon, & Karni, 2002; Saint-Cyr, 2003). Once learned, the sequence of movements can be carried out seemingly effortlessly with the same or similar effector groups used during practice. Many studies have employed the serial reaction time (SRT) task to study simple human motor skill learning (Grafton et al., 1995; Willingham, Salidis, & Gabrieli, 2002). For example, subjects can be asked to press a series of buttons in an order instructed by target lights that appear either in a random sequence or in a predetermined, repeated sequence. With practice, the subjects become faster, especially with the repeated sequences. If the subject is told about the sequence beforehand, the reaction time advantage for the repeating sequence is thought to occur by virtue of declarative learning, but to involve nondeclarative, implicit learning if the subject does not know about the repeating sequence (or is distracted by a second task). Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies have demonstrated heightened activation in the putamen, along with a network of cortical areas, in the implicit condition (Grafton et al., 1995;

Hazeltine, Grafton, & Ivry, 1997; Willingham et al., 2002), and in some explicit conditions as well (Willingham et al., 2002; Doyon et al., 2003; Doyon & Benali, 2005).

Learning and performing a sequence of finger movements by trial and error with auditory feedback evokes activation of the striatum also, both in learning of a new sequence and in the execution of a pre-learned sequence (Jenkins, Brooks, Nixon, Frackowiak, & Passingham, 1994). The acquisition phase favors more anterior activation (caudate nucleus, anterior putamen) by comparison with performance of a pre-learned sequence (Jueptner, Frith, Brooks, Frackowiak, & Passingham, 1997; Jueptner, Stephan, et al., 1997). Similar anterior-to-posterior shifts also occur in the frontal cortex during learning (Jueptner, Frith, et al., 1997). Attention to action may in part underlie the shift. When subjects attend to their next action in a pre-learned (automized) sequence, the caudate nucleus, but not the (more posterior) putamen, exhibits differentiated activation (Jueptner, Frith, et al., 1997). Quite similar anterior-posterior gradients have been found in primates (Miyachi, Hikosaka, Miyashita, Karadi, & Rand, 1997; Nakamura, Sakai, & Hikosaka, 1998, 1999; Hikosaka et al., 1999).

If we think back to the anatomy of cortico-basal ganglia loops, we can see that these and other studies (Shadmehr & Brashers-Krug, 1997; Honda et al., 1998; Jueptner & Weiller, 1998; Karni et al., 1998; Peterson et al., 1998) suggest that the acquisition of motor skills probably engages the activity of a number of corticostriatal loop systems, and that which loops are engaged changes during different stages of learning, from the first learning of the basic structure of the task (its "rules" or constraints) to an eventual engagement of particular muscle groups in sequence without conscious calling up of the single parts of the behavior. The early stages activate cortico-basal ganglia loops in which the caudate nucleus and anterior putamen participate, and later stages activate putamen-based loops. Interestingly, contrary to the activation of the putamen in motor skill learning, perceptual skill learning (e.g., a mirror reading task) is linked to activation of the caudate nucleus (Poldrack & Gabrieli, 2001). The cerebellum is also activated in such tasks. One interesting idea is that early phases of S-R sequential learning engage spatial coordinate frames and later phases motor coordinate frames (Hikosaka et al., 1999).

More cognitive versions of S-R learning tasks, requiring implicit learning by feedback of probabilistic classifications, also differentially activate the caudate nucleus (Saint-Cyr, Taylor, & Lang, 1988; Knowlton, Squire, & Gluck, 1994; Poldrack et al., 1999). The medial temporal lobe, by contrast, is activated when such tasks are acquired through observation (paired-association tasks) rather than through guessing and learning by trial and error (Poldrack & Gabrieli, 2001). Supporting the idea of antagonistic

activity of striatal and hippocampal systems raised by studies in experimental animals, imaging studies in human subjects demonstrate deactivation of the medial temporal lobe during acquisition of the feedback-based task. The activities of the caudate nucleus and of the medial temporal are negatively correlated (Poldrack & Gabrieli, 2001). Patients with Parkinson's disease and Huntington's disease perform more poorly in the feedback-based probabilistic classification task than do patients with localized frontal lobe lesions, suggesting that it is not only a dysfunction of the frontal part of the frontobasal ganglia loop, but, more likely, deficits in neuronal processing in the striatum itself that lead to learning deficits in Parkinson's disease patients (Knowlton, Mangels, & Squire, 1996).

Impairments in motor and perceptual skill learning have been demonstrated in patients with Huntington's disease and Parkinson's disease (Martone, Butters, Payne, Becker, & Sax, 1984; Heindel, Butters, & Salmon, 1988; M. A. Smith, Brandt, & Shadmehr, 2000). Patients with OCD have deficits in performing the implicit form of SRT tasks when a second task is introduced (Deckersbach et al., 2002), and they fail to exhibit activation of the striatum during the acquisition of SRT tasks (Rauch et al., 2001).

We have concentrated on the dorsal striatum (the caudate nucleus and putamen), but evidence suggests that the ventral striatum is also critical to reinforcement-based learning, together with its dopaminergic input from the ventral tegmental area. For example, neurons of the ventral striatum can apparently keep track of how close a monkey is to receiving reward (Bowman, Aigner, & Richmond, 1996; Shidara, Aigner, & Richmond, 1998; Rolls, 1999). Cues related to reward, and reward itself, can actuate these neurons (Ito, Dalley, Robbins, & Everitt, 2002; Phillips, Stuber, Heien, Wightman, & Carelli, 2003; Tanaka et al., 2004; Zald et al., 2004; Taha, Nicola, & Fields, 2007; Lansink et al., 2008). Lesions of the ventral striatum can block acquisition of approach maze task problems (Atallah, Lopez-Paniague, Rudy, & O'Reilly, 2007).

The striosomes of the dorsal striatum, by virtue of their connections with many of the same brain structures as the ventral striatum, are likely also to be important in the learning and execution of rewarded tasks (Aosaki, Kimura, & Graybiel, 1995; White & Hiroi, 1998). As the dorsal striatum and ventral striatum are believed to participate in different forms of learning (nondeclarative and declarative, respectively), it is possible that the reward evaluation function of the ventral striatum is taken over by striosomes in nondeclarative learning. As we noted above, activity in striosomes is correlated with maladaptive, perseverative responses following psychomotor stimulant exposure, raising the possibility that they could be involved also in stereotypic behaviors in OC-spectrum disorders.

Chunking of action repertoires as a common theme for basal ganglia function

We have considered here three categories of hypotheses about the functions of the basal ganglia, ranging from the selective facilitation and inhibition of movements (or thoughts), to the assignment of saliences and attention to stimuli, to behavioral learning, especially feedback-based learning. There are other behavioral categories that should also be considered, including sequencing of movements or cognitive acts, scaling or timing of these acts, and preparing for the next movement or thought. But regardless of the behavioral categorization, we still must remember that the basal ganglia are embedded in circuits that engage the thalamus and cerebral cortex and other sites as well. How can we learn what part of any function to attribute to the basal ganglia, and what part to other structures in these basal ganglia-based circuits?

One important recent finding from primate physiology is that identified corticostriatal neurons in the motor cortex have quite different response properties than even very nearby motor cortex neurons projecting to the spinal cord (Turner & DeLong, 2000). In trained monkeys, at least, the responses of the neurons seem tuned to very discrete contexts, and they are nearly all direction-selective. This finding suggests that the information reaching the striatum is not an exact copy (efference copy or corollary discharge) of the motor command sent to the spinal cord. But it could be, for example, that cortical inputs to the subthalamic nucleus (hyperdirect pathway) are; this is not yet known. There is also suggestive evidence that inputs from the motor cortex tend to activate striatal neurons of the indirect pathway more than those of the direct pathway (Berretta, Parthasarathy, & Graybiel, 1997; Parthasarathy & Graybiel, 1997; Lei, Jiao, Del Mar, & Reiner, 2004), and that the reverse is true for thalamostriatal inputs (Y. Smith, Bevan, Shink, & Bolam, 1998). Even these two examples indicate that our understanding of cortico-basal ganglia networks is still primitive.

Another approach to the circuit issue has been to record in the striatum as animals undergo training in behaviors that are thought to require striatal function—as was discussed above, procedural, S-R, habit or “win-stay” learning. For example, in the experiment illustrated in figure 39.11, rats were trained to run down a simple T-maze to obtain reward at one or the other of the end arms, and conditional auditory cues were given during the maze run to tell the animal which arm was baited (Jog et al., 1999). Each day during training, physiological recordings of the firing of ensembles of striatal neurons were made with tetrodes chronically implanted in the sensorimotor sector of the striatum. As shown in figure 39.11, there was a dramatic change in response patterns of striatal neurons during learning. Responses during the turn

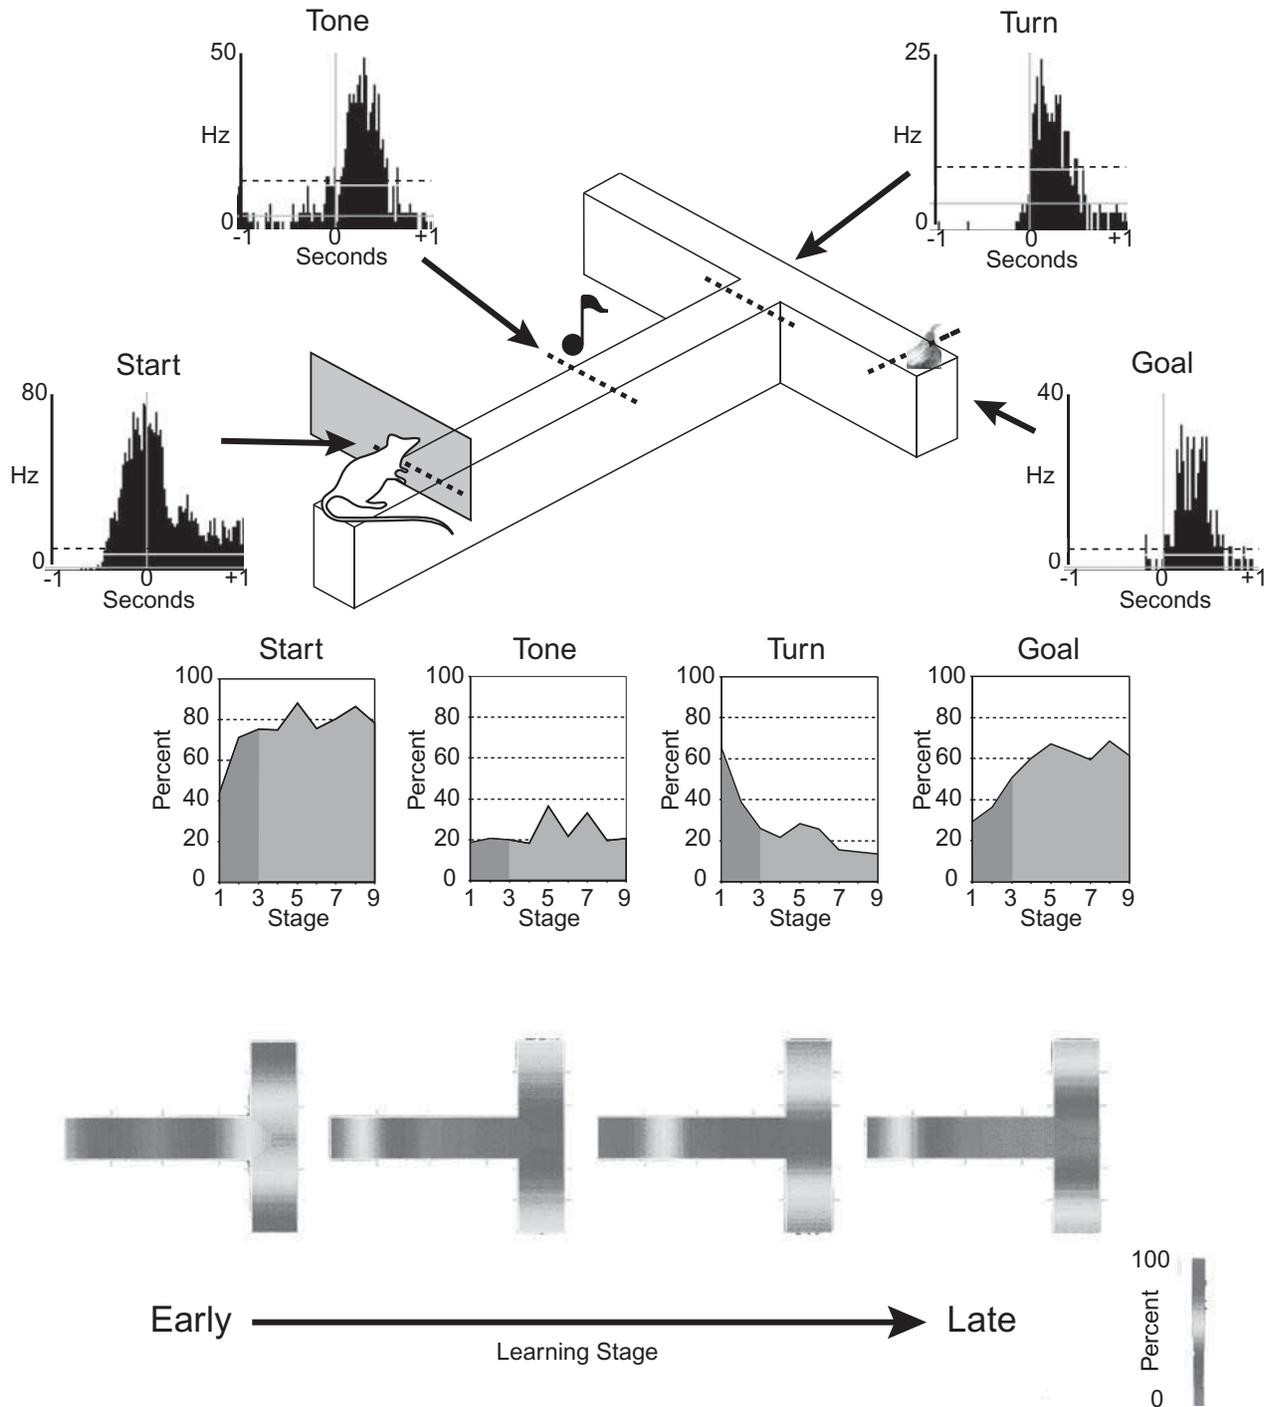

FIGURE 39.11 Event-related ensemble activity of neurons in the dorsolateral striatum of rats recorded during the acquisition and performance of an auditory conditional turning task in a T-maze. Perievent histograms displayed around the T-maze show examples of the activities of single striatal neurons in relation to start, tone, turn, and goal events. Plots below the maze illustrate the reorganiza-

tion of task-related activity patterns of the striatal neurons that occurs during the acquisition of the task. The behavioral criterion for acquisition was at stage 3. Color plots at bottom illustrate schematically the gradual changes in the response profiles of the striatal neurons during the course of behavioral learning. (Modified from Jog et al., 1999; Graybiel and Kubota, 2003.) (See color plate 52.)

part of the task declined, but responses at the start and end of the task increased. In this experiment, at least, what seemed to happen is that the task boundaries became emphasized by ensemble activity in the striatum, and in-between parts of the task became less prominently represented (Jog et al., 1999; Graybiel & Kubota, 2003). This start and end accentuation has been replicated (Barnes et al., 2005) and has now been found in corticostriatal loops in awake behaving primates, suggesting that the representation of action boundaries could be an important aspect of encoding for cortico-basal ganglia circuits (Fujii & Graybiel, 2003).

How could this work? One idea is that, through activity in cortico-basal ganglia loops, the representations of actions that are repeated over and over again get recoded: Representations related to entire sequences of actions making up a behavior are built so that each individual element of the behavior is no longer coded in detail in the loop in question. In this case, the basal ganglia could be viewed as structures that help to remap action representations into expressible units. By analogy to memory units, these have been called chunks (Graybiel, 1998). This could potentially be a common theme tying together the apparently different categories of behavior attributed to the basal ganglia and discussed here. For example, the release-inhibition function, seen in these terms, would suggest that for automated behaviors, the behaviors are releasable (or repressible) as a whole, not necessarily element by element. For the attention and assignment of salience, cortico-basal ganglia circuits, through repetition, could be remapped so that particular salient sensory cues or “contexts” could trigger entire responses. This is, in fact, one definition of habit (James, 1890). Similarly, response selection, through repetition and learning, could be automated by such a chunking process. Finally, in this view, learning functions would be seen as critical and core functions of cortico-basal ganglia networks and, in particular, of corticostriatal networks.

40 Computational Neuroanatomy of Voluntary Motor Control

REZA SHADMEHR AND JOHN W. KRAKAUER

ABSTRACT We review some of the impairments in motor control, motor learning, and higher-order motor control in patients with lesions of the cerebellum, parietal cortex, and basal ganglia. We attempt to explain some of these impairments in terms of computational ideas such as state estimation, optimization, prediction, cost, and reward. We suggest that a function of the cerebellum is system identification: to build internal models that predict sensory outcome of motor commands and correct motor commands through internal feedback. A function of the parietal cortex is state estimation: to integrate the predicted proprioceptive and visual outcomes with sensory feedback to form a belief about how the commands affected the states of the body and the environment. A function of basal ganglia is related to optimal control: learning costs and rewards associated with sensory states and estimating the “cost-to-go” during execution of a motor task.

Over the last 25 years, a large body of experimental and theoretical work has been directed toward understanding the computational basis of motor control, particularly visually guided reaching. Roboticians and engineers largely initiated this work, with the aim of deriving from first principles some of the strikingly stereotypical features of movements observed in people and other primates. That is, they aimed to understand why we move the way that we do. The theories began to explain why in reaching to pick up a cup or in moving the eyes to look at an object, there was such consistency in the detailed trajectory of the hand and the eyes. In many ways, the approach was reminiscent of physics and its earliest attempts to explain regularity in motion of celestial objects except that the regularity was in our movements, and the search was for theories that explained our behavior. Here, we will summarize these theories and then link them to experimental findings in healthy subjects and in patients with neurological disease.

JOHN W. KRAKAUER The Motor Performance Laboratory, Department of Neurology, Columbia University College of Physicians and Surgeons, New York, New York

The computational problem of motor control

In 1954, Fitts published a short paper in which he reported that there were regularities in people’s movements (Fitts, 1954). He asked volunteers to move a pen from one “goal region” to another as fast and accurately as they could. He found that the movement durations grew logarithmically as a function of the distance between the goals (figure 40.1). This relationship was modulated by two factors. One factor was the size of the goal region. As the goal region became smaller, movements slowed down. A second factor was the mass of the pen. People slowed their movements when they moved a heavier pen. To explain these results, consider that the target box was surrounded by two penalty regions, so it seems rational to aim for the center of the target box. What if the penalty region was only on one side? Now one should aim for a point farther away from the penalty region and not at the center of the target box (Trommershauser, Gepshtein, Maloney, Landy, & Banks, 2005). This is because movements have variability, and one will maximize reward (in terms of sum of hits and misses) if one takes into account this variability. This variability explains the speed of movements in Fitt’s experiment and the sensitivity to pen weight: Rapid movements are more variable than slow movements, so one should slow down if there is a need to be accurate. Moving heavier objects tends to increase movement variability, again requiring a reduced speed to maintain accuracy. Therefore in planning our movements, our brain takes into account movement variability because variability affects accuracy, which in turn affects our ability to acquire reward.

Harris and Wolpert (1998) began formalizing these ideas by linking variability and movement planning. They noted that larger motor commands required larger neural activity, which in turn produced larger variability owing to a noise process that grew with the mean of the signal. Therefore, motor commands carried an accuracy cost because the larger the command, the larger the standard deviation of the noise that rides on top of the force produced by the muscles (Jones, Hamilton, & Wolpert, 2002). Noise makes movements inaccurate.

In a sense, the theory restated the purpose of movements using language of mathematics: Be as fast as possible,

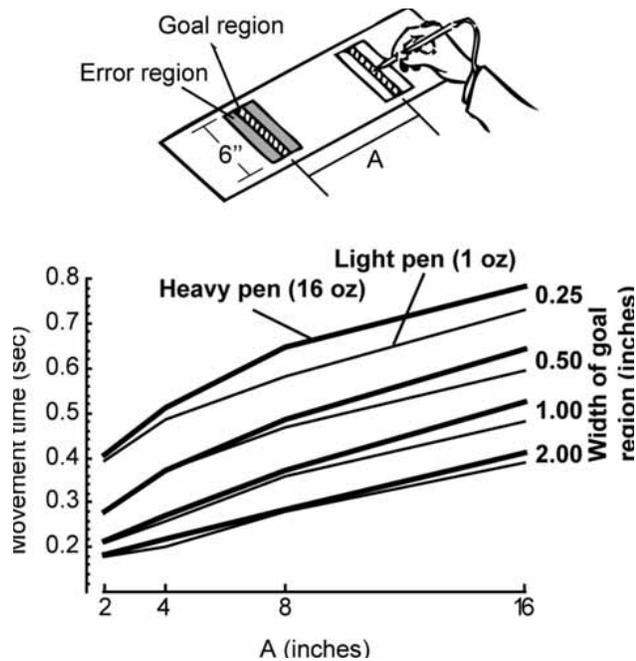

FIGURE 40.1 Accuracy constraints affect control of reaching. Volunteers were instructed to tap the two goal regions with a pen as many times as possible during a 15-s period. Movement time increased as the accuracy requirements increased (width of target region decreased) and as the weight of the hand-held pen increased. (Figure constructed from data in Fitts, 1954.)

while trying to be as accurate as the requirements imposed by the task. However, by doing so, it forced the theorists to think how one would actually achieve this optimality. Certainly, the solution to the problem could not be “hard wired.”

First, costs and rewards of tasks are not constant. Take the simple saccade task in which an animal is given more reward for certain visual targets and less for others. Hikosaka and colleagues (Takikawa, Kawagoe, Itoh, Nakahara, & Hikosaka, 2002) examined eye trajectories when a monkey was asked to make saccades to various target locations. They noted that peak speeds tended to be higher and less variable when saccades were to rewarded target locations. Therefore, when the expected rewards of the task change, movement planning responds to these changes.

Second, the brain alters movement planning as the dynamics of the body or a tool change (e.g., the light versus heavy pens in figure 40.1). That is, the nervous system cannot rely on a motor plant that is time-invariant. Rather, it seems more reasonable that the nervous system should monitor these changes and form an *internal model* of the plant and/or the tool (Shadmehr & Mussa-Ivaldi, 1994). Indeed, maintaining performance in something as simple as a saccade or a reach probably requires constant adjustment of this internal model (Smith, Ghazizadeh, & Shadmehr, 2006; Kording, Tenenbaum, & Shadmehr, 2007).

Todorov and Jordan (2002) recognized that a key component of the problem was presence of feedback. One type of feedback is from sensory receptors that monitor the state of the body and the world. Another type of feedback is from internal models that monitor the motor output and predict their sensory consequences, effectively providing a form of internal feedback. Internal predictions can be made long before sensory feedback, making some very rapid movements such as saccades depend entirely on internal feedback (Chen-Harris, Joiner, Ethier, Zee, & Shadmehr, 2008). However, for longer movements, the two kinds of information would need to be combined to form a belief about the state of the body. Todorov and Jordan (2002) suggested that a more appropriate mathematical approach was to first describe the constraints of the task in terms of a function that included explicit terms for gains and losses and then maximize that function in the framework of *feedback control*. This new formulation was a breakthrough because it formally linked motor costs, expected rewards, noise, sensory feedback, and internal models into a single, coherent mathematical framework (see chapter 42 for a thorough introduction).

We summarize this framework in figure 40.2A. At the heart of the approach is the idea that we make movements to achieve a rewarding state. The rewards we expect to get and the costs we expect to pay determine the trajectory we choose to execute and how we will respond to sensory feedback. To make the “best” movement, our brain needs to solve three kinds of problems: We need to be able to accurately predict the sensory consequences of our motor commands (this is called *system identification*), we need to combine these predictions with actual sensory feedback to form a belief about the state of our body and the world (called *state estimation*), and then given this belief about the state of our body and the world, we have to adjust the gains of the sensorimotor feedback loops so that our movements maximize some measure of performance (called *optimal control*).

Here, we will suggest a specific computational neuroanatomy of the motor system (figure 40.2B). In this framework, the basal ganglia help to form the expected costs of the motor commands and the expected rewards of the sensory states. The cerebellum plays the role of predicting the sensory consequences of motor commands, that is, the expected changes in proprioceptive and visual feedback. The parietal cortex combines the expected sensory feedback with the actual sensory feedback, computing a belief about the current proprioceptive and visual states. Given the motor costs and expected rewards of the sensory states, the premotor and the primary motor cortex assign “feedback gains” to the visual and proprioceptive states, respectively, resulting in sensorimotor maps that transform the internal belief about states into motor commands.

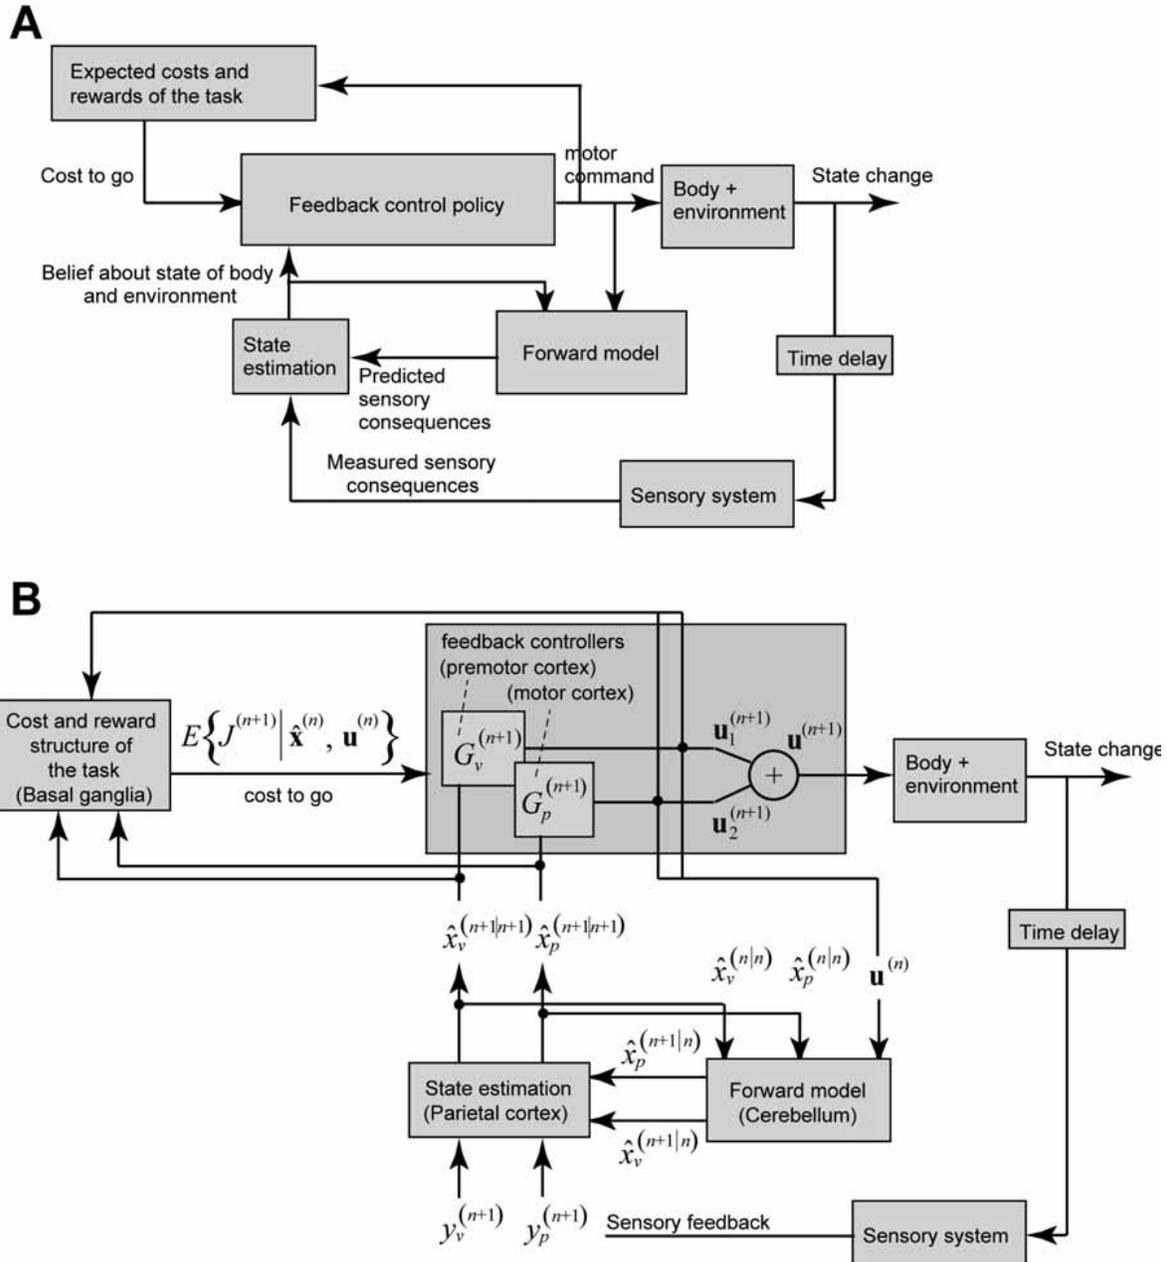

FIGURE 40.2 A schematic model for generating goal-directed movements. See the text for explanation of variables and box labels.

The computational problem in reaching

Let us use the well-studied reach adaptation paradigm to formulate the problem in the framework outlined in figure 40.2. What are the costs and rewards of a reaching task? Suppose that we are instructed to hold a tool and move it so that a cursor displayed on a monitor arrives at a target. If we accomplish this in a specific time period, we are provided a monetary reward, or juice, or perhaps a “target explosion.” We can sense the position of the cursor \mathbf{y}_v and the target \mathbf{r} via vision and position of our arm \mathbf{y}_p via proprioception. Through experience in the task, we learn that

the objective is to minimize the quantity $(\mathbf{y}_v^{(t)} - \mathbf{r})^T (\mathbf{y}_v^{(t)} - \mathbf{r})$ at time $t = N$ after the reach starts (e.g., this is the time that the movement is rewarded if the cursor is in the target). Superscript T is the transpose operator. To denote the fact that this cost is zero except for time N , we write it as

$$\sum_{t=1}^N (\mathbf{y}_v^{(t)} - \mathbf{r})^T Q^{(t)} (\mathbf{y}_v^{(t)} - \mathbf{r})$$

where the matrix Q is a measure of our cost at each time step (which may be zero except at time N). That is, matrix Q specifies how important it may be for us to put the cursor

in the target. If we value the reward, then we set this variable to be large.

There is also a cost associated with motor commands \mathbf{u} . This cost may reflect a desire to be as frugal as possible with our energy expenditure, or it may reflect the fact that the larger the motor commands, the larger the noise in the forces that are produced by the muscles, resulting in variability. This variability increases the difficulty in controlling the movement. As a result, we want to produce the smallest amount of motor commands possible. Now the total cost becomes

$$\mathcal{J} = \sum_{t=1}^N (\mathbf{y}_v^{(t)} - \mathbf{r})^T Q^{(t)} (\mathbf{y}_v^{(t)} - \mathbf{r}) + \mathbf{u}^{(t)T} L \mathbf{u}^{(t)} \quad (1)$$

where matrix L is a measure of the costs associated with the motor commands. The relative weight of Q and L is an internal measure of expected value of achieving the goal versus expected motor costs.

To be successful in this task (consistently arrive at the target in time), we need to find the motor commands that, on the one hand, are as small as possible and, on the other hand, are large enough to get the cursor to the target in time. To do so, we need some way to relate motor commands to their outcomes. This is called an internal model. For example, through observation, we learn that moving the tool moves the cursor on the screen. In particular, motor commands $\mathbf{u}^{(t)}$ are expected to produce proprioceptive and visual feedback $\hat{\mathbf{y}}^{(t)} = [\hat{\mathbf{y}}_v^{(t)}, \hat{\mathbf{y}}_p^{(t)}]$. These are the expected sensory consequences of our action. Here, we write this “internal model” as a linear function of motor commands:

$$\begin{aligned} \hat{\mathbf{x}}^{(t+1|t)} &= \hat{A} \hat{\mathbf{x}}^{(t|t)} + \hat{B} \mathbf{u}^{(t)} \\ \hat{\mathbf{y}}^{(t)} &= \hat{H} \hat{\mathbf{x}}^{(t)} \end{aligned} \quad (2)$$

where $\hat{\mathbf{x}}^{(t|t)}$ represents the predicted state (of our body and the world) at time t given the sensory feedback up until that time, H is a transformation of those states to expected sensory feedback $\hat{\mathbf{y}}^{(t)}$ (i.e., proprioception and vision), and $\hat{\mathbf{x}}^{(t+1|t)}$ is predicted state at time $t + 1$ given the state and motor command at time t . Equation 2 describes an internal model of the dynamical system that we are trying to control. The actual dynamics of that system may be more complicated. For example, the motor commands may carry signal-dependent noise $\hat{\mathbf{a}}_u^{(t)}$, that is, a noise in which the standard deviation grows with the size of the motor command. In general, there may be similar signal-dependent noises on our sensory system, $\hat{\mathbf{a}}_v^{(t)}$. In sum, a reasonable representation of the stochastic system that we are trying to control might be written as

$$\begin{aligned} \mathbf{x}^{(t+1)} &= A \mathbf{x}^{(t)} + B (\mathbf{u}^{(t)} + \hat{\mathbf{a}}_u^{(t)}) \\ \mathbf{y}^{(t)} &= H (\mathbf{x}^{(t)} + \hat{\mathbf{a}}_v^{(t)}) \end{aligned} \quad (3)$$

In Equation 1, we introduced a motor cost $\mathbf{u}^{(t)T} L \mathbf{u}^{(t)}$, i.e., the larger the motor commands, the larger the cost. Using

Equation 3, we can now give a rationale for this cost: the larger the motor commands, the larger the variance in the state of the system that we are trying to control. Therefore, motor costs implicitly attempt to reduce the variance of the movement.

As motor commands are generated, we receive a continuous stream of sensory feedback \mathbf{y} . We combine the predicted sensory feedback with the observed quantities to form a *belief* about states:

$$\hat{\mathbf{x}}^{(t+1|t+1)} = \hat{\mathbf{x}}^{(t+1|t)} + K^{(t+1)} (\mathbf{y}^{(t+1)} - \hat{\mathbf{y}}^{(t+1)}) \quad (4)$$

In this equation, the term $\hat{\mathbf{x}}^{(t+1|t+1)}$ is the belief state at time $t + 1$, given that we have acquired sensory information at that time. K is a mixing gain (or a Kalman gain) that determines how much we should change our belief on the basis of the difference between what we predicted and what we observed. Therefore, equation 2 describes how we make predictions about sensory feedback, and equation 4 describes how we combine the actual sensory observations with predictions to update beliefs about states.

Our task is to perform the movement in a way that maximizes our chances for reward. If equation 2 is an accurate model of how motor commands produce changes in the states, then we can use it as a set of constraints with which to minimize equation 1. Because there is noise in our system, the cost \mathcal{J} in equation 1 is a stochastic variable. At each time point during a movement, the best that we can do is minimize the expected value of this cost, given the state that we believe to be in and the motor commands that we have produced: $E\{\mathcal{J}^{(t)} | \hat{\mathbf{x}}^{(t-1)}, \mathbf{u}^{(t-1)}\}$. The term $E\{\mathcal{J}^{(t)}\}$ reflects the expected value of the cost-to-go, that is, the total cost remaining in the current trial. The result is a feedback control “gain”:

$$\begin{aligned} \mathbf{u}^{(t)} &= -G^{(t)} \hat{\mathbf{x}}^{(t|t-1)} \\ &= -G_p^{(t)} \hat{\mathbf{x}}_p^{(t|t-1)} - G_v^{(t)} \hat{\mathbf{x}}_v^{(t|t-1)} \end{aligned} \quad (5)$$

The new variable G is a matrix that changes with time during a movement. It tells us how at time t , we can transform beliefs in sensory states (in terms of proprioception and vision) into motor commands so that we maximize performance in the remaining task time. Therefore, in this framework, motor planning refers to the time-sequence of sensorimotor gains $G^{(t)}$.

Some examples

As an example, consider a simple task first described by Uno, Kawato, and Suzuki (1989) and shown in figure 40.3A. The objective is to reach from point T1 to T2. In one condition, the subject is holding a lightweight tool that moves freely in air. In a second condition, the tool is attached to a spring that pulls the hand to the right. Without the spring, people reach in a straight line. This is the path that minimizes the cost. However, once the spring is attached, the straight path incurs

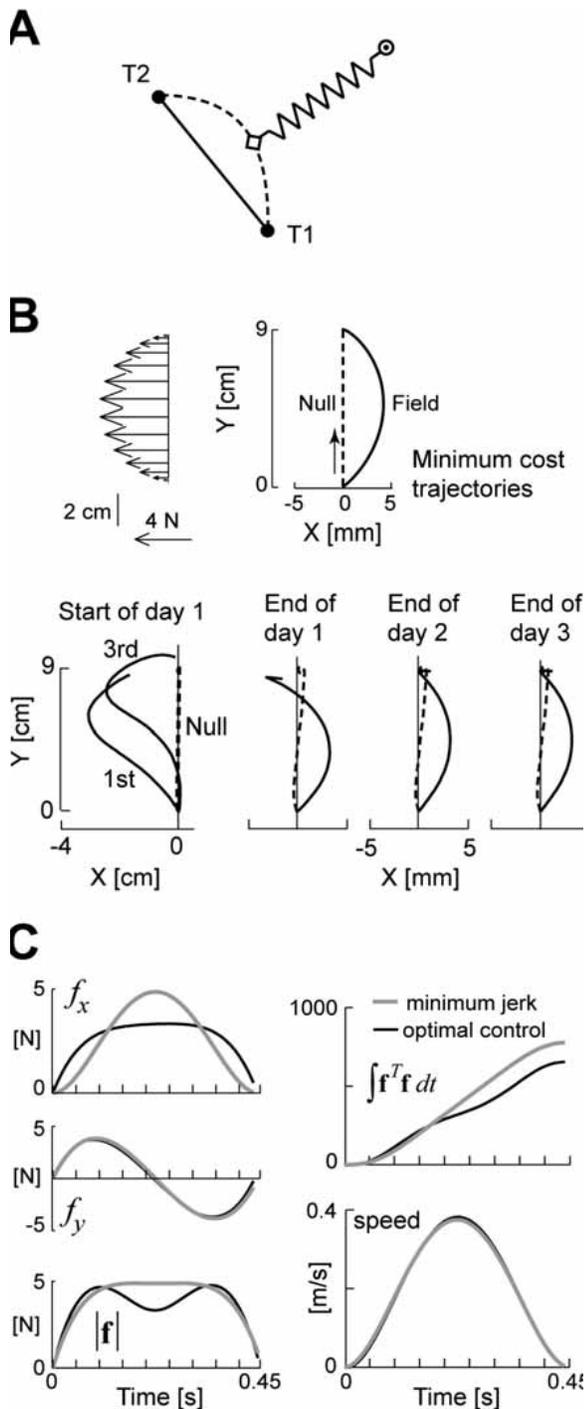

FIGURE 40.3 Task dynamics affect reach trajectories. (A) The task is to reach from point T1 to T2. In one condition, the reach takes place in free space (straight line). In another condition, a spring is attached to the hand. In this case, the subject chooses to move the hand along an arc. (B) A velocity-dependent force field pushes the hand perpendicular to its direction of motion. For example, for an upward movement, the forces push the hand to the left. The motion that minimizes cost of equation 1 is not a straight line but one that has a curvature to the right. The data show hand paths for a typical subject at start of training on day 1 and then at the end of training each day. Except for the first and third trials, all other trajectories are an average of 50 trials. (C) A rationale for why a curved movement is of lower cost. The curves show simulation results on forces that the controller produces and speed of movement in the optimal control scenario of equation 1 and in a scenario where the objective is to minimize jerk. (A is redrawn from Uno et al., 1989. Data in parts B and C are from Izawa et al., 2008.)

longer a straight line (Izawa, Rane, Donchin, & Shadmehr, 2008). For example, if the field pushes the hand to the left, the policy that produces the least cost in terms of equation 1 is one that moves the hand slightly to the right of a straight line, resulting in a curved movement that appears to overcompensate for the forces (figure 40.3B). As subjects train, their hand paths converge to this curved trajectory. To see the rationale for this behavior, figure 40.3C plots the forces produced by the optimal controller and compares it to forces that must be produced if a mass is moving along a “minimum-jerk” trajectory. By moving the hand along a curved path, the optimal controller produces less total force: It overcompensates early into the movement when the field is weak but undercompensates at peak speed when the field is strongest. Therefore, the curved path actually produces less total force than a straight trajectory does. People produce similarly curved trajectories when they move in such fields (Thorouhman & Shadmehr, 2000).

The cerebellum: Predicting sensory consequences of motor commands

According to the theory, we generate motor commands on the basis of beliefs about the state of our body and the environment (equation 5). This state estimate depends on two quantities: a prediction and an observation. The prediction comes from an internal model that uses a copy of the motor commands to estimate the state change that is expected to occur. The observation comes from the sensory system that provides a measure of those state changes. That is, our beliefs are not based on our observations alone. Rather, our beliefs are a combination of what we predicted and what we observed (Kording & Wolpert, 2004a; Vaziri, Diedrichsen, & Shadmehr, 2006).

Some movements are so fast that there is no time for the sensory system to play a role. A prominent example is

substantially more motor costs than a curved path. The curved path is the one that subjects choose (Uno et al., 1989).

In our second example, the task is to move one’s hand from one point to another in a given amount of time (450 ms), but now instead of a spring, there is a velocity-dependent field that pushes the hand perpendicular to its direction of motion. Before the field is imposed, the motion that minimizes the cost (and maximizes probability of reward) is simply a straight line with a bell-shaped velocity profile. However, when the field is imposed, the solution is no

control of saccades (rapid eye movements that move the eyes to a new location typically within 50–80 ms). Such movements are too brief for visual feedback to influence saccade trajectory. In fact, the brain actively suppresses visual processing during saccades to reduce the perception of motion (Thiele, Henning, Kubischik, & Hoffmann, 2002). Furthermore, proprioceptive signals from the eyes do not play any significant role in controlling saccade trajectories (Keller & Robinson, 1971; Guthrie, Porter & Sparks, 1983). Thus the brain must guide saccade trajectories in the absence of sensory feedback. How is this accomplished? A plausible solution is for the brain to use an internal estimate of the state of the eye, derived from a copy of ongoing motor commands (Robinson, 1975). This internal feedback probably accounts for the fact that variability at saccade initiation is partially corrected as the saccade progresses (Quaia, Pare, Wurtz, & Optican, 2000). That is, saccades are steered midflight via an internal feedback system (Chen-Harris et al., 2008).

What are the neural substrates of this internal feedback? The available evidence points to the cerebellum (Optican & Quaia, 2002; Optican, 2005). That is, the cerebellum appears to act as a forward model of the plant to produce midflight corrections. A simple experiment can test whether the cerebellum plays a role in predicting consequences of self-generated motor commands. Nowak, Timmann, and Hermsdorfer (2007) asked subjects to hold a force transducer that measures grip force, and then they attached a basket to the transducer. The experimenter dropped a ball into the basket. When the ball dropped, it exerted a downward force on the hand. The subject responded by squeezing the transducer so that it would not slip out of his or her hand. Because there are delays in sensing the impact of the ball, the grip response came about 100 ms after the ball's impact. Nowak and colleagues (2007) described patient HK, who did not have a cerebellum, owing to a very rare developmental condition. When the experimenter dropped the ball into the basket, both the healthy individuals and HK showed the delayed response. Therefore, the sensory feedback pathways appeared to be intact. In a subsequent trial, the subject (rather than the experimenter) dropped the ball. In a healthy individual, the brain can predict that the release of the ball will soon result in an impact that will increase the downward load. In anticipation of this event, the healthy individual squeezed the basket's handle harder around the time when the ball was released. HK, however, could not make this anticipatory adjustment. Rather, she responded to the perturbation in the same way that she responded when the ball was dropped by the experimenter. Therefore, the cerebellum appears to be required for the ability to predict the sensory consequences of motor commands (Wolpert, Miall, & Kawato, 1998).

The cerebellum and construction of internal models

It is not easy to make accurate predictions about the sensory consequences of motor commands; our muscles respond differently depending on their fatigue state, and our limbs move differently depending on whether we are holding a light or heavy object. To maintain accuracy of the predictions, our brain needs to learn from the sensory feedback and adapt its internal model. This adaptation can be simple, such as changing parameter values of a known structure (changing A , B , or H in equation 2), or complex, such as identifying the structure de novo (replacing the linear form of equation 2 with some nonlinear function). Adjusting the parameters of an existing model produces rapid adaptation, whereas learning a new structure is likely to require much practice. The cerebellum appears to be one of the crucial sites for both processes.

Cerebellar damage often prevents individuals from learning how to use novel tools. For example, when subjects are asked to move the handle of a robotic tool to manipulate cursor positions, they may not be able to learn to compensate for forces generated by the robot (Maschke, Gomez, Ebner, & Konczak, 2004; Smith & Shadmehr, 2005) or to compensate for the novel visual feedback through a mirror (Sanes, Dimitrov, & Hallett, 1990). If the cerebellum is the crucial site for learning internal models, then it probably makes its contribution to control of reaching via its outputs to the thalamus, which in turn projects to the cerebral cortex. In humans, it is possible to reversibly disrupt this pathway. Essential tremor patients are occasionally treated with deep-brain stimulators that artificially disrupt the ventrolateral thalamus, improving their tremor. However, these patients learn the reach task better when the stimulator is turned off (Chen, Hua, Smith, Lenz, & Shadmehr, 2006). In contrast, patients with damage to the basal ganglia showed little or no deficit in adaptation with either the robot task (Smith & Shadmehr, 2005) or the mirror task (Agostino, Sanes, & Hallett, 1996; Gabrieli, Stebbins, Singh, Willingham, & Goetz, 1997). Therefore it seems quite likely that the cerebellum is a key structure that allows us to learn tool use.

Experiments show that the cerebellar damage causes abnormalities in adaptation to both kinematic (Tseng, Diedrichsen, Krakauer, Shadmehr, & Bastian, 2007) and force (Smith & Shadmehr, 2005) perturbations. One unifying concept is that the cerebellum may be the site of the internal model that predicts the sensory consequences of motor commands (equation 2). The output of the internal model could be used to generate a prediction error that drives adaptation and also be used to update a previous estimate of limb state. Support for this idea comes from a recent experiment in which transcranial magnetic stimulation was used to disrupt the lateral cerebellum in human subjects while they slowly

moved their arm in preparation for making a rapid reaching movement (Miall, Christensen, Owen, & Stanley, 2007). Reaching errors in initial direction and final finger position suggested that the reaching movements had been made from an estimated hand position that was approximately 140 ms out of date, consistent with a role for the cerebellum in iteratively updating limb state.

Learning the rewarding nature of sensory states

You might expect that a severely amnesic individual who was performing a novel task would have to be regularly reminded of the task's instructions. For example, if it is a reaching task, we might have to repeat "try to move the cursor to the target fast enough so it explodes." However, when we examined the severely amnesic patient HM on the standard reach adaptation task with the robot (Shadmehr, Brandt, & Corkin, 1998), after he had exploded a few targets, he no longer needed verbal reminders. The visual appearance of the target was enough for him to initiate a reaching movement. Strikingly, when he returned a few hours later (or the next day), he voluntarily reached for the robot handle and began preparing for onset of targets by moving the cursor to the center location (naïve individuals avoid touching the machine). It was clear that despite having no conscious recollection of having done the task before, some part of HM's brain recognized that the contraption was a tool that had a particular purpose: to manipulate cursors on a screen. This behavior suggested that during the first session, he implicitly learned the reward basis of the task (equation 1). (For HM, the target explosion triggered a childhood memory of going bird hunting. As he was performing the task and was able to get a target explosion, he would spend the next few minutes describing the memory in detail: the type of gun that he used, the porch in the rear of his childhood home, the terrain of the woods in his backyard, and the kinds of birds that he hunted.) What brain regions were involved in learning the rewarding nature of bringing the cursor to the target?

Experiments on action selection in rodents provide important insights into this question. For example, suppose that a rat is released into a pool of water from some random starting point. A platform is positioned in a specific location just below the water line and cannot be seen. The platform is always at the same location in the pool. Rats dislike being wet and will try to find a way to elevate themselves. The normal rat can learn to locate the platform position by paying attention to the visual cues that surround the pool. This requires learning a spatial map of where the platform is located with respect to the surrounding visual cues. With repeated swims, the animal learns a spatial map. This spatial map is analogous to a reward function that associates places

in the pool with the likelihood of the platform (and therefore the likelihood of not having to be wet).

Once the map has been learned, the animal can find the platform regardless of where the rat is released into the water because the map is with respect to the cues on the walls. If the platform is removed, the normal animal will spend most of the time searching in the region where the platform should be. Sometimes, certain cues are rewarding no matter where they are located. Consider a pool where there are two hidden platforms: one that is large enough for the rat to mount and one that is too small. Both have a distinct visual cue associated with them: a little flag attached to each platform, each of a different color, sticking out of the water. Suppose that the flag attached to the large platform is red and the flag attached to the small platform is green. The platforms may be positioned in any part of the pool and will change from trial to trial. Therefore, in this experiment, the animal needs to learn that the red flag indicates the location of the suitable platform and is a rewarding object. In another version of the experiment, the large platform will always be located in a particular spatial location, but the flag on top of it will be a random color. In this version of the experiment, the animal needs to learn that it is not the color of the flag that is important, but the spatial location.

We see that there is a natural competition between the learning systems that might be involved in these two conditions: Is the platform in the same "place" as before (where place refers to a location in the spatial map), or is the platform always where the red flag is located? Packard and McGaugh (1992) performed both experiments by having their animals swim eight times per day for a number of days. They recorded the number of times the animals mounted the small platform and labeled these as errors. In the first experiment, in which reward was associated with the red flag, healthy animals gradually learned to swim to the red flag. Interestingly, animals with damage to the medial temporal lobe learned the task just as well as the healthy controls did. However, animals with damage to the caudate nucleus were much slower in learning the association. After days of training, they continued to attempt to mount the platform under the green flag. Therefore it appears that the ability to associate reward to stimuli regardless of its spatial location depends on the basal ganglia.

In the second experiment, in which reward was associated with a spatial location, healthy animals gradually learned to swim to that location and ignore the color of the flag. Animals with damage to the caudate nucleus performed similarly to the healthy controls. However, animals with damage to the medial temporal lobe were much slower in learning the association. Therefore the ability to associate reward to a spatial location depends on the medial temporal lobe.

Returning to our observations in HM, we would speculate that it was his basal ganglia that learned that if he were to place the cursor in the box on the screen and do so rapidly, a rewarding state would be experienced (explosions, which triggered a pleasant childhood memory). During the later sessions, the visual appearance of the machine and the act of holding its handle likely triggered a recall of this reward structure.

Effects of striatal damage on the assessment of movement costs and rewards

One of the striking features of damage to the human striatum is micrographia, an impairment of writing in which letters become very small and writing speed becomes slow. This condition is most common in degenerative diseases of the basal ganglia such as Parkinson's disease (Van Gemmert, Teulings, & Stelmach, 2001). However, it can also occur with focal lesions. Consider patient FF, an individual who suffered an ischemic stroke in the left basal ganglia, in the head of the caudate nucleus and the anterior part of the putamen (Barbarulo, Grossi, Merola, Conson, & Trojano, 2007). When FF was asked to copy a four- or eight-letter string of characters, writing with the right hand was much smaller than with the left hand. Micrographia reflects an abnormal choice of speed and amplitude and is one manifestation of generalized slowing of movement (bradykinesia).

In the optimal control framework, there are no desired trajectories for our movements. Rather, the path is a result of a control policy (equation 5), which itself is a result of minimization of a cost (equation 1). The cost depends on two quantities: spatial accuracy (error cost) and required effort (energy cost). Accuracy requirements influence speed selection, due to the signal-dependent noise property of motor commands. The desired accuracy of a movement sets an upper limit on the maximum speed of a movement. The accuracy term of the cost function offers an explanation for the wealth of experimental data demonstrating speed-accuracy tradeoff in reaching movements. Normal movements, however, do not appear to be made at the limits imposed by the speed-accuracy tradeoff: We can reach for an object faster than usual without appreciable loss of accuracy. Although very little experimental data exist on spontaneous speed selection, the effort term of the cost function offers a potential explanation for this phenomenon; that is, perhaps micrographia is an indication of an abnormally high motor cost.

One of us recently tested this idea that in Parkinson's disease, there may be an abnormally high cost associated with motor commands (Mazzoni, Hristova, & Krakauer, 2007). We required healthy control subjects to make accurate reaching movements of specified speeds. As the required

speed increased, subjects took longer (required more trials) to accumulate a set number of movements at the required speed. This reluctance to move faster could be explained by the increase in required energy as well as by the degradation of spatial accuracy and thus did not disambiguate the contribution of these two costs. We then compared the performance of patients with Parkinson's disease to that of control subjects in this task. Parkinson's disease patients demonstrated normal spatial accuracy in each condition but required more trials than controls to accumulate the required number of movements in each speed range. The patients' increased reluctance to execute movements requiring greater effort, in spite of preserved spatial accuracy, provided experimental demonstration of the contribution of energy cost to speed selection, independent of spatial accuracy. The implication is that bradykinesia results when striatal dysfunction changes the value of effort minimization (increased sensitivity to effort cost; L in equation 1) relative to that of accuracy optimization (error cost; Q in equation 1). Thus it appears that the basal ganglia either provides the motor motivation signal, which is then used to compute the cost-to-go elsewhere, or is where the cost-to-go is computed.

Parietal cortex damage and state estimation

Sometimes goal states change as the task is being performed. For example, when one reaches to pick up a pen, the pen may start rolling away. Healthy individuals have no problems adjusting their movements to compensate for this change. However, parietal patients show particular difficulties with this task. For example, if parietal damage impairs representation of visual states contralateral to the fixation, then motion of the goal state to this region during a movement impairs the ability to adjust the reach mid-flight. Grea and colleagues (2002) observed this phenomenon in a patient with bilateral posterior parietal cortex damage. The patient had no problems reaching to targets in central fixation. However, when the target shifted to the right at reach onset, the subject continued to reach to the original location of the target as if the target had not moved.

Disruption of the parietal cortex in healthy individuals can produce a similar phenomenon. Desmurget and colleagues (1999) provided a single pulse via a transcranial magnetic stimulator as the reach to the target began. On trials in which the target jumped, most of the participants had hand movements that disregarded the shift in the target location.

Let us examine these results in the framework of figure 40.2. The relevant state variables in this task include position of the limb (in proprioceptive and visual coordinates) and the position of the target (in visual coordinates). As motor commands are generated, the forward model should update its predicted state of the limb. Generally, we expect targets

to remain stationary, and therefore the output of the forward model should continue to predict the target position. Together, these predictions represent the prior belief about the state of the body and the world. The sensory feedback from proprioception and vision is integrated with this prediction to make a posterior belief. When the target jumps, the novel sensory information needs to be integrated with the output of the forward model. If it is not, the reach will continue to the prior expectation of its location. The results noted above suggest that either this integration step is affected by damage or stimulation of the parietal cortex or that the sensory information outside the central fixation region cannot reach the integration step.

Limitations in applying the theory to biological motor control

This review of motor control has been written within the framework of optimal feedback control. At the heart of the theory is the conjecture that animals make voluntary movements in order to acquire the most reward while expending the least effort. However, the theory cannot make a behavioral prediction unless we can specify three kinds of information: (1) what the costs and rewards are; (2) what the constraints are, that is, dynamics of the task; and (3) what the mechanisms of state estimation are. In this review, we have chosen a specific set of equations to represent each kind of information. However, it is not difficult to find examples of behavior that are inconsistent with our formulation.

The cost that we wrote in equation 1 is perhaps the simplest possible cost function for goal-directed movements. How seriously can we take this specific representation? As demonstrated by attempts to reverse-engineer the cost (Kording & Wolpert, 2004b), the quadratic cost function should not be taken too seriously.

Consider a set of experiments that highlighted the importance of costs associated with postural stability, a quantity that we did not include in equation 1. Scheidt and Ghez (2007) explored a task in which continuous random noise perturbed the hand at rest. This constraint encouraged increasing the cocontraction levels of muscles. However, the noise was present only during the postural phase of the task and disappeared when subjects made a reaching movement. They found that if a kinematic perturbation required adaptation of the movement, the learning did not generalize to the postural phase at the end of the movement. They suggested that the control processes that moved the limb appeared distinct from control processes that set muscle activity levels during posture. If so, do these processes have separate costs? A recent study suggests that the answer is yes, the weighting of postural cost is flexible and can be determined by task context (Liu & Todorov, 2007).

Finally, consider an experiment by Jax and Rosenbaum (2007) in which they asked subjects to make arm movements to an array of 12 targets positioned in a 16-cm radius circle on a vertical screen. Targets were presented randomly, and in some trials, an obstacle was presented halfway between the start and the target. The same target was never shown twice in a row. Interestingly, whenever a no-obstacle trial followed an obstacle trial, subjects made curved rather than straight trajectories. However, the movements straightened out when a no-obstacle trial followed another no-obstacle trial. Why make a suboptimal curved trajectory when you see that there is no obstacle?

These results highlight a number of important problems with our framework. First, without knowing precisely the costs and rewards of a movement, it will not be possible to make quantitatively reliable predictions of behavior. Without a priori predictions, how can the theory be falsified?

Second, what are the timescales of optimization? Is optimization computed in the reaction time of each trial *de novo*? The timescale appears to be longer than a single trial, as exemplified by the example from Jax and Rosenbaum (2007). Certainly, new costs can be conjured up. For example, in this case, we can assume that finding feedback control gains that minimize a cost requires neural processing that itself has a cost, so it might be more efficient to allow the solution in one trial to linger on to influence the solution in the next trial. Or perhaps there is a cost in switching control policies.

Third, what is the timescale of system identification? Our body changes over multiple timescales. Muscles fatigue and recover quickly, objects are lifted and replaced rapidly, yet aging can produce gradual loss of motor neurons and transformation of muscle fibers. In other words, the parameters of the constraint equation and perhaps its structure are changing over multiple timescales. Unfortunately, we cannot make optimized movements unless we have an accurate set of constraint equations, that is, an accurate internal model. When we see a suboptimum movement, can we dissociate the effects of an inaccurate internal model from effects of an inaccurate cost function?

Finally, what is the alternative hypothesis to this theory? At this time, the alternative is another cost or constraint, not a fundamentally distinct theory. However, formalization of a theory is the key step that accelerates its evolution toward acceptance or rejection.

Conclusions

The relationship between theories and the neural machinery that implements them is still in the courtship stage, but despite the separation, it has begun to bear modest fruit; theories have informed the neural basis of motor control in patients, while lesion studies have informed the algorithms

and representations that implement the computational theories. The result is the functional anatomy of voluntary movements outlined in figure 40.2B. In this framework, a role for the cerebellum is system identification, that is, predicting the changes in state that arise as a result of motor commands. A role for the parietal cortex is state estimation, in which predictions about sensory feedback are integrated with visual and proprioceptive observations to form beliefs about states of our selves and objects/people around us. The basal ganglia may play a role in computing a cost-to-go function, estimating value of states and costs of motor commands. Finally, once a goal state has been selected, motor cortical areas minimize this cost function and transform state estimates into motor output by formulating a feedback control policy.

41 Forward Models and State Estimation in Posterior Parietal Cortex

GRANT H. MULLIKEN AND RICHARD A. ANDERSEN

ABSTRACT During on-line control of movement, the posterior parietal cortex (PPC) serves as a functional bridge between sensory and motor areas in the brain. One of the sensorimotor functions of this area appears to be prediction of the state of the arm during movement. Because sensory information is substantially delayed, it has been proposed that the brain makes use of an internal forward model that integrates both sensory and motor feedback signals to estimate current and upcoming positions and motions of the limb during reaching. These predicted states are more useful for rapid on-line control than are delayed sensory signals. The first part of this chapter focuses on investigations of on-line control mechanisms in PPC. The results of these studies indicate that one of the functions of PPC is to serve as a forward model. The second section highlights research that aims to read-out forward state estimates from PPC neurons and harness them for direct control of neural prostheses.

A growing body of clinical and psychophysical evidence supports the theory that the brain makes use of an internal model during control of movement; a sensorimotor representation of the interaction of one's self with the physical world (Jordan, 1995; Kawato, Furukawa, & Suzuki, 1987). Two primary types of internal models for sensorimotor control have been proposed: the forward model and the inverse model. A forward model (i.e., forward output model) predicts the sensory consequences of a movement (Jordan & Rumelhart, 1992; Miall & Wolpert, 1996; Wolpert, Ghahramani, & Jordan, 1995). That is, it mimics the behavior of a motor system by predicting the expected, upcoming state of an end effector (e.g., sensory feedback of one's own limb) using knowledge of the characteristic dynamics of the system as well as stored copies of recently issued motor commands. Conversely, an inverse model encodes the motor commands necessary to produce a desired outcome (Atkeson, 1989). That is, an inverse model estimates the set of proce-

dures (e.g., motor commands) that will cause a particular state of the motor system to occur. While inverse models likely play an important role in sensorimotor control, they will not be discussed further in this chapter; instead, we will place emphasis on the forward model and, in particular, the role of the posterior parietal cortex (PPC) in forward state estimation for motor planning and control.

Movement intention and anticipation in PPC

PPC is a critical node for bridging sensory and motor representations in the brain. PPC associates multiple sensory modalities (e.g., visual—the dominant sensory input to PPC, somatosensory, and auditory) and transforms these inputs into a representation that is useful for guiding actions to objects in the external world (Andersen & Buneo, 2002). Evidence from lesions studies indicates that damage to PPC results in an inability to link the sensory requirements of a task with the appropriate motor behavior necessary to complete it. For example, parietal lesion patients can have difficulty planning skilled movements, a condition known as apraxia (Geshwind & Damasio, 1985). Impairments from apraxia can range from an inability to properly perform an instructed or desired arm movement to how to coordinate a specific sequence of movements to accomplish an end goal.

Numerous neurophysiological studies in monkeys have shed light on the neural correlates of reach planning in PPC. Monkeys have served as a successful model for studying sensorimotor representations in humans since the two species engage in a variety of similar sensorimotor behaviors. Moreover, functional magnetic resonance imaging (fMRI) studies have provided evidence that PPC's functional role is similar in both monkeys and humans (Connolly, Andersen, & Goodale, 2003; DeSouza et al., 2000; Pellijeff, Bonilha, Morgan, McKenzie, & Jackson, 2006; Rushworth, Paus, & Sipila, 2001). When trained monkeys plan a reach to an illuminated target, the firing rates of neurons in the medial bank of the intraparietal sulcus (MIP) generally reflect a combination of both sensory and motor parameters

GRANT H. MULLIKEN Computational and Neural Systems, California Institute of Technology, Pasadena, California
RICHARD A. ANDERSEN Computation and Neural Systems, Division of Biology, California Institute of Technology, Pasadena, California

(Andersen & Buneo, 2002; Mountcastle, Lynch, Georgopoulos, Sakata, & Acuna, 1975; Robinson, Goldberg, & Stanton, 1978). Importantly, during a memory period in which the monkey must maintain a reach plan to the remembered location of an extinguished target, elevated neural activity persists in PPC before the reach is executed, suggesting that these neurons likely encode the *intention* to reach rather than the visual stimulus location (Snyder, Batista, & Andersen, 1997). Furthermore, neural responses in MIP are generally correlated more strongly with the motor goal, and not the visual cue, during antireach paradigms in which the target cue direction is dissociated from the reach direction (Eskandar & Assad, 1999; Gail & Andersen, 2006; Kalaska & Crammond, 1995).

PPC is a reasonable location for a forward model of the arm to reside (which would predict the sensory consequences of an upcoming arm movement command) given its substantial reciprocal connections with downstream motor areas (Johnson, Ferraina, Bianchi, & Caminiti, 1996; Jones & Powell, 1970). Along these lines, many researchers have suggested that the “early” discharge of neurons in area 5 prior to initiation of an arm movement might reflect the integration of an efference copy signal fed back to PPC from frontal motor areas (Kalaska, Caminiti, & Georgopoulos, 1983; Seal, Gross, & Bioulac, 1982). Interestingly, Seal and colleagues also showed that area 5 responses that occurred prior to movement onset were generally not sensory in origin and further demonstrated that these early responses persisted even after deafferentation. However, some caution should be advised in attempting to infer the causal flow of information in parietofrontal circuits during reach preparation using single-area correlation analyses. For instance, it is possible that planning and forward model prediction (which relies on efference copy) may be carried out by distinct neural processes within PPC. Future simultaneous multiarea recordings, combined with microstimulation approaches, may help to shed light on the directional flow of information in these recurrent interarea circuits during movement preparation.

A FORWARD MODEL FOR EYE POSITION PPC is also a possible candidate for a forward model of eye position, since a variety of eye behavior–related signals, such as saccade and fixation responses, have been described in this region (Mountcastle et al., 1975). Area 7a saccade responses begin largely after a saccade occurs, while lateral intraparietal (LIP) saccade responses can occur before, during, or after saccades (Andersen, Essick, & Siegel, 1987). Interestingly, Duhamel, Colby, and Goldberg (1992) showed that the receptive fields (RFs) of neurons in LIP can update their receptive fields before an eye movement occurs. Forty-four percent (16 out of 36) of their LIP sample anticipated the sensory outcome of an impending saccade (i.e., a stimulus

appearing in the future location of the RF), and adjusted their responses approximately 80 ms before the saccade was launched. It is conceivable that this predictive updating relies upon a forward model of eye position within PPC, which estimates the upcoming eye position from oculomotor commands, though direct evidence of the anticipatory eye position signal itself in PPC has not been reported. An eye position signal in PPC could potentially be derived from passive sensory feedback from the eye muscles (Wang, Zhang, Cohen, & Goldberg, 2007) and/or the integration of saccade command signals. It would be interesting to see whether a component of the eye position signal in PPC might also encode anticipatory information (ahead of passive sensory feedback) about the current state of the eye position during fixations between saccades. Evidence of updating RFs has also been reported in other brain areas; therefore it is quite possible that multiple regions are involved in encoding a forward model of the state of the eye. For instance, Sommer and Wurtz (2006) discovered a feedback circuit in which the superior colliculus conveys a copy of the oculomotor command (i.e., corollary discharge) to the frontal eye field (FEF), which they showed to be necessary for accurate updating of RFs in the FEF. Last, response field updating neurons in PRR, which predominantly encode an intended reach direction in eye-centered coordinates, update their response fields when an intervening saccade occurs and thereby maintaining an eye-centered motor plan even when gaze is shifted (Batista, Buneo, Snyder, & Anderson, 1999; Buneo, Jarvis, Batista, & Andersen, 2002). It would be interesting to test whether the reach response fields of these PRR neurons also exhibit anticipatory updating just before the eye moves, similar to the cells found in LIP by Duhamel and colleagues (1992).

REAFFERENCE CANCELLATION IN PPC A forward model’s ability to predict the sensory consequences of an action is useful to an organism because a given sensory outcome can be produced by a variety of potential causes (Claxton, 1975; Cullen, 2004; Poulet & Hedwig, 2003; Roy & Cullen, 2004; Sperry, 1950; Weiskrantz, Elliott, & Darlington, 1971). In particular, the output of a forward model can be used as an internal reference signal to cancel the sensory effects of self-motion. For example, motion on our retina can occur because of movement in the physical world (afference) or because of motion induced by an eye movement itself (reafference). Therefore to correctly perceive the motion of an external stimulus, the brain must distinguish afferent motion from reafferent motion. A subtractive comparison between a forward model’s estimate of the expected sensory outcome of an eye movement and the actual sensory signals could remove this retinal shift from our perception. For example, such an internal reference signal is used for perceptual stability during smooth-pursuit eye movements

(Bradley, Maxwell, Andersen, Banks, & Shenoy, 1996; Haarmeier, Bunjes, Lindner, Berret, & Thier, 2001). Interestingly, clinical evidence presented by Haarmeier, Thier, Repnow, and Peterson (1997) suggested that parieto-occipital regions may be involved in performing the comparison between self-induced and external sensory motion during smooth-pursuit eye movements.

Reafference generation and comparison mechanisms are also likely employed for the perception of arm movements, for example, to distinguish self-generated arm movement from movement in the environment (e.g., the movement of others) and/or the movement of one's arm by an external force. Positron emission tomography (PET) imaging studies have provided evidence supporting PPC's role in reconciling intentions with sensory consequences. For instance, Fink and colleagues (1999) displayed nonveridical visual feedback of a subject's left hand by displaying a mirror image of a subject's right hand while they performed a bimanual coordination task. Such incongruent visual feedback resulted in an increase in bilateral PPC activation (area 40 and area 7) as well as bilateral dorsal prefrontal cortex activation. Later, Farrer and colleagues (2003) performed an experiment in which they systematically manipulated the degree of control with which subjects were able to perform a joystick task by perturbing visual feedback of their hand movements, rotating the direction of the virtual hand movement by a variable amount (i.e., 25°, 50°, and a condition with no correspondence). They found a graded activation in the inferior parietal lobule, such that regional cerebral brain flow increased with decreasing levels of control felt by the subject.

Lesion studies have shown that damage to PPC can lead to deficits in the attribution of agency. For example, Sirigu, Daprati, Pradat-Diehl, Franck, and Jeannerod (1999) showed that apraxia patients with left parietal lesions have a greater tendency to confuse their own movements with the movements of an experimenter. When patients' visual feedback was substituted with the hand movements of an experimenter (who attempted to perform the same movement), patients were more likely to confuse their right hand with the "alien" hand (19% correct ownership judgment), relative to normal control subjects (79% correct). Since the patient's intention and the outcome of the experimenter's movement were largely congruent, patients needed to detect subtle spatiotemporal discrepancies between the time-varying state of the expected state of their hand and the virtual hand on the computer screen. The authors suggested that these deficits were caused by damage to an internal model, which maintains a time-varying representation of a movement in space. In a related study, MacDonald and colleagues tested whether transient disruption of PPC using transcranial magnetic stimulation (TMS) could affect subjects' ability to determine the agency of an observed movement (MacDonald & Paus, 2003). Specifically, they introduced a lag time into the

display of the visual feedback of the subject's hand on the computer screen and asked subjects to detect trials in which they perceived a delay between the onset of their own hand movement and the onset of the virtual movement on the screen. Interestingly, the researchers found that during self-generated movement, TMS impaired subjects' ability to detect asynchrony between the onset of actual and virtual hand movements. In contrast, when subjects' hands were passively moved without prior notice to the subject, their judgments were not significantly impaired from pre-TMS control conditions. These results suggest that PPC maintains a time-dependent representation of action that relies upon anticipatory mechanisms (and not only sensory feedback), such as a forward model, to update the state of the arm. This internal state representation is important for making decisions about both the temporal state and the attribution of agency of a movement.

Forward state estimation for on-line control

During execution of a goal-directed arm movement to continuously guide the arm to a target, the brain must maintain an estimate of the time-varying state of the arm (e.g., position and velocity of the arm, coded in a variety of potential coordinate frames) and compare that state measurement with the desired state of the movement. Unfortunately, the human brain, in particular PPC, does not have direct access to the true state of the arm owing to delayed and noise-corrupted measurements of the state from the visual and proprioceptive domains; for example, visual signals typically reach sensorimotor association areas of cortex after a delay of approximately 90 ms (Raiguel, Xiao, Marcar, & Orban, 1999), or 30 ms in the case of proprioception (Petersen, Christensen, Morita, Sinkjaer, & Nielsen, 1998). Subsequent processing delays are incurred during control, owing to sensorimotor integration, motor command generation, and execution, resulting in an average loop delay of more than 100 ms for proprioceptive control (Flanders & Cordo, 1989) and over 200 ms for visuomotor control (Georgopoulos, Kalaska, & Massey, 1981; Miall, Weir, Wolpert, & Stein, 1993). These long delay times severely limit a feedback control system's ability to make rapid adjustments to an ongoing movement and thus increase the likelihood that a reach trajectory might become erroneous and/or unstable.

THE OBSERVER FRAMEWORK Fortunately, the brain can also monitor recently issued motor commands (i.e., efference copy), which can be transmitted centrally (e.g., from frontal motor areas) with little delay time (e.g., one synapse + transmission time < 10 ms) and used by a forward model to form an estimate of the current or upcoming state of the arm well in advance of late-arriving sensory information.

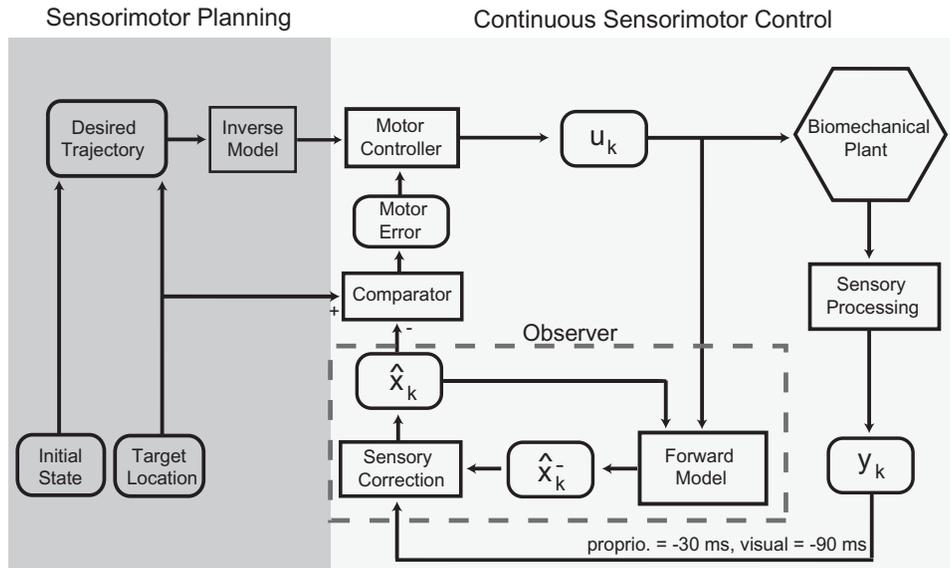

FIGURE 41.1 Flow diagram illustrating sensorimotor integration for reach planning and on-line control. Items in rounded boxes denote pertinent sensorimotor variables; computational processes are contained in rectangular boxes. Prior to a reach, an intended trajectory is formulated as a function of both the initial state of the arm and the desired endpoint, the target location. An inverse model is used to determine a set of motor plans that will result in the desired trajectory. Motor plans are then issued (e.g., by primary motor cortex, M1) and subsequently executed by muscles acting upon the physical environment (i.e., biomechanical plant hexagon).

Since the output of the forward model reflects a best guess of the next state of the arm, errors due to various sources of noise will inevitably accumulate over time for this estimate. Therefore it is likely that sensory observations, which arrive at later times, are also continually integrated by the brain to update and refine the estimate of the forward model (Miall & Wolpert, 1996) (figure 41.1). A system that estimates the state of a movement by combining the output of a forward model with sensory feedback about the state is generally referred to as an observer (Goodwin & Sin, 1984). For linear systems in which the noise is additive and Gaussian, the optimal (i.e., in the mean squared error sense) observer is known as a Kalman filter (Kalman, 1960). Wolpert and colleagues first applied the Kalman filter to model how subjects estimate the sensorimotor state of the hand during goal-directed reaches. They showed that a Kalman filter could accurately account for subjects' estimates of the perceived end location of their hand while making arm movements in the dark (Wolpert et al., 1995). Therefore the Kalman filter can serve as a useful theoretical model for studying sensorimotor state estimation in the brain.

Two linear stochastic equations govern the basic operation of the Kalman filter:

$$x_k = A_k x_{k-1} + B u_{k-1} + w_{k-1} \quad (\text{forward model}) \quad (1)$$

Following movement onset, the state of the arm is continuously monitored and corrected, if necessary, to ensure successful completion of the reach. Critical to rapid on-line correction of movement is the forward model, which generates an anticipatory, a priori estimate of the next state of the arm, \hat{x}_k , as a function of the previous state and efference copy. Intermittent sensory feedback is used to refine the a priori estimate of the forward dynamics model (observer). The a posteriori current state estimate, \hat{x}_k , can then be evaluated to make corrections to subsequent motor commands. (After Desmurget & Grafton, 2000.)

$$y_k = H_k x_k + v_k \quad (\text{state observation model}) \quad (2)$$

where x_k is the time-varying state of the arm at time step k and is modeled as a linear function of the previous state, x_{k-1} , and the control term, u_{k-1} . The control term is considered to be a known motor command, which is likely specified by frontal motor areas (e.g., primary motor or premotor cortex) and then fed back to sensorimotor circuits performing state estimation. For instance, the motor command at each time step might be determined by using an optimization procedure that minimizes a cost function associated with carrying out a particular trajectory (Todorov, 2006). Here, y_k is a sensory measurement (visual and proprioceptive) made at time step k . (Note that sensory feedback is in fact a delayed representation of the state of the arm.)

To estimate the state of the arm at each time step k , the output of the forward model, \hat{x}_k^- (i.e., the a priori estimate), is linearly combined with the difference between the output of the observation model (i.e., the predicted sensory measurement) and the actual sensory measurement. This discrepancy, the "sensory innovation," is then optimally scaled by the Kalman gain, K_k , to produce an a posteriori estimate of the state of the arm:

$$\hat{x}_k = \hat{x}_k^- + K_k (y_k - H_k \hat{x}_k^-) \quad (3)$$

In brief, discrete state estimation consists of a two-step recursive procedure such that the forward model generates an a priori estimate of the state, which is next refined by potentially innovative information gleaned from the sensory input to form the final, a posteriori estimate. PPC, specifically the parietal reach region (PRR) and area 5, seems to be a reasonable site for an observer for on-line control to reside, since it has access to two key inputs to the observer model: a large number of internal feedback connections from frontal areas (i.e., efference copy) and substantial sensory input from both visual and somatosensory domains (Johnson et al., 1996; Jones & Powell, 1970).

Continuous sensorimotor control and state estimation in PPC

Clinical and psychophysical studies in humans have established that PPC is involved not only in specifying movement plans, but also in the execution and control of ongoing movement. For example, it is well known that lesions in parietal cortex often lead to optic ataxia, that is, impairment in locating and reaching to stimuli in three-dimensional space (Balint, 1909; Perenin & Vighetto, 1988; Rondot, Recondo, & Ribadeaudumas, 1977). For instance, optic ataxia patients have difficulty making rapid and “automatic” corrective movements when guiding the hand to targets that have been jumped (Pisella et al., 2000). Similarly, Grea and colleagues (2002) reported a patient with bilateral parietal lesions who was unable to amend her movement to pick up a cylinder after it had been jumped to a new location at movement onset. Interestingly, instead of making corrective movements during an initial trajectory, the subject needed to perform two distinct movements: one that represented the initial plan and a second movement to reach to the new location of the cylinder. Using TMS applied to the posterior parietal cortex, Desmurget and colleagues (1999) were able to transiently disrupt the ability of most of their subjects to correct reaching trajectories made to targets that were displaced around the time of movement onset. Later, Della-Maggiore, Malfait, Ostry, and Pans (2004) showed that TMS applied to PPC interfered with the ability of subjects to adapt to novel force-field environments. An intriguing, potentially unifying explanation for all of these deficits, which was originally suggested by Wolpert, Goodbody, and Husain (1998), is that PPC may serve as an observer, which forms an internal estimate of the state of the arm during movement. A failure to accurately maintain this estimate on-line could result in an inability to monitor and therefore correct an ongoing movement. For example, Wolpert, Goodbody, and Husain reported a parietal lesion patient who was unable to maintain an internal estimate of the state of her hand. She could not maintain a constant precision grip force in absence of vision; with no vision of her station-

ary arm, she perceived it to drift slowly in space over 10–20 seconds until eventually reporting it to disappear. When she was asked to make slow-pointing movements to peripheral targets while maintaining central fixation, large errors accumulated in her trajectories (although self-paced movements were not impaired).

MENTAL SIMULATION OF MOVEMENT Evidence that PPC is involved in sensorimotor state estimation also comes from the study of the mental simulation of movement, which presumably activates circuits that overlap with those engaged during motor control but inhibits execution of a movement itself (Decety, 1996; Gerardin et al., 2000; Stephan et al., 1995). When normal healthy subjects imagine making a goal-directed movement, mental simulation time typically matches the time needed to execute that same movement (Decety & Michel, 1989; Donders, 1969). This suggests that the brain is able to maintain a realistic estimate of the state of the hand over time while imagining a movement, despite sensory feedback being unavailable. Shadmehr and Krakauer (2008) interpreted this finding in the context of observer theory, suggesting that this capability indicates that the brain/observer is able to rely entirely upon the output of a forward model (in the absence of sensory feedback) to estimate the state of the arm during mental simulation (e.g., Kalman gain in equation 3 is set to zero). Interestingly, patients with unilateral motor cortex lesions (Sirigu et al., 1995) who show prolonged movement times compared to normal control subjects are still able to accurately imagine the duration of their movements (i.e., the simulation time and execution time remain well matched for these patients). Therefore, aberrant motor commands (u in equation 1) that are produced by the motor cortex could theoretically still be used by an intact observer to predict the correct temporal sequence of hand states (and therefore the trajectory duration), even for an impaired movement. Similarly, patients with lesions of the cerebellum (Kagerer, Bracha, Wunderlich, Stelmach, & Bloedel, 1998) and of the basal ganglia (Dominey, Decety, Broussolle, Chazot, & Jeannerod, 1995) also do not show a difference between simulation and execution times.

While M1, the cerebellum, and the basal ganglia do not appear to be critically involved in state estimation during simulated movements, PPC, by contrast, does appear to be essential for maintaining an internal representation of the state of the hand, which is necessary for producing a consistent relationship between simulation and execution time. Sirigu and colleagues (1996) later reported an impairment in the ability to simulate a movement in patients with right PPC lesions: the time needed to mentally simulate a movement was significantly different (generally less) than the time needed to execute the same movement. (Note that, similar to motor cortex lesion patients, actual execution time was

prolonged in comparison to control subjects.) This inconsistency suggests that the brain was unable to reliably estimate the state of the hand after damage to PPC. This impairment could be explained by multiple possible failures of the observer model: (1) an error in the forward model (i.e., faulty A or B matrices in equation 1), (2) an error when incorporating sensory feedback into the a priori estimate of the forward model (i.e., faulty H or K matrices in equation 3) or (3) a combination of these. On the basis of known strong sensory input to PPC, it is probable that PPC is involved in integrating sensory feedback into the state estimate. However, because visual and proprioceptive inputs were effectively removed during the above mental simulation tasks (e.g., eyes were closed, muscle activity was absent), it is less likely that erroneous state estimation was due exclusively to faulty integration of sensory feedback. Also, most parietal lesion patients significantly underestimated the time it would take to complete a movement when simulating it. Such a systematic decrease in imagined movement duration may have arisen due to an erroneous a priori estimate made by a forward model, whose transition matrices A and B govern the rate at which the arm propagates through space. Therefore these mental simulation results suggest that PPC is also involved in propagating the state of the arm forward in time using a forward model (equation 1). If we assume that PPC incorporates sensory information into the forward model state estimate as well, then PPC would be best described as an observer, as Wolpert and colleagues suggested.

Neural correlates of sensorimotor state estimation in PPC

Psychophysical and clinical reports have pointed to both the parietal lobe and the cerebellum as candidate neural substrates for a forward model (Blakemore & Sirigu, 2003; Miall et al., 1993; Wolpert, Goodbody, & Husain, 1998; Wolpert, Miall, & Kawato, 1998). For example, Desmurget and colleagues suggested that PPC encodes a forward model of the arm's dynamics, from which it may also compute an estimate of the motor error (i.e., the difference between the target vector and the movement vector), which could then be transformed into a corrective motor command by the cerebellum (Desmurget & Grafton, 2000). While numerous studies have shown that PPC and the cerebellum are likely to be involved in forward model control, finding direct neural correlates of forward model state estimation in the brain has proven difficult.

ON-LINE DIRECTIONAL CONTROL SIGNALS IN PPC Previous encoding studies have shown that area 5 neurons are correlated with a variety of movement- and task-related parameters (most notably velocity and target position)

during reaching movements made with a manipulandum (Ashe & Georgopoulos, 1994; Averbach, Chafee, Crowe, & Georgopoulos, 2005). These studies concluded that area 5 largely encodes a sensory (i.e., proprioceptive) representation that slightly lags the state of the movement (i.e., lag time = -30 ms). More recently, we further investigated the neural representation of on-line directional control signals in both area 5 and MIP while monkeys performed center-out and obstacle avoidance joystick trajectories under central eye fixation (Mulliken, Musallam, & Andersen, 2008a) (figures 41.2A and 41.2B). We analyzed the correlations of single neurons recorded in both area 5 and PRR with the static goal angle (fixed angle from the starting cursor position to the target) and the dynamic movement angle of the cursor (angle of heading) during a joystick task.

To characterize a neuron's dynamic tuning for movement angle, we constructed a space-time tuning function (STTF). Each horizontal slice in the STTF plots a neuron's instantaneous firing rate as a function of the angle measured at a particular lag time (Paninski, Fellows, Hatsopoulos, & Donoghue, 2004). For each lag time in the STTF, we also calculated the mutual information between firing rate and movement angle. The resultant temporal encoding function (TEF) indicated how strongly a neuron's instantaneous firing rate encoded the movement angle at different lag times (i.e., from past (lag time < 0) to future (lag time > 0) angles). The lag time corresponding to the peak of the TEF was considered to be the optimal lag time (OLT). Figure 41.2C shows a representative movement angle STTF for a single neuron. This neuron encoded the most information about the movement angle at an OLT of 0 ms and therefore best encoded the current state of the movement angle (figure 41.2D).

For our PPC population, during the center-out task, 56% of task-related neurons encoded significant information about the movement angle, and 75% of these significantly encoded the goal angle (note that PPC neurons appeared to be more engaged during the obstacle task: 79% encoded movement angle, and 93% encoded goal angle). Interestingly, we found an anatomical correlate for the representation of goal angle and movement angle in PPC: Mutual information for goal angle increased gradually with recording depth in the sulcus, while movement angle information (peak information measured at OLT) decreased with depth. A stronger encoding of target-related signals deeper in the intraparietal sulcus (IPS) and, conversely, a favored representation of hand movement-related activity in surface regions of the IPS are consistent with findings from previous PPC studies of reach planning, in which eye-centered target signals were commonly found in deeper structures such as PRR and more hand-related activity was reported for surface area 5 neurons (Buneo et al., 2002).

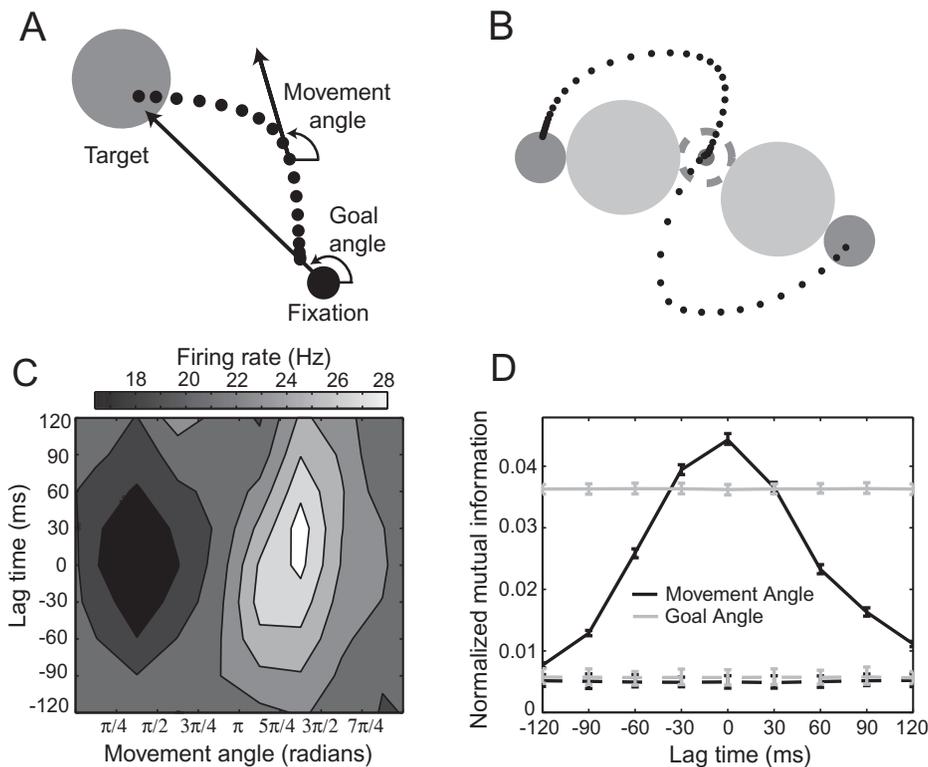

FIGURE 41.2 Experimental design and representative neuron. (A) Example center-out trajectory showing the goal angle and movement angle, and their respective origins of reference. Large and medium-sized circles represent the target and fixation point, respectively. Dots denote cursor position sampled at 15-ms intervals along the trajectory. (B) Example trajectories for obstacle task. The dashed circle depicts the starting location of the target and is not visible once the target has been jumped to the periphery. The large gray circles represent the visual obstacle. (C) Movement angle space-time tuning function (STTF). The contour plot shows the average firing rate of a cell that occurred for different movement

Neurons that are significantly tuned for goal angle persistently encode the static direction to the target, independent of the changing state of the cursor. These cells were consistent with previous reports of target-sensitive tuning in area 5 (Ashe & Georgopoulos, 1994). Therefore, the intended goal of the trajectory is maintained in PPC during on-line control of movement. PPC neurons that are tuned for movement angle encode dynamic information about the time-varying state of the cursor. Figure 41.3A shows TEFs for the movement angle population. The histogram in figure 41.3B summarizes the distribution of OLTs for the movement angle population, which was centered at 0 ± 90 ms and 30 ± 90 ms, for the center-out and obstacle tasks, respectively (median \pm interquartile range (IQR)). These plots show that movement angle neurons contained a temporal distribution of information about the state of the ongoing movement; some neurons best represented states in the near future (positive-lag time), some best represented states in the recent

angles measured over a range of lag times ($-120 \text{ ms} \leq \tau \leq 120 \text{ ms}$) relative to the firing rate. (D) Movement angle temporal encoding function (TEF) and corresponding goal angle TEF, where mutual information between firing rate and movement angle is plotted as a function of lag time. The firing rate contained the most information about the movement angle at an optimal lag time of 0 ms. The dashed lines denote surrogate TEFs, for both movement (black-dashed) and goal (gray-dashed) angles, that were derived from surrogate spike trains and actual angles. (Reprinted with permission from Mulliken, Musallam, & Andersen, 2008a.)

past (negative-lag time), and many peaked around the current state (zero-lag time).

It is helpful to interpret the OLT results in the context of the observer framework. Passive sensory feedback (e.g., y in equation 2) would require at least 30–90 ms (proprioceptive-visual) to reach PPC; consistent with some of the negative OLTs (≤ -30 ms) observed here (Decety et al., 1994; Flanders & Cordo, 1989; Miall & Wolpert, 1996; Petersen et al., 1998; Rigalet et al., 1999). Conversely, if PPC neurons were responsible for generating outgoing motor commands (u in equation 1), subsequent stages of processing and execution of the movement would require at least 90–100 ms to produce the corresponding cursor motion (Miall & Wolpert, 1996). For instance, similar analyses for velocity have been performed in the primary motor cortex and report average OLTs of approximately 90–100 ms (Ashe & Georgopoulos, 1994; Paninski et al., 2004). Therefore, it is unlikely that PPC is primarily driving motor

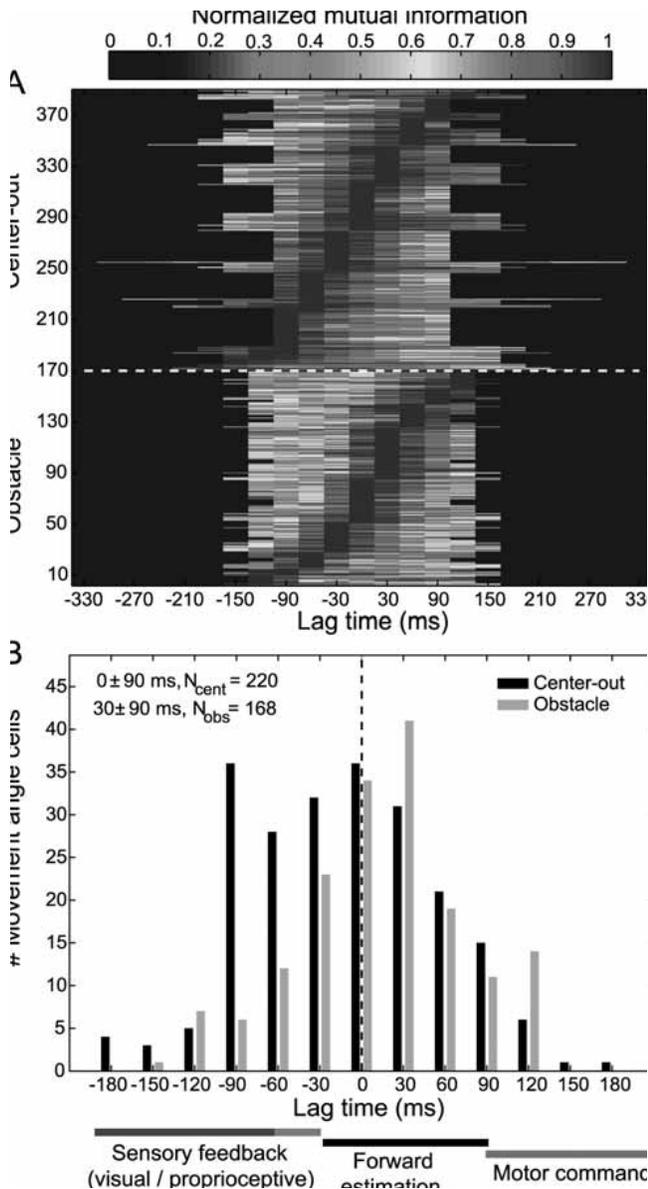

FIGURE 41.3 Population temporal encoding results. (A) Population TEFs plotted for all movement angle neurons showing cell-normalized mutual information as a function of lag time. (B) Histogram summarizing the OLTs for movement angle neurons for both center-out and obstacle tasks (summary statistic in upper-left corner: median \pm interquartile range). Many of these neuron's OLTs were consistent with a forward estimate of the state of the movement angle, which did not directly reflect delayed sensory feedback to PPC, nor were they compatible with outgoing motor commands from PPC. (Reprinted with permission from Mulliken, Musallam, & Andersen, 2008a.) (See color plate 53.)

cortex with feedforward commands, since it would be expected that PPC should lead the movement state by more than motor cortex does, on average (i.e., $OLT > 90$ ms). Neither passive sensory feedback nor efferent motor explanations best account for the responses of neurons whose OLTs fall between -30 and 60 ms. Instead, these cells appear to encode a forward-state estimate,

which allows PPC to monitor the current and upcoming states of the movement angle prior to the arrival of delayed sensory feedback. It does not appear that this current-state estimate is merely a blend of incoming sensory and outgoing motor representations (i.e., a simple summation of two modal distributions centered at negative and positive lag times should result in a bimodal or potentially “flat” distribution), since our OLT distributions appear to show a pronounced unimodal peak around 0 ms. Furthermore, the peak information (mutual information at the OLT) encoded by neurons that were most clearly forward-estimating ($0 \leq OLT \leq 60$ ms) was significantly larger than the peak information encoded by the remaining population of movement angle neurons ($OLT \leq -30$ ms, or $OLT \geq 90$ ms). Therefore not only does PPC have a central tendency to encode the current state of the movement angle, but forward-estimating neurons also contained significantly more information about the movement state than did neurons with other OLTs, suggesting that these state estimates are generated by some active computational process (i.e., a forward model).

While it is likely that PPC relies upon a forward model to estimate the current state of the cursor (i.e., a priori estimate), it is also possible that sensory information is integrated by PPC to update this estimate. As mentioned above, it has been suggested that the a priori state estimate is generated by the cerebellum and then sent to PPC (Shadmehr & Krakauer, 2008). In this situation, these authors suggested that PPC is responsible only for processing afferent signals (i.e., matrix H in equation 2), specifying the Kalman gain to optimally incorporate sensory information into a refined, a posteriori state estimate. Given known afferent projections to PPC (both visual and proprioceptive) as well as evidence from our data demonstrating that some movement angle neurons appear to encode a passive sensory representation of the state (i.e., $OLT \leq -30$ ms), it seems likely that PPC does integrate delayed sensory information. However, on the basis of our data and evidence from the mental simulation literature (discussed above), we suggest that PPC is also involved directly in performing forward model computations, perhaps within a reciprocal, functional loop that includes the cerebellum (Blakemore & Sirigu, 2003). That is, the forward state estimates found in PPC most likely reflect the output of an observer, which is involved in both performing the computations of the forward model and integrating sensory feedback into the state estimate.

DYNAMIC TUNING AND SEPARABILITY OF MOVEMENT ANGLE STTF Further support for state estimation in PPC was obtained from analyzing the spatiotemporal encoding properties of movement angle STTFs. We measured changes in the preferred direction of a neuron, θ_{pds} over a range of

lag times. θ_{pd} is the movement angle at which a neuron fired maximally for a particular lag time. We reasoned that if θ_{pd} did not vary significantly as a function of lag time compared to changes that occurred in the movement angle itself, then that neuron encoded a mostly straight trajectory. Across the population of movement angle neurons, most neurons' STTFs exhibited small changes in θ_{pd} as a function of lag time, which were significantly less than changes observed in the actual movement angle in the trajectories themselves (figure 41.4*AB*).

We performed an additional separability analysis to further characterize the relationship between angle and lag time encoded by a neuron's STTF. A perfectly separable STTF indicates that the lag time and angle were encoded independently of one another. We determined that the population of movement angle neurons was largely separable in the angle-time plane by using singular value decomposition (SVD) (Mazer, Vinje, McDermott, Schiller, & Gallant, 2002; Pena & Konishi, 2001). We calculated the fractional energy contained in the singular values for each cell's movement angle STTF; $92.0 \pm 14.7\%$ and $78.9 \pm 25.8\%$ of energy (median + IQR) was contained in the first singular value, for

the center-out and obstacle tasks, respectively (figure 41.4*C*). The distribution of fractional energies contained in the first singular value is shown in figure 41.4*D*.

These results suggest that dynamic sensorimotor control mechanisms in PPC encode mostly straight and instantaneous trajectories, with a less substantial component of the neurons' firing rates arising because of nonlinear encoding mechanisms that may reflect the slight curvature we observed in the STTFs. This interpretation is consistent with PPC neurons encoding a state estimate of the movement direction, such that the majority of information is encoded at a cell's OLT, with decreasing information encoded away from the OLT. (Note that a perfectly instantaneous state estimate, that is, a delta function, should not be expected due to auto-correlation present in continuous motor variables such as movement angle.)

Reading out the dynamic state of a cursor from PPC

It would be interesting to test whether a dynamic state estimate in PPC, presumably reflecting the operation of an observer, could be used to causally control an external device

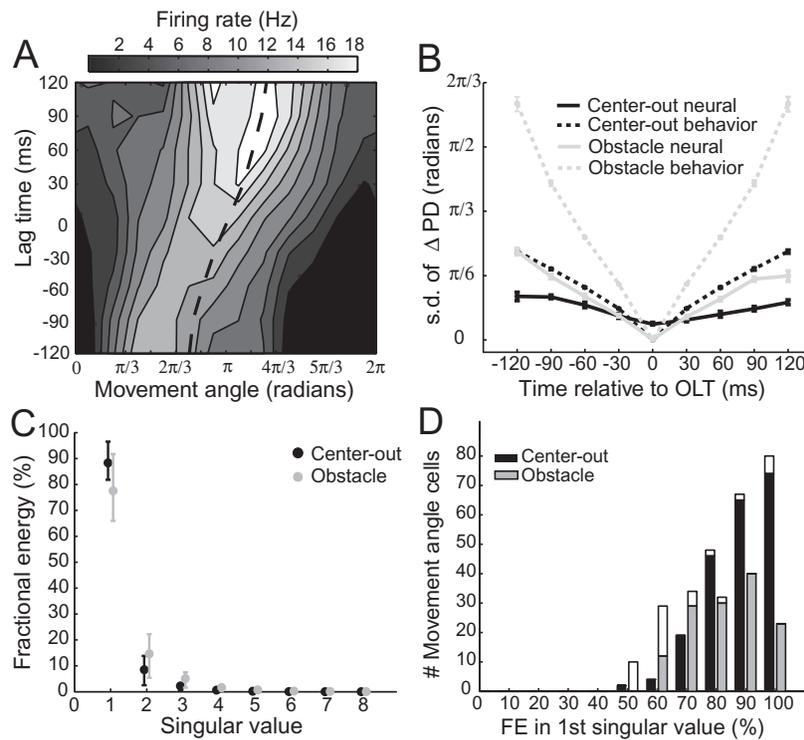

FIGURE 41.4 Curvature and separability of STTFs. (A) Example STTF containing slight curvature. The θ_{pd} of this cell (dashed line) changed smoothly but slightly as a function of lag time. (B) Standard deviation of the population's distribution of θ_{pd} changes ($\sigma_{d\theta}$), plotted as a function of time relative to the OLT. For both center-out and obstacle tasks, the population $\sigma_{d\theta}$ (neural, solid lines) was significantly less than the $\sigma_{d\theta}$ for the actual movement angle (behavior, dashed lines) over the same time range. (C) Population summary

of fractional energy (FE) accounted for by each singular vector in the singular vector decomposition (SVD) analysis. The majority of energy in movement angles STTFs was captured by the first singular vectors for the center-out and obstacle tasks, respectively. (D) Population histogram showing distribution of FE of the first singular value for all movement angle cells. (Reprinted with permission from Mulliken, Musallam, & Andersen, 2008a.)

besides our own limbs. During recent years, several groups have leveraged the findings from decades of primate neurophysiology toward the development of an important medical application: a neural prosthesis to assist paralyzed individuals. A neural prosthesis would directly read out the desired movement intentions of a patient from regions of the brain that are not affected by injury or disease.

Several groups have successfully extracted continuous movement information (i.e., trajectories) from motor cortices, such as M1 and dorsal premotor cortex (PMd) (Carmena et al., 2003; Kennedy, Bakay, Moore, Adams, & Goldwaight, 2000; Musallam et al., 2004; Patil, Carmena, Nicolelis, & Turner, 2004; Santhanam, Ryu, Yu, Afshar, & Shenoy, 2006; Serruya, Hatsopoulos, Paninski, Fellows, & Donoghue, 2002; Shenoy et al., 2003; Taylor, Tillery, & Schwartz, 2002; Wessberg et al., 2000; Wolpaw & McFarland, 2004). In contrast to signals extracted from M1, which are more likely to encode movement execution signals that are represented in a musculoskeletal reference frame, high-level visuomotor signals can be found in earlier stages of the dorsal visual pathway, such as in PPC or PMd. For example, the goal of a reach in visual coordinates has been decoded successfully from both PPC and PMd neurons

(Musallam, Corneil, Greger, Scherberger, & Andersen, 2004; Santhanam et al., 2006). Sensorimotor areas of cortex, particularly those that are strongly innervated by visual feedback projections (e.g., PPC) represent candidate regions that are potentially useful for driving a neural prosthesis since a primary source of input, visual information, is typically uncompromised after paralysis (figure 41.5).

OFFLINE DECODING OF TRAJECTORIES We recently built upon the work of Musallam and colleagues and demonstrated that a PPC prosthesis can also be used to perform continuous control of a computer cursor (Mulliken, Musallam, & Anderson, 2008b). First, we showed that we could reliably reconstruct monkeys' trajectories off-line using a small ensemble of PPC cells. For example, decoding from just five single neurons using a Kalman filter, we demonstrated that we could account for more than 70% of the variance in the cursor position. Interestingly, by extracting information about the goal of a trajectory (i.e., target information that is also known to be encoded in PPC) and incorporating it into the Kalman filter framework, we were able to significantly improve the accuracy of the decoded estimate (on average by 17% over a standard Kalman filter).

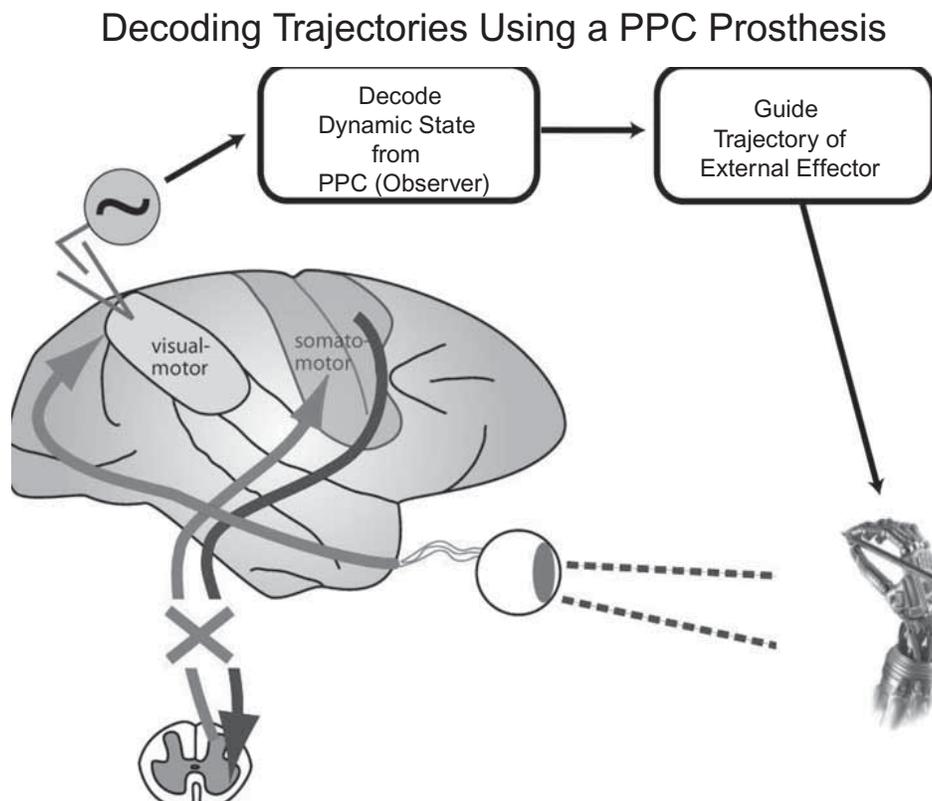

FIGURE 41.5 A neural prosthesis using PPC for trajectory control. A spinal cord injury can render communication (afferent and efferent) between somatosensory and motor areas of cortex and the limbs useless. However, the integrity of the “vision for action”

pathway may still be largely intact, which includes PPC. Decoding algorithms are designed to optimally estimate the state of the effector from the measurement of neural activity from PPC ensembles.

In these decoding experiments, we presumably were decoding from the output of an observer, thereby harnessing a forward estimate of the expected (e.g., current) sensorimotor state of the cursor. To verify this, we also decoded the state (in this situation, the position and velocity) of the cursor shifted in time relative to the instantaneous firing rate measurement, with lag times ranging from -300 ms to 300 ms, in 30 -ms steps (where negative lag times correspond to past movement states and positive lag times correspond to future movement states). The optimal lag time (OLT) for decoding velocity using the G-Kalman filter was 10 ms in the future, consistent with previous claims that PPC best represents the current state of the velocity (Mulliken, Musallam, & Andersen, 2008a). The position of the cursor was best decoded slightly further into the future, at an OLT of approximately 40 ms. These temporal decoding results suggest that the current or upcoming state of the cursor could be best extracted from the PPC population by using the Kalman filter. These results are by and large similar to the encoding analyses reported above, and they suggest that PPC is involved in maintaining an estimate of the current and upcoming state of the cursor, consistent with the output of a forward model.

CLOSED LOOP BRAIN CONTROL DECODING In addition to off-line decoding, we demonstrated that we could decode trajectories during closed loop brain control sessions, in which the real-time position of the cursor was determined solely by a monkey's thoughts. Initially, the monkey performed brain trajectories at approximately a 30% success rate (for eight targets), but he quickly improved his performance to an 80% success rate after just four to five sessions. This increase in behavioral performance was accompanied by a corresponding enhancement in neural tuning properties, showing that learning effects occurred in the PPC ensemble. For instance, off-line analyses showed that the neurons' average tuning depth increased by more than 70% , the average coverage of two-dimensional space of the population increased by 35% , and the off-line decoding performance (i.e., R^2) of the PPC ensemble increased by more than twofold. These data show that PPC ensembles can be harnessed independently for real-time continuous control of a cursor. In addition, the ability of PPC to causally control a cursor indicates that the state representation in PPC does not rely entirely on visual/proprioceptive information but instead may reflect current and future state estimates generated by a forward model. Last, we expect, on the basis of our findings here and PPC's known functional role in combining visual and motor representations, that PPC will be particularly well suited to serve as a target for a prosthesis that relies upon visually guided feedback for continuous control and error-driven learning.

The ability to extract both trajectory and goal information from neural activity makes this brain area an attractive target for a neural prosthesis. For example, a continuous decoder that estimates the dynamic state of the cursor could be improved by using target information to constrain the decoded trajectory on the basis of its inferred endpoint (Srinivasan & Brown, 2007). The observation that these neurons appear to encode mostly straight lines in visual space may prove to be more straightforward to decode. For instance, PPC neurons may be more flexible for controlling a variety of end effectors, including but not limited to the human arm. Finally, when training a prosthetic in a clinical setting, the operator must rely on a patient's ability to imagine moving an effector in space. Motor imagery studies suggest that PPC is a critical node for maintaining an accurate estimate of the state of the hand during mental simulation of movement. Therefore, we expect that PPC will be a useful site for extracting time-varying trajectory information that accurately matches the desired, real-time sensory outcome of an intended movement trajectory. These findings mark an important step forward in the development of a neural prosthesis using signals from PPC.

42 Parallels between Sensory and Motor Information Processing

EMANUEL TODOROV

ABSTRACT The computational problems solved by the sensory and motor systems appear very different: One has to do with inferring the state of the world given sensory data, the other with generating motor commands appropriate for given task goals. However recent mathematical developments summarized in this chapter show that these two problems are in many ways related. Therefore information processing in the sensory and motor systems may be more similar than was previously thought—not only in terms of computations, but also in terms of algorithms and neural representations. Here, we explore these similarities and clarify some differences between the two systems.

Similarity between inference and control: An intuitive introduction

Consider a control problem in which we want to achieve a certain goal at some point in time in the future—say, grasp a coffee cup within 1 s. To achieve this goal, the motor system has to generate a sequence of muscle activations that result in joint torques that act on the musculoskeletal plant in such a way that the fingers end up curled around the cup. Actually, the motor system does not have to compute the entire sequence of muscle activations in advance. All it has to compute are the muscle activations right now, given the current state of the world (including the body) and some description of what the goal is. If the system is capable of performing this computation, then it will generate the resulting muscle activations, the clock will advance to the next point in time, and the computation will be repeated.

How can this control problem be interpreted as an inference problem? Instead of aiming for a goal in the future, imagine that the future is now and the goal has been achieved. More precisely, shift the time axis by 1 s and create a fictive sensory measurement corresponding to the hand grasping the cup. The inference problem is now as follows: Given that the fingers are around the cup and that the world was at a certain state 1 s ago, infer the muscle activations that caused the observed state transition. As in the control problem, all that needs to be inferred are the muscle activations at a

single point in time (1 s ago); if this can be done, then the clock will advance (to say 0.99 s ago), and the computation will be repeated.

The above inference problem does not have a unique solution, because there are many sequences of muscle activations that could have caused the state transition we are trying to explain. Even at the final time, the arm could be in many postures that all correspond to a successful grasp; thus the fictive measurement is incomplete. The same ill-posedness is present in the control problem and is known as motor redundancy (Bernstein, 1967). Inference problems do not normally involve this kind of redundancy. Indeed, the inference here is rather unusual: There is a period of time (1 s in our example) when there are no sensory measurements, and the only available measurement at the end of the movement is incomplete. We could consider a different control problem that corresponds to a more usual inference problem involving complete sensory measurements. That control problem is one in which we are given a detailed goal state at each point in time, that is, a reference trajectory for all musculoskeletal degrees of freedom, and have to generate muscle activations so as to force the plant to track this trajectory. When the latter control problem is mapped into an inference problem, the sequence of detailed goal states turns into a sequence of complete sensory measurements, thus eliminating redundancy. It is important to realize, however, that trajectory tracking represents only a small fraction of ecologically relevant behaviors (Todorov & Jordan, 2002). Thus the natural control problem (which involves a large amount of redundancy) corresponds to an unnatural inference problem (in which sensory data are very sparse) and vice versa. Inference is easier if complete sensory measurements are available at all times; similarly, control is easier if detailed goal states are specified at all times.

This reasoning suggests that control is a harder problem than inference, at least in the temporal domain. Indeed, inference in the absence of measurements is called prediction (except that here it is performed backward in time), and prediction tends to be hard. On the other hand, redundancy makes it possible to be sloppy most of the time and still achieve the goal. This is because, even if the initial part of the movement somehow goes wrong, there is time later in

EMANUEL TODOROV Department of Cognitive Science, University of California San Diego, San Diego, California

the movement to observe what happened and take corrective action. The analog of this property in the inference domain is that long-term predictions tend to be inaccurate, while short-term predictions (which correspond to motor commands close to the goal) are more accurate.

The above transformation from control to inference has been instantiated in formal models (Attias, 2003). This is done by setting up a dynamic belief network (see below) that represents the states and actions at different points in time, treating the goal state as being observed, and performing Bayesian inference to find the actions. The shortcoming of this approach is that inference is performed over the product space of states and actions, which for a typical motor control problem is prohibitively large. In the rest of the chapter, we will pursue a different approach, in which the control problem will turn out to be equivalent to an inference problem involving only states. Actions will be defined implicitly as transitions between inferred consecutive states.

Now let us ask the opposite question: Can we start with an inference problem and transform it into a control problem? Consider the problem of estimating the current state of the world, given our previous estimate and the current sensory measurement. One way to do this is to use a predictor-corrector method: Combine the previous estimate with a model of one-step dynamics to obtain a prediction of the current state, and then correct the prediction so as to make it more compatible with the current measurement. The corrected estimate will achieve some tradeoff between being close to the prediction and agreeing with the measurement. The corresponding control formulation is as follows. The entity being controlled (internally) is the state estimate. The control signal corresponds to the correction needed to achieve better agreement with the measurement. Suppose the control is chosen so as to minimize a sum of two costs: an energy cost and an accuracy cost. The energy cost is minimal when there is no correction. The accuracy cost is minimal when the correction is complete. The control that minimizes the sum of these costs will lie somewhere in between the two extremes, thus achieving a similar tradeoff as the predictor-corrector method.

We now see that in the spatial domain, inference can be harder than control. This is because the estimator “controls” (i.e., corrects) all aspects of the estimated state. In the coffee-drinking example, the estimator may deal not only with the arm and the cup, but also with the picture on the wall, the mountains we can see through the window, and many other things that have no relevance to motor actions. Note, however, that this implies a somewhat outdated view of perception in which all aspects of the sensory input are processed in parallel on equal footing. In reality, perception may be geared toward serving the needs of the ongoing behavior, which in our example means ignoring the picture and the

mountains and focusing on the arm and cup. In the latter view, inference and control have similar spatial complexity in terms of what needs to be computed (state estimate versus control signal). However, the input to this computation (sensory data versus task goal) is always higher-dimensional for the sensory system.

The above transformation from estimation to control corresponds to the idea of minimum-energy filtering (Mortensen, 1968), in which estimation is formulated as a minimum-energy tracking problem and is solved by using optimal control methods. The shortcoming of this approach is that it yields only point estimates, while a lot of evidence (see below) indicates that the brain computes probability distributions rather than point estimates. In the rest of the chapter, we will pursue a different approach in which the estimator computes the full Bayesian posterior.

To summarize the main points in this section, the similarities between control and estimation arise when task goals are associated with sensory measurements and control signals are associated with corrections to the state estimate. Our discussion was framed in the context of optimal control and optimal/Bayesian inference, which was not a coincidence. Indeed, we will see below that optimality is the source of these similarities.

Duality of Bayesian inference and optimal control in isometric tasks

Here, we provide a concrete example illustrating the duality between Bayesian inference and optimal control. Let \mathbf{u} be a vector of muscle activations, \mathbf{t} the resulting vector of joint torques, and M the matrix of moment arms that maps muscle forces (proportional to muscle activations under isometric conditions) to joint torques: $\mathbf{t} = M\mathbf{u}$. *Isometric* means that there is no movement. Since there are more muscles than joints, a desired torque \mathbf{t}^* can be achieved by infinitely many muscle activations \mathbf{u} . This is a manifestation of motor redundancy. To select one out of all possible \mathbf{u} , the motor system needs some selection criterion. Suppose that this criterion is to keep the sum of squared muscle activations as small as possible. Then \mathbf{u} can be found by minimizing the cost function:

$$\frac{1}{2}\|\mathbf{t}^* - M\mathbf{u}\|^2 + \frac{1}{2}r\|\mathbf{u}\|^2 \quad (1)$$

The first term is an accuracy cost that is minimal when the desired torque is exactly achieved. The second term is an energy cost that is minimal when all muscle activations are zero. The parameter r determines the relative importance of the two. Quadratic cost functions are usually scaled by a factor of $\frac{1}{2}$ for convenience. We have shown (Todorov, 2002) that the above cost function as well as more realistic versions of it predict the empirical phenomenon of cosine tuning, that is, the fact that muscle activation varies with the

cosine of the angle between the mechanical pulling direction of the muscle and the direction of end-effector force (Hoffman & Strick, 1999).

We now turn to the corresponding inference problem, which involves a Gaussian prior over the elements of \mathbf{u} with mean 0 and variance $1/r$ and a fictitious measurement corresponding to goal achievement, namely, $\mathbf{y} = \mathbf{t}^*$. Bayesian inference requires a generative model, that is, a model of how the (noisy) sensory measurement was generated given the state. In this case, the generative model is $\mathbf{y} = M\mathbf{u} + \boldsymbol{\varepsilon}$, where the elements of $\boldsymbol{\varepsilon}$ are Gaussian with mean 0 and variance 1. Applying Bayes rule (see below) and using the formula for a Gaussian, we obtain the posterior probability of \mathbf{u} given \mathbf{y} :

$$p(\mathbf{u}|\mathbf{y}) \propto p(\mathbf{y}|\mathbf{u})p(\mathbf{u}) \propto \exp\left(-\frac{1}{2}\|\mathbf{t}^* - M\mathbf{u}\|^2 - \frac{1}{2}r\|\mathbf{u}\|^2\right) \quad (2)$$

Thus the posterior probability in the inference problem (equation 2) coincides with the exponent of the negative cost in the control problem (equation 1); in particular, the most probable muscle activations coincide with the optimal muscle activations.

This completes our example of duality in isometric tasks. Although it is a simple example that does not involve state variables changing over time, it nevertheless illustrates a key idea that is used extensively later. The idea is that costs and probabilities are related by an exponential transformation. This is to be expected; costs add while probabilities multiply, and it is the exponential transformation that turns sums into products. The same transformation shows up in other fields as well. In statistical mechanics, for example, the energy of a given state and the probability of finding the system in that state at thermal equilibrium are related by the Gibbs distribution, which is the exponent of the negative energy.

We are now ready to develop a general form of duality between optimal control and optimal/Bayesian inference over time. To this end, we will first review the concepts of optimality in sensory and motor processing and note the similarities and differences between the two formalisms. This analysis will then indicate how the control problem should be phrased so as to become mathematically equivalent to Bayesian inference.

Optimality in sensory and motor processing

While all aspects of neural function have evolved to produce behavior that is beneficial to the organism, the evolutionary pressures on real-time sensory and motor processing may have been particularly strong and direct because of the crucial role that such processing plays in getting food to the mouth, escaping predators, and generally keeping the organism alive. It is, then, not surprising that the underlying neural mechanisms perform about as well as any

information-processing system that is subject to the same constraints could perform—in other words, near optimally. Indeed, optimality is becoming the theoretical framework of choice in studying both sensory and motor systems (Todorov, 2004; Kording & Wolpert, 2006; Doya, Ishii, Pouget, & Rao, 2007).

In the sensory domain, optimality corresponds to Bayesian inference. In the simplest setting, it involves three probability distributions over the (relevant) state of world: the prior, the likelihood, and the posterior. They are related according to Bayes' rule:

$$\text{posterior}(x) \propto \text{likelihood}(y|x)\text{prior}(x) \quad (3)$$

The prior summarizes everything that we know about the state of the world before observing the measurement. The likelihood (which formalizes the generative model) is the probability of measurement y being generated when the world is in state x . The posterior summarizes everything that we know after the measurement is taken into account. If there are multiple independent measurements, the right-hand side of equation 3 contains the product of the corresponding likelihoods. The latter setting is used in models of cue integration, in which subjects are presented with two (often incompatible) sensory cues and asked to estimate some property of the world. Such experiments have provided the simplest and perhaps most compelling evidence that perception relies on Bayesian inference (e.g., Ernst & Banks, 2002). The probability distributions that are used in these studies are typically Gaussian.

Unlike the static nature of many cue integration experiments, sensory processing in the real world takes place in time and requires integration of measurements obtained at different points in time. This is called recursive estimation or filtering. The basic update scheme that is applied at each point in time has the predictor-corrector form:

$$p(x) \propto l(y|x) \sum_{x_{prev}} d(x|x_{prev}) p(x_{prev}) \quad (4)$$

Here, $p(x)$ is the posterior at the current state, $p(x_{prev})$ is the posterior at the previous state (which we have already computed at the previous time step), $l(y|x)$ is the likelihood function, and $d(x|x_{prev})$ is the stochastic one-step dynamics of the world. In estimating the state of the body, the dynamics d will also depend on the control signal that is available to the sensory system in the form of an efference copy. The product of d and p , which is being summed over, is the joint probability of x and x_{prev} . The sum marginalizes out x_{prev} and yields a prediction (or prior) over x . In this way, the posterior at one point in time is used to compute the prior at the next point in time. The multiplication by the likelihood l is the sensory-based correction discussed earlier.

A number of experimental findings support the notion of Bayesian inference over time (Wolpert, Gharahmani, & Jordan, 1995; Kording & Wolpert, 2004; Saunders & Knill,

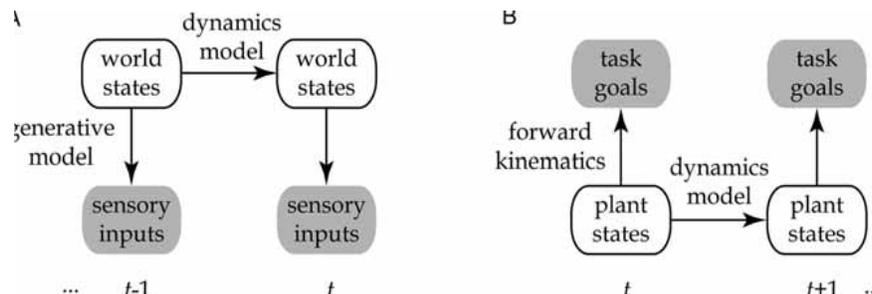

FIGURE 42.1 Belief networks for Bayesian inference and optimal control. (A) Shaded nodes correspond to observed quantities; open nodes correspond to random variables whose (marginal) probabilities are to be computed. The dynamics model is the probability distribution of the next state given the current state. The generative model is the probability distribution of the sensory input given the state. (B) The optimal control problems in this chapter are mathe-

matically equivalent to Bayesian inference problems; thus they can be represented with belief networks. The forward kinematics play the role of a generative model and indicate whether the goal is achieved by the current state of the plant. The actual generative model specifies a probability distribution proportional to $\exp(-q(x))$, where $q(x)$ is the state cost.

2004). These studies typically use arm movements, not so much for the purpose of studying the motor system but as a continuous readout of perception. Such studies demonstrate that subjects take into account multiple sources of information over time (visual and proprioceptive, along with internal predictions) and rely on that information to guide movements. As in cue integration, the probability distributions that are assumed here are typically Gaussian. When the dynamics are linear and all noise is Gaussian, the posterior is also Gaussian and can be computed by using the Kalman filter.

There is a graphical representation of Bayesian inference problems (figure 42.1A) that is known as a graphical model or a belief network (dynamic belief network when time is involved). This representation is very popular in statistics and machine learning (Pearl, 1988). Belief networks help us to understand the mathematical models intuitively and will also be useful later in clarifying the relationship between estimation and control. To avoid confusion, keep in mind that unlike neural networks, the nodes in belief networks do not correspond to neurons, and the arrows do not correspond to synaptic connections. Instead, the nodes correspond to collections of random variables, whose probabilities are presumably represented by populations of neurons. Strictly speaking, the arrows encode conditional probabilities, but in reality they often correspond to the causal relations in the world, as illustrated in figure 42.1A. We show only part of the network containing the states of the world at two consecutive points in time as well as the corresponding sensory measurements/inputs. Solid gray circles denote variables whose values are observed and that therefore contribute a likelihood function. Open circles denote variables whose values are to be inferred. The forward arrows encode the stochastic dynamics of the world, that is, the one-step transition probability d . The downward arrows encode how

sensory measurements are generated as a function of world states. This generative model may incorporate a model of optics in vision or a model of acoustics in audition plus a model of sensory transduction in the corresponding modality. One can think of perception as a computational process that inverts the generative model in a probabilistic sense (this idea goes back to Helmholtz).

Optimality has also been applied in motor control, perhaps even more extensively than in perception. This may be because, apart from its general appeal as an organizing principle, optimality appears to be the right way to resolve redundancy. There is a wealth of experimental data (for reviews, see Todorov, 2004; Kording & Wolpert, 2006) suggesting that the motor system generates actions that maximize task performance or utility. Optimal control models have accounted in parsimonious ways for numerous features of motor behavior on the levels of kinematics, dynamics, and muscle activity. There are two general approaches: open loop control and closed loop control. Open loop control precomputes the entire sequence of motor commands from now until the goal is achieved, while closed loop control (or feedback control) computes only the current motor command given the current state estimate and then uses information about the next state to compute the next command. Since movements are under continuous sensory guidance, the latter type of model corresponds more closely to what the brain does. Although optimal feedback controllers are harder to construct, we now have efficient algorithms and fast computers that enable us to explore such models.

Here is how optimal feedback control works in a nutshell: Define an instantaneous cost that accumulates over time and yields a cumulative cost. The instantaneous cost is usually a sum of a control cost $r(u)$, which encourages energetic efficiency, and a state cost $q(x)$, which encourages accuracy or, more generally, getting to desirable states and avoiding

undesirable states. Also define the one-step stochastic dynamics $d_u(x_{next}|x)$, which is similar to the one-step transition probability in Bayesian inference except that it now depends on the control u explicitly. The objective is to find an optimal control law, that is, a mapping from states to controls that minimizes the expected cumulative cost. This computation is facilitated by the optimal cost-to-go function $v(x)$, defined as the cost that is expected to accumulate if the plant is initialized at state x and is controlled optimally thereafter. The optimal cost-to-go function plays a key role because it summarizes all relevant information about the future and allows us to compute the optimal control at the present time using greedy optimization without look-ahead. This function is the unique solution to the Bellman equation:

$$v(x) = \min_u \left[q(x) + r(u) + \sum_{x_{next}} d_u(x_{next}|x) v(x_{next}) \right] \quad (5)$$

The control u that achieves the minimum is the optimal control at the current state x . This equation is quite intuitive; it says that the optimal cost-to-go can be broken down into the instantaneous cost incurred at the current state when applying the optimal control plus the optimal cost-to-go for the movement originating at the next state. The expectation (sum over x_{next}) is needed because the dynamics are stochastic and the next state is known only in a probabilistic sense. Equation 5 can always be solved numerically by using dynamic programming, which involves computing the minimum over u and assigning it to $v(x)$ for each x and each time step. For large problems, however, this computation is often intractable.

One special case in which equation 5 can be solved efficiently is the case of linear dynamics, Gaussian noise, and quadratic costs. In such problems (known as LQG), the optimal cost-to-go is quadratic and can be computed with a method very similar to the Kalman filter. Note that a Gaussian is the exponent of a quadratic function, the product of two Gaussians is the exponent of the sum of the corresponding quadratics, and a sum of quadratics is again a quadratic (as illustrated in the isometric task example). So both the Kalman filter and the LQG optimal controller are based on manipulating quadratics; indeed, the underlying equations are identical. This duality was discovered by Kalman (1960) and was the first indication that optimal estimation and optimal control are closely related. We recently showed (Todorov, 2008) that Kalman's duality is special to the LQG setting and does not generalize. However, there exists another form of duality that does generalize. It was developed by Mitter and Newton (2003) in continuous time and by Todorov (2006, 2008) in discrete time. The two developments are technically quite different yet yield related results. Our presentation in the next section will use the discrete-time version, which is more intuitive and also turns out to

be more general. The continuous-time version can be obtained as a special case by assuming Gaussian noise and taking a certain limit.

General duality of Bayesian inference and optimal control

Comparing equations 4 and 5, we can already see a similarity between optimal control and Bayesian inference. The state cost q and the likelihood l are related in the sense that they both inject new information about x in each step of the recursive process. The optimal cost-to-go v and the posterior p are related in the sense that they both accumulate information about x over time. The one-step dynamics d are present in both control and estimation. One equation involves sums, while the other involves products, but sums can be turned into products by the exponential transformation. Yet we also see a difference: While equation 4 specifies the posterior p directly via an explicit formula, equation 5 specifies the optimal cost-to-go v indirectly as the solution to an unsolved optimization problem. Neither the control cost $r(u)$ nor the dependence of d_u on u has an analog in 4, suggesting that whether or not the optimal control problem is dual to a Bayesian inference problem will depend on how we define $r(u)$ and d_u .

To establish a general duality, we will define the control signal as a probability distribution over possible next states. This is unusual but in retrospect natural. What controls do is affect the plant dynamics. So we can characterize them directly in terms of how they affect the plant dynamics. For a stochastic plant, this characterization takes the form of a probability distribution $u(x_{next})$. Thus the one-step dynamics are simply

$$d_u(x_{next}|x) = u(x_{next}) \quad (6)$$

According to this definition, the controller has the power to impose on the plant whatever dynamics it wishes. We will restrict this power somewhat, by defining the passive dynamics $d(x_{next}|x)$ in the same way as in the inference problem and allowing u to be nonzero only if d is nonzero. The passive dynamics capture the effects of gravity, interaction forces, and motor noise. The above restriction means that the control signals can cause only those state transitions that could have occurred by accident, that is, the noise and the controls are restricted to act in the same subspace. For musculoskeletal plants in which the controls correspond to muscle activations, the noise model should be restricted to muscle space and should not be allowed to act directly on, say, arm position (which would be physically unrealistic anyway). The above restriction also means that we cannot model external perturbations acting on objects of interest. Such perturbations are often used experimentally to probe

the visual feedback control laws; however, they are uncommon in the real world.

Having a model of passive or uncontrolled dynamics allows us to define the control cost in a natural way. Intuitively, such a cost should measure how large the control signals are. Larger control signals have larger effects on the plant dynamics; that is, they push the plant farther away from its passive dynamics. This suggests a control cost that measures the difference between the probability distributions $u(x_{next})$ and $d(x_{next}|x)$. Differences between probability distributions are most commonly measured by using Kullback-Liebler (KL) divergence; thus the control cost will be defined as

$$r(u) = \text{KL}(u, d) = \sum_{x_{next}} u(x_{next}) \log \frac{u(x_{next})}{d(x_{next}|x)} \quad (7)$$

Definitions 6 and 7 yield a family of control problems that still satisfy the Bellman equation 5 but have additional structure that can be exploited. A control problem in our family is defined by specifying the state cost $q(x)$ and passive dynamics $d(x_{next}|x)$. Once q and d are given, we can substitute equations 6 and 7 into equation 5 and observe that the minimization with respect to u can be performed analytically, owing to properties of the KL divergence. We omit the derivation and summarize the results. The results are expressed most conveniently in terms of a desirability function defined as

$$z(x) = \exp(-v(x)) \quad (8)$$

When the optimal cost-to-go $v(x)$ is small, the function $z(x)$ is large, hence the term *desirability*. It also rhymes with *probability*, which is appropriate because z will turn out to behave like a probability distribution. It can now be shown that the

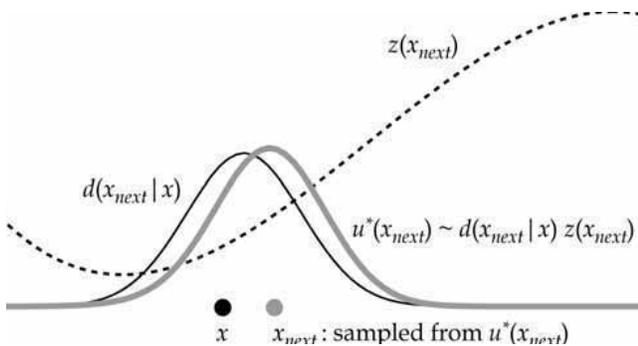

FIGURE 42.2 Optimal control with probability distributions. The passive dynamics $d(x_{next}|x)$ is the probability distribution of the next state when the system is not controlled. The control $u(x_{next})$ is the probability distribution of the next state when the system is controlled. The optimal control $u^*(x_{next})$ is proportional to the product of the passive dynamics $d(x_{next}|x)$ and the desirability function $z(x_{next})$. Multiplying a narrow probability distribution by a smooth function has the effect of shifting the distribution along the gradient of that function. Thus the optimal control is similar in shape to the passive dynamics but is shifted towards more desirable states.

optimal control (i.e., the optimal next-state probability distribution) at state x is

$$u^*(x_{next}) \propto d(x_{next}|x) z(x_{next}) \quad (9)$$

This form of control is illustrated in figure 42.2. Given the current state x , we multiply the one-step passive dynamics $d(x_{next}|x)$ by the desirability $z(x_{next})$, normalize to obtain a proper probability distribution $u^*(x_{next})$, and sample the next state from it. Note that multiplication by the desirability z has the effect of shifting the passive dynamics d toward more desirable states.

We still need to compute z . This is done by substituting the optimal control (equation 9) into the Bellman equation (equation 5), dropping the min operator, and exponentiating so as to obtain an update for z rather than v . The resulting update is

$$z(x) = \exp(-q(x)) \sum_{x_{next}} d(x_{next}|x) z(x_{next}) \quad (10)$$

The similarity with Bayesian inference (equation 4) is now obvious: The desirability z corresponds to the posterior probability p , the exponentiated state cost $\exp(-q)$ corresponds to the likelihood l , and the one-step transition probability d plays the same role in both cases. The only difference is that z is updated backward in time, while p is updated forward in time. This is because control is about the future, while inference is normally about the past. However, if we construct the inference problem as outlined earlier, that is, provide fictive sensory measurements in the future, then Bayesian inference and optimal control become mathematically equivalent.

Optimal control can then be represented with the belief network shown in figure 42.1B. This network is drawn upside-down so as to highlight an important difference between inference and control. In inference, the known quantities (sensory measurements) are near the periphery, while in control, the known quantities (task goals) are deep inside the CNS. Conversely, the outputs of the sensory system are deep inside the CNS, while the outputs of the motor system are close to the periphery. Both diagrams are oriented so that the CNS is up and the periphery is down. One network involves “world states,” and the other involves “plant states”; however, these two notions of state may actually be similar. This is because the motor system has to represent not only the state of the body (plant), but also all relevant aspects of the state of the environment, while the sensory system may not represent all aspects of the world but instead may focus on those relevant to the ongoing behavior.

Thus far, estimation and control have been discussed separately, while in the brain they are performed simultaneously. Can we think of both sensory and motor processing as being part of the same computation? This can be done by combining the two belief networks in figure 42.1 and

performing Bayesian inference on the composite network. The sensory measurements in the past would be real, while those in the future would be fictive. The probability over past states would encode what we believe has already happened, while the probability over future states would encode what we believe will happen if we act optimally. The control problem was set up in such a way that having a prediction about the future is equivalent to specifying a control signal that turns this prediction into reality. Note that such a unified computational scheme would be only approximately optimal, because the controller here was designed with the assumption that the current state is known with certainty. This form of approximation tends to be quite accurate and is often used in control engineering (it is known as certainty equivalence control). The approximation fails when the uncertainty about the state affects the optimal actions, as in tasks that involve tradeoffs between exploration and goal achievement. In that case, the state in the control problem can be augmented with the uncertainty about the state in the inference problem (Simpkins, de Callafon, & Todorov, 2008).

To summarize this section, we described a family of optimal control problems that are mathematically equivalent (i.e., dual) to Bayesian inference. The state costs and the passive dynamics in our formulation are completely general and can be defined in whatever way is necessary. The only constraints are that the control signals must act in the same subspace as the passive dynamics and the control cost must equal the KL divergence between the controlled and passive dynamics. In the continuous-time limit, this control cost reduces to the familiar quadratic energy cost. Control problems that do not satisfy the above constraints do not seem to have exact duals, yet they can often be approximated with problems that satisfy the constraints (Todorov, 2006).

Intermediate representations: Sensory features and motor synergies

On the system level, sensory processing performs a transformation from sensory inputs to inferred states, while motor processing performs a transformation from task goals to motor commands. However, neither transformation is performed monolithically by a single brain area. Instead, multiple brain areas are involved, and most of them use neural representations that correspond to neither the input nor the output of the overall computation but to something in between. Similarly, if we analyze a typical computer program, we will notice that most of the variables that are declared in it are internal variables that represent intermediate results. How do such intermediate representations relate to the overall computation? One way to address (or rather avoid) this question is the computer science way, adapted to neuroscience by Marr (1982). In this approach, one makes a strict distinction between the problem being solved, the

algorithm for solving it, and the implementation of the algorithm in software, hardware, or wetware. While this approach has many merits, a significant drawback is that computational-level analyses tell us little about the underlying neural representations and the interactions among them. In this section, we outline a somewhat different approach that enables us to relate intermediate representations to the overall computation more directly. We will first develop the idea for sensory systems and then see how it applies to motor systems.

Intermediate sensory representations are often called “features” and are thought to be features of the “stimulus.” But what is a stimulus? Is it the sensory input, or is it the relevant aspect of the world reflected in the input? If features are defined as functions of the sensory input, then they do not belong on the computational level, and we are back to Marr’s strict separation. Suppose instead that features are statements about the state of the world. For example, suppose that the activity of an “edge detector” in primary visual cortex is not a statement about the presence of an edge in the retinal image, but a statement about the state of the world that caused the retinal image to contain an edge. In this view, features are part of the generative model (figure 42.3A). The sensory input is modeled as a (probabilistic) function of the features instead of the other way around. Bayesian inference can be applied to such a hierarchical generative model without modification. One prediction is that at every intermediate level of sensory processing, there will be both bottom-up and top-down effects. This is because the probability of any variable in a belief network generally depends on all other variables. The beauty of this approach is that different levels of the generative model can be instantiated in different brain areas, and as long as the communication within and between areas corresponds to Bayesian inference, the entire distributed system will perform a single computation, using perhaps a single algorithm (see below) that operates in parallel on multiple representations.

Let us now apply the same idea to the motor system. The closest analog of a sensory feature in motor control is the notion of a motor synergy. It corresponds to some intermediate representation that is more abstract than the full musculoskeletal state but more detailed than the task goal. By analogy to the sensory system, we propose that synergies are part of a hierarchical generative model, which in the case of the motor system is a (probabilistic) mapping from plant states to task goals. Synergies are often thought to be related to motor commands rather than plant states; however, recall that in our formulation, motor commands are implicit and can be recovered from the probability of the future states under the optimal controls. As illustrated in figure 42.3B, synergies can be used for both spatial and temporal abstraction. For example, a synergy might be a statement about the shape of the fingertip trajectory over a short period of time.

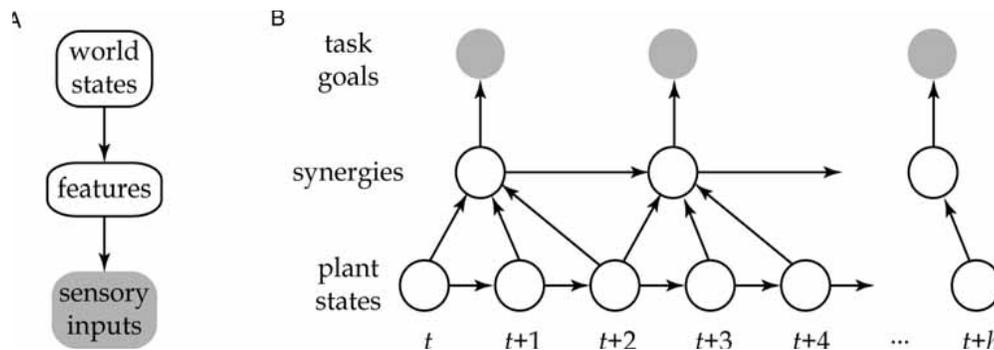

FIGURE 42.3 Belief networks for hierarchical Bayesian inference and optimal control. (A) By defining intermediate sensory representations (features), we can construct hierarchical generative models. The features become part of the model of how sensory inputs depend on states of the world. They are not needed to build generative models but presumably facilitate the inversion of such models using Bayesian inference. (B) By defining intermediate motor representations (synergies) that depend on only some aspects of the state but over extended periods of time, we can achieve both

spatial and temporal abstraction. This is done by using cost functions of the form $q(h(x_t \dots x_{t+d}))$, where h are the synergy states and d is the temporal abstraction horizon. The synergies become part of the model of how goal achievement depends on the plant state. Control is about achieving goals that are removed in time, which requires unfolding the time axis and representing multiple time steps. Limiting this unfolding to a fixed number of steps into the future is called receding horizon control. At the horizon $t + h$, we need some approximation of the desirability function $z(x_{t+h})$.

The fact that the synergy corresponds to a period of time and not a single point in time yields temporal abstraction. The fact that the synergy corresponds to only some aspects of the state of the plant and not the entire state (e.g., it does not specify all the joint angles but only the fingertip position) yields spatial abstraction. Different forms of spatial and temporal abstraction have played an important role in designing automatic controllers for complex tasks, suggesting that the brain may also rely on such tools.

Thus intermediate representations in both sensory and motor systems can be thought of as being part of hierarchical generative models. One might ask, however, what is the point of having such representations when generative models can be built without them. For example, given the full state of the arm, we can directly compute where the fingertips are, without the help of motor synergies. Similarly, we can directly compute the retinal image resulting from a given configuration of three-dimensional objects and light sources, without relying on sensory features (this is what computer graphics does). Indeed, intermediate representations not only are unnecessary to build generative models, but may even complicate the construction of such models. However, the goal of both the sensory and motor systems is not so much to build generative models but rather to invert them. The inversion is the harder problem and is also the problem that has to be solved in real time. Intermediate representations are likely to facilitate this inversion, by providing various forms of abstraction and enabling the inference algorithm to construct the final answer in manageable pieces. Thus intermediate representations may exist not for the sake of representation but because they facilitate the computation.

One might also ask where intermediate representations come from. In sensory systems, it has been shown that unsupervised learning applied to collections of natural sensory inputs can recover the features that are observed experimentally. The most notable examples come from the visual system (Olshausen & Field, 1996), although the approach has also been applied successfully to the auditory system (Lewicki, 2002). Unsupervised learning looks for statistical regularities in high-dimensional data. Traditional unsupervised learning methods such as principal components analysis reduce the dimensionality of the data. In contrast, the forms of unsupervised learning that are thought to be used by sensory systems tend to increase dimensionality, that is, they form overcomplete (and sparse) representations. This might seem counterproductive; however, it resonates well with recent computational approaches in which increasing dimensionality simplifies computation. Support vector machines and kernel methods in general are based on this idea (Scholkopf & Smola, 2001). Liquid state machines in neuroscience have the same flavor (Maass, Natschlagler, & Markram, 2002).

Unsupervised learning has also been applied in motor control to extract candidate synergies (D'Avella, Saltiel, & Bizzi, 2003; Santello, Flanders, & Soechting, 1998). However, the situation here is qualitatively different. While in sensory systems, unsupervised learning is applied to sensory data that are available to the brain during learning/development, in motor systems, it is applied to movement data that are available to the brain only after it has mastered the motor task. If we agree that appropriate synergies must exist before successful movements can be generated in a given task, then the brain cannot learn those synergies from successful move-

ments. In other words, the unsupervised learning methods that are used by motor control researchers are not a feasible model of learning by the motor system. A feasible model should learn on the basis of information that is available at the time of learning. The one thing that is always available is the input, which in the case of the motor system corresponds to the task goals. Thus the analog of learning features from sensory inputs would be learning synergies from task goals. Unfortunately, the task goals are not directly accessible to an external observer, so the application of unsupervised learning as outlined here is not easy; yet we suspect that it is worth pursuing.

Another insight into motor synergies that comes from the analogy with sensory systems is the number of synergies. It is widely believed that motor synergies serve the purpose of dimensionality reduction; indeed, they are usually defined as the outputs of dimensionality reduction algorithms. However, as was discussed earlier, dimensionality expansion rather than reduction may be more beneficial in terms of simplifying computation. Furthermore, the number of different neural activation patterns in, say, primary motor cortex greatly exceeds the number of musculoskeletal degrees of freedom. If we agree to think of neural activity in motor areas as representing synergies, in the same way that we think of neural activity in sensory areas as representing features, the dimensionality expansion point of view becomes unavoidable.

This view represents a significant departure from the established thinking about motor synergies and might at first seem incompatible with the evidence that large amounts of variance (in movement kinematics, electromyograms, or isometric forces) can be explained by small numbers of components. How can behavioral evidence for dimensionality reduction be reconciled with intermediate representations performing dimensionality expansion? One answer comes from our work on optimal control (Todorov & Jordan, 2002; Todorov, 2004), in which we showed that an optimally controlled redundant system will exhibit signs of dimensionality reduction regardless of how the controller is implemented. If that is the case and the motor system is good at approximating optimal controllers, then a lot of the dimensionality reduction results that are currently taken as evidence for synergies might instead be indirect evidence for optimality. The overcomplete intermediate representations that we propose to call synergies may be the mechanism that enables the motor system to perform near optimally.

Algorithms for learning and online computation

Bayesian inference and optimal control are of interest in many fields (e.g., statistics, computer science, signal processing, control engineering, economics). Consequently, many

algorithms have been developed. While none of them can yet compete with biological sensory and motor systems on complex real-world problems, this repository of algorithmic knowledge is an important source of insights into what the brain might be doing. We refer the reader to the work of Doya and colleagues (2007) for an extended discussion. Here, we make only a few points that are relevant to this chapter.

One class of Bayesian inference algorithms, known as belief propagation (Pearl, 1988), are reminiscent of computation in recurrent neural networks except that the messages that are being exchanged are probability distributions (presumably encoded by populations of neurons). The analog in optimal control is dynamic programming, which for the family of control problems described above is reduced to belief propagation. An important corollary of the estimation control duality is that sensory population codes that are thought to represent probability distributions (Doya et al., 2007) can be equally useful in motor control. Both belief propagation and dynamic programming are global methods in the sense that they aim to compute functions over the entire state space. For large problems, this is unlikely to be doable in real time. In the control domain, this point is well appreciated; indeed, dynamic programming is normally applied off-line so as to precompute/learn the optimal control law. The latter is then used online to generate motor commands as a function of plant states and goal parameters (e.g., target positions). The equivalent in Bayesian inference would be to learn a direct mapping from sensory inputs to state estimates, which is not how people usually think about inference. There may be several reasons for this: (1) The input to the sensory system is so high-dimensional that learning such a mapping is infeasible; (2) inference is an easier problem than control (recall our discussion of redundancy), so the computation is easier to perform online; and (3) the brain actually learns direct mappings from sensory inputs to estimated states, but this is not yet reflected in most Bayesian inference algorithms. One exception here is the Helmholtz machine (Dayan, Hinton, Neal, & Zemel, 1995), which is a belief network augmented with a mechanism for learning the direct mapping discussed above (i.e., the inverse of the generative model).

Regardless of whether and how much of the transformation is learned, it is clear that a lot of processing takes place in real time in both the sensory and motor systems. There is a simple way to combine the advantages of learning and on-line computation: Learn a global but approximate transformation, use it on-line for initialization, and then apply an on-line algorithm to refine the solution locally around the current state. Locally, probabilities and costs can be approximated by simplified models (e.g., Gaussians and quadratics), which afford faster computation. Such local approximation

methods are available in both estimation (the extended Kalman filter) and control (iterative LQG or differential dynamic programming). In the case of control, local improvement requires unfolding the time axis up to a certain horizon. This is known as receding horizon control. For our family of control problems, it is illustrated with the belief network in figure 42.3B. If the motor system relies on such methods, we should expect to find neurons coding the state of the plant at multiple points in time in the future. Indeed, it has often been noted (e.g., Kalaska, Sergio, & Cisek, 1998) that the latency between neural firing and motor behavior has a broad distribution and, on average, is substantially longer than what one would expect from conduction latencies alone. Such data can tell us how much unfolding is taking place in the motor system. The answer is on the order of 200 ms for reaching movements, although more complex tasks (for which we do not have data) may require unfolding over longer time horizons.

Bayesian inference problems can also be solved by using sampling methods. An example is Gibbs sampling, which works by choosing a node to be updated, resampling its value from the conditional probability given the current values of its neighbors, choosing another node, and so on. After a “burn-in” period, the samples that are generated in this way match the correct Bayesian posterior. The estimation-control duality makes it possible to apply sampling algorithms to optimal control problems as well. Sampling algorithms have not been seriously considered as models of brain function, but perhaps they should be, for several reasons. First, these are the only algorithms that are actually guaranteed to solve the problem (even though it may take a long time). All other algorithms when applied to continuous state variables require function approximation and, as a result, may never converge or may converge to the wrong answer. Second, sampling is inherently parallel. Other algorithms can be parallelized but not to the same extent. This is an important consideration, given the staggering number of neurons in the brain. Third, sampling is inherently stochastic. Implementing it in a deterministic computer requires a pseudo-random number generator. The brain has internal sources of noise (e.g., failures of synaptic transmission) that could be used as random number generators, implying that neural noise may be a feature rather than a nuisance.

In summary, a range of algorithms for Bayesian inference and optimal control have been developed in multiple fields. Furthermore, the estimation control duality makes it possible to take estimation algorithms and apply them to control problems and vice versa. Such algorithms are very relevant to neuroscience because they solve the same problems that the sensory and motor systems appear to be solving. Which of these algorithms resemble the ones used by the brain is not yet clear (but see Doya et al., 2007). Algorithmic issues

have generally received limited attention in neuroscience, perhaps because they are hard to address experimentally. This is in contrast to system-level computations, which can be addressed by using behavioral data, and neural representations, which can be addressed by using single neuron data. Indeed, a lot is already known about both system-level computations and neural representations, in both the sensory and motor systems. This knowledge imposes strong constraints, which, in conjunction with algorithmic insights from multiple fields, may soon enable us to go after the brain’s algorithms in a systematic way.

43 The Mirror Neuron System: A Motor-Based Mechanism for Action and Intention Understanding

GIACOMO RIZZOLATTI, LEONARDO FOGASSI, AND VITTORIO GALLESE

ABSTRACT In this chapter we provide evidence that the cortical motor system is involved in action and intention understanding. In the first part of the chapter, we show that at the core of the cortical motor system, formed by ventral premotor and inferior parietal cortex, there are vocabularies of motor acts, such as grasping, holding, and breaking. Neurons that form these vocabularies code the goal of motor acts independent of how the goal is achieved. Many of these motor neurons also respond to the observation of the same motor acts they motorically code (mirror neurons). In the second part, we show that mirror neurons are involved in both the understanding of motor acts done by others and the understanding of the intention behind the acts. In the last part of the chapter we show that the mirror system in humans also plays a role in action and intention understanding. We conclude by presenting data suggesting that some of the deficits present in the autistic syndrome could be caused by an impairment of the mirror system.

Traditionally, it has been assumed that understanding actions done by others, and even more so their intentions, occurs by applying a kind of reasoning not much different from that used to solve a logical problem. According to this view, when witnessing the actions of others, we process the actions with our sensory system; this information is then elaborated by some sophisticated cognitive apparatus and compared with other similar, previously stored data. At the end of this process, we know what others are doing and why.

Such complex cognitive operation likely occurs in many situations, for example, when the behavior of the observed person is difficult to interpret (Brass, Schmitt, Spengler, & Gergely, 2007). Yet the simplicity and lack of effort with which we usually understand what the others are doing suggest an alternative solution. The actions done by others,

after being processed in the observer's visual system, are directly mapped on his or her motor representations without any need of cognitive mediation.

Strong evidence in favor of the existence of a direct mechanism of understanding others' actions by matching them on the observer's own motor system came from the discovery of mirror neurons (MNs), a class of visuomotor neurons that discharge both when a monkey performs goal-related motor acts (e.g., grasping) and when it observes or hears another individual (monkey or human) doing similar acts. Neurons with these properties are found in the rostral sector of the ventral premotor cortex (area F5) and in a sector of the posterior parietal cortex (essentially corresponding to area PFG) that is anatomically connected with area F5. Thus, premotor and parietal MNs form a cortical mirror neuron system that translates sensory information about biological actions into a motor format.

There is evidence that in addition to the parietofrontal mirror neuron system, there are other mirror systems, at least in humans. One, most likely present also in monkeys, is involved in translating observed emotions into a visceromotor pattern that expresses the same emotions (see Gallese, Keysers, & Rizzolatti, 2004). In addition, humans are endowed with a mirror system for phonemes (Fadiga, Craighero, Buccino, & Rizzolatti, 2002) and one for coding non-goal-directed movements (Fadiga, Fogassi, Pavesi, & Rizzolatti, 1995).

In the present chapter, we will focus on the parietofrontal mirror system for actions. We will first review the anatomical and functional properties of the mirror system in monkeys and humans and address the issue of how action is represented within primates cortical motor system. We will then discuss a neurophysiological model of how actions and the intentions that promote them are understood. Finally, we will discuss some implications of this model for our understanding of autism.

Mirror neuron system in monkeys

ANATOMY OF THE MIRROR NEURON SYSTEM MNs were first discovered in area F5, which occupies the rostralmost sector of ventral premotor cortex. This region has recently been parcellated (Nelissen, Luppino, Vanduffel, Rizzolatti, & Orban, 2005; Belmalih et al., 2009) into three sectors occupying the cortical convexity (F5c), the posterior bank of the inferior limb of the arcuate sulcus (F5p), and the fundus of the inferior limb of the arcuate sulcus (F5a) (figure 43.1). MNs are generally found in area F5c.

Parietal MNs have been found in the rostral part of the inferior parietal lobule (IPL) convexity (see Rizzolatti & Craighero, 2004), particularly in area PFG (Pandya & Seltzer, 1982; Gregoriou, Borra, Matelli, & Luppino, 2006), and in the anterior intraparietal area (AIP).

Both these areas are connected with the cortex located inside the superior temporal sulcus (STS), including two areas that are selectively active during hand action observation: STPm and LB2 (Nelissen et al., 2005; Perrett et al., 1989). The first one is specifically connected with PFG, while the other, which is also shape sensitive, conveys information to AIP.

Hodological studies (Matelli, Camarda, Glickstein, & Rizzolatti, 1986; Rozzi et al., 2006) showed a reciprocal pattern of connectivity between areas PFG, AIP, and F5. Given the similarity between the functional properties of premotor and parietal MNs, these anatomical data corroborate the idea that areas F5, PFG, and AIP constitute the mirror system for action. As far as the STS areas are concerned, although fundamental for providing visual information on biological motion, they cannot be considered as

part of the mirror system in a strict sense, because they do not appear to have motor properties.

GOAL-RELATEDNESS AND GOAL-CHAINING IN THE VENTRAL PREMOTOR CORTEX AND IN THE INFERIOR PARIETAL LOBULE The functional properties of MNs can be better understood by framing them within the conception that the basic organization of the cortical motor system is in terms of goal-directed movements (Rizzolatti, Luppino, & Matelli, 1998; Rizzolatti, Fogassi, & Gallese, 2000; Crutcher & Alexander, 1990; Alexander & Crutcher, 1990; Kakei, Hoffman, & Strick, 1999, 2001; Hoshi & Tanji, 2000) and not in terms of elementary body part displacements, as was classically thought. Goal-directed movements (i.e., motor acts) are the nuclear building blocks around which action is organized and understood (Rizzolatti et al., 1988; Murata et al., 1997; Raos, Umiltà, Fogassi, & Gallese, 2006; Umiltà et al., 2008).

Particularly important for establishing this concept have been the studies in which single neurons were recorded in a naturalistic context. These studies showed that, typically, the discharge of F5 neurons correlates much better with a motor act than with the movements forming it. Thus many neurons discharge when a motor act (e.g., grasping) is performed with effectors as different as the right hand, the left hand, or the mouth. Furthermore, for the vast majority of neurons, the same type of movement (e.g., an index finger flexion) that is effective in triggering a neuron during a motor act (e.g., grasping) is not effective during another one (e.g., scratching).

By using motor act as classification criterion, F5 neurons were subdivided into various categories such as “grasping-

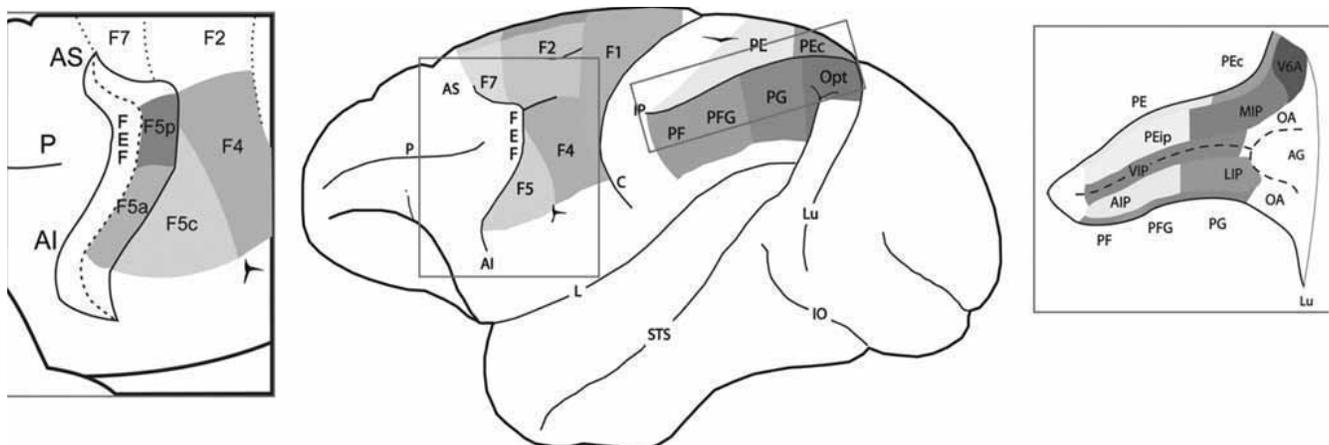

FIGURE 43.1 Lateral view of the monkey brain showing the parcellation of the motor and the posterior parietal cortex. The areas located within the arcuate and the intraparietal sulcus are shown in an unfolded view of these sulci in the left and right parts of the figure, respectively. For the nomenclature and definition, see Rizzolatti, Luppino, and Matelli (1998), Nelissen et al. (2005), and

Gregoriou et al. (2006). Abbreviations: AI, inferior arcuate sulcus; AS, superior arcuate sulcus; C, central sulcus; FEF, frontal eye-fields; IP, intraparietal sulcus; IO, inferior occipital sulcus; L, lateral fissure; Lu, lunate sulcus; P, principal sulcus; STS, superior temporal sulcus. (See color plate 54.)

with-the-hand-and-the-mouth” neurons, “grasping-with-the-hand” neurons, “holding” neurons, “tearing” neurons, and “manipulating” neurons.

In each class, many neurons (about 80%) code specific types of hand shaping, such as precision grip (the grip type most represented), whole hand prehension, and finger prehension. Whether they are specific or not for a certain type of prehension, these neurons show a variety of temporal relations with the prehension phases. Some neurons discharge during the whole motor act, sometimes starting to fire at stimulus presentation. Some other neurons are mostly active during the opening of the fingers, and some are mostly active during finger closure (see Jeannerod, Arbib, Rizzolatti, & Sakata, 1995).

On the basis of these properties, it has been suggested that F5 contains a “vocabulary” (a storage) of *motor act representations*. The vocabulary is constituted by “words,” each of which is represented by a set of F5 neurons. Some words indicate the general goal of a motor act (grasping, holding, tearing, etc.). Other words indicate the way in which a specific motor act must be executed (e.g., precision grip or finger prehension). Finally, other words are concerned with the temporal segmentation of the motor act into smaller chunks, each coding a specific phase of the grip (e.g., hand opening, hand closure).

A crucial demonstration of this notion was recently achieved by Umiltà and colleagues (2008). In this study, hand-related neurons were recorded from premotor area F5 and the primary motor cortex (area F1) in monkeys that had been trained to grasp objects using two different tools: “normal pliers” and “reverse pliers” (figure 43.2A). These tools require opposite movements to grasp an object: With normal pliers, the hand has to be first opened and then closed, as when grasping is executed with the bare hand; with reverse pliers, the hand has to be first closed and then opened. The use of the two tools enabled the researchers to dissociate the neural activity related to hand movement from that related to the goal of the motor act.

All tested neurons in area F5 and half of neurons recorded from the primary motor cortex discharged in relation to the accomplishment of the goal of grasping—when the tool closed on the object—regardless of whether in this phase the hand opened or closed, that is, regardless of the movements that were employed to accomplish the goal (figure 43.2B). These data indicate that goal coding is at the basis of the organization of grasping in area F5 and also in the primary motor cortex, although to a minor extent. Goal coding is therefore not an abstract, merely mentalist and experience-independent property, but a distinctive functional feature upon which the cortical motor system is organized.

An organization based on goal-directed hand motor acts is also present in AIP and in PFG (Murata et al., 2000;

Fogassi et al., 2005; Rozzi, Ferrari, Bonini, Rizzolatti, & Fogassi, 2008). In both these areas, there are neurons that code specific motor acts and specific types of grips. At present, there are no systematic studies in which the functional properties of these areas have been compared with F5. As far as one can deduce from the available studies, there are strong similarities between neurons with motor properties in these areas (Raos et al., 2006). Taken together, these data indicate that the rostral part of the inferior parietal lobule is functionally part of the motor system in the same way as the premotor areas that belong to it.

Recent data by Fogassi and colleagues (2005) showed that the discharge of IPL neurons coding grasping is influenced by the action in which grasping is embedded. In this study, PFG grasping neurons were tested in two main conditions. In one, the monkey reached for and grasped a piece of food located in front of it and brought the food to its mouth. In the other, the monkey reached for and grasped an object and placed it into a container (figure 43.3A). The results showed that the majority of the recorded neurons discharged with a different intensity depending on the final goal of the action (eating or placing) in which grasping was embedded (“action-constrained” neurons) (figure 43.3B). A series of controls for grasping force, kinematics of reaching movements, and type of stimuli showed that neuron selectivity was not due to these factors. Thus, the differential discharge of these grasping neurons appeared to reflect the goal of the action of which the motor act was part. A similar organization has recently been reported for area F5 (Fogassi et al., 2007).

These neural properties suggest that most neurons of the PFG-F5 circuit code individual motor acts (e.g., grasping) in prewired chains, each of them coding a specific action (e.g., eating). This organization is very appropriate for providing fluidity to action execution, because each neuron not only codes a specific motor act, but, being embedded into a specific action, is also linked with neurons that code the next motor acts and possibly facilitates them. In favor of a model that assumes a facilitatory interaction between neurons forming a given chain is the organization of the receptive fields of IPL. For example, there are IPL neurons that respond to passive stimulation of the hand, flexion of the forearm, and discharge during mouth grasping (Yokochi, Tanaka, Kumashiro, & Iriki, 2003; Rozzi et al., 2008). These data support the existence of chains of neurons that code specific actions such as that of bringing food to the mouth.

FUNCTIONAL PROPERTIES OF MNS As has already been stated, mirror neurons are a distinct class of visuomotor neurons that discharge both when individuals perform a specific motor act *and* when they observe the same motor act done by another individual (figure 43.4). Among the motor acts that they code both visually and motorically, the most

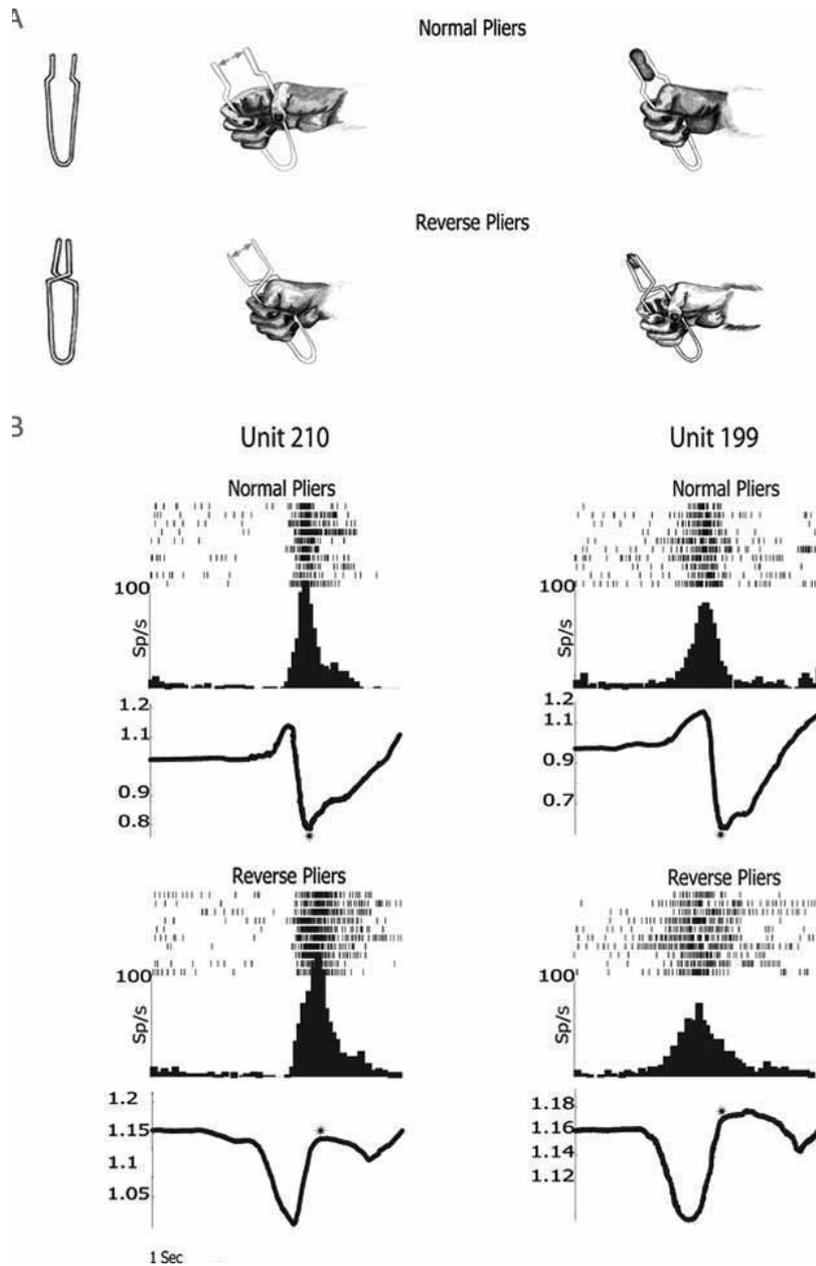

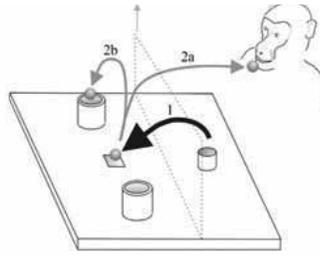

FIGURE 43.2 Examples of F5 neurons active during execution of grasping with normal and reverse pliers. (A) Illustration of the experimental paradigm. To grasp the object with the normal pliers (upper part), the monkey has to close its hand, while to grasp the object with the reverse pliers (lower part), the monkey has to open its hand. (B) Two neurons recorded in area F5. Rasters and histograms are aligned with the end of the grasping closure phase

(asterisk). The traces below each histogram indicate the hand position, recorded with a potentiometer, expressed as a function of the distance between the pliers handles. When the trace goes down, the hand closes; when the trace goes up, it opens. The values on the vertical axes indicate the voltage change measured with the potentiometer. (Modified from Umiltà et al., 2008.)

represented are grasping, holding, manipulating, and tearing. Unlike another category of visuomotor neurons that are present in area F5 (“canonical neurons”) (Murata et al., 1997; Raos et al., 2006), they do not fire in response to simple presentation of objects, including food. The observation of intransitive motor acts, including mimed motor acts, is also ineffective.

Mirror neurons show a close relationship between their visual and motor responses. Using as classification criterion the congruence between the executed and observed motor acts that are effective in triggering them, mirror neurons have been subdivided into two broad classes: strictly congruent and broadly congruent neurons (Gallese, Fadiga, Fogassi, & Rizzolatti, 1996). They are defined as *strictly congruent* when

Motor responses of parietal neurons

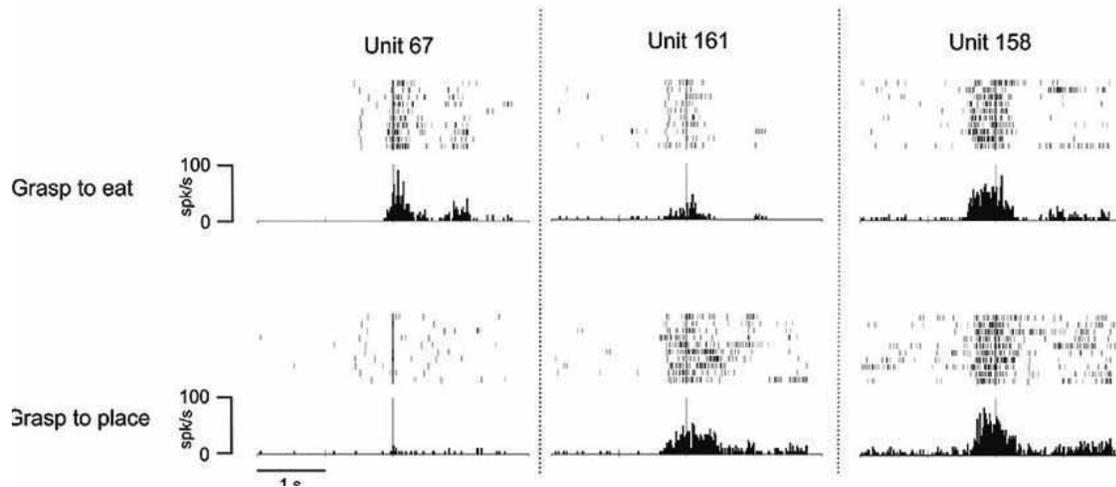

FIGURE 43.3 Examples of the activity of parietal motor neurons during execution of two different actions. (A) Apparatus and paradigm used for the motor task. In one condition (grasping for eating), the monkey reached for and grasped a piece of food located on a plane in front of it (1) and brought the food to its mouth (2a). In another condition (grasping for placing), the monkey reached for and grasped an object located in front of it (1) and placed the object into a container (2b). In the first condition, the monkey ate the food that it had brought to the mouth; in the second condition, the monkey was rewarded after correct accomplishment of the task. (B) Activity of three IPL neurons during grasping in the two experi-

mental conditions. Unit 67 discharges were stronger during grasping to eat than during grasping to place, Unit 161 discharges were stronger during grasping to place. Unit 158 did not show any difference in discharge between the two conditions. Rasters and histograms are aligned with the moment when the monkey touched the object or food to be grasped. Red bars: Monkey releases the hand from the starting position. Green bars: Monkey touches the container. Abscissa: Time, bin = 20 ms; Ordinate: Discharge frequency in spikes per second. (Modified from Fogassi et al., 2005.) (See color plate 55.)

the observed and executed effective motor acts are identical in terms of goal (e.g., grasping) and in terms of the way in which that goal is achieved (e.g., precision grip). In contrast, mirror neurons are defined as *broadly congruent* when there is a similarity, but not identity, between the observed and executed effective motor acts. Among the different types of broadly congruent neurons, the most common is constituted of neurons that become active during the execution of a specific motor act made by the monkey (e.g., grasping, holding, or manipulating) but visually respond to more than one motor act (e.g., manipulation and grasping).

In the first studies on mirror neurons, it was reported that these neurons do not discharge during the observation of goal-directed actions done by using tools (Gallese et al., 1996; Rizzolatti, Fadiga, Gallese, & Fogassi, 1996). Subsequently, however, it was shown that following a rela-

tively long period during which monkeys observed the experimenters performing actions using tools, some mirror neurons respond, although weakly, also to this type of action (Rizzolatti & Arbib, 1998). More recently, Ferrari, Rozzi, and Fogassi (2005) reported that in a specific ventral sector of F5, there are neurons that discharge very vigorously to the observation of tool use (e.g., a stick or a pair of pliers). It is not clear whether these neurons, like those previously observed, derived this property because of prolonged action observation.

The most widely accepted hypothesis on the functional role of mirror neurons is that they play a role in understanding the goal of the observed motor acts (Rizzolatti et al., 2000). The proposed mechanism is the following: individuals know the outcome of their motor acts. Thus, when the mirror neurons of an observing individual, which code a

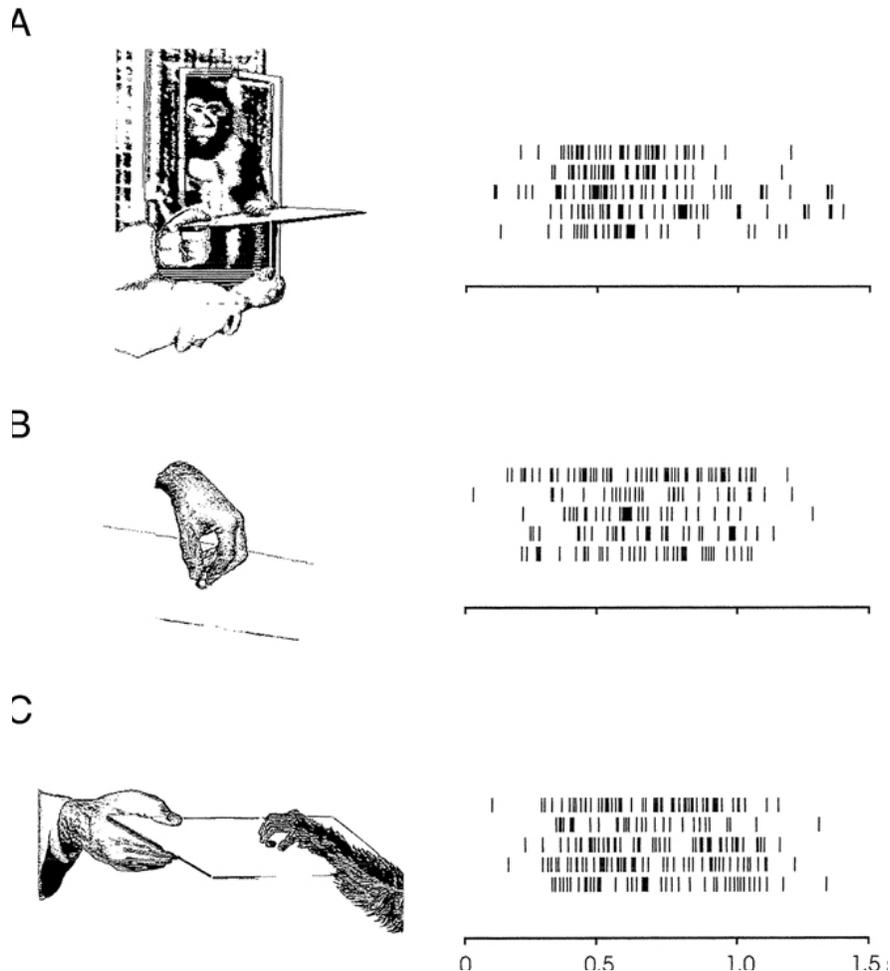

FIGURE 43.4 Example of the activity of an F5 mirror neuron during the observation of a grasping movement performed by another monkey (A) or an experimenter (B) and during execution of grasping by the recorded monkey (C). (Modified from Rizzolatti et al., 1996.)

given motor act (e.g., grasping), discharge in response to the observation of that motor act (grasping) done by another individual, the observer understands its goal, because that discharge corresponds to the one that occurs when the observer wants to achieve the same goal.

To provide evidence in favor of the view that mirror neurons play a role in understanding motor acts done by others, neurons' responses were investigated when the monkeys could comprehend the goal of a motor act without actually seeing it. If mirror neurons truly mediate understanding, their activity should reflect the meaning of the motor act rather than its visual features. Two series of experiments were carried out for this purpose.

The first series tested whether mirror neurons could recognize motor acts merely from their sounds (Kohler et al., 2002). The activity of mirror neurons was recorded while a monkey was observing a motor act, such as ripping a piece of paper or breaking a peanut shell, that is normally accompanied by a distinctive sound. Then the monkey was presented with the sound alone. It was found that many mirror

neurons that had responded to visual observation of acts accompanied by sounds also responded to the sound alone. These neurons were named “audiovisual” mirror neurons.

In the second series of experiments, the researchers hypothesized that if mirror neurons are involved in understanding a motor act, they should also discharge when the monkey does not actually see the motor act but has sufficient clues to create a mental representation of it. Therefore, F5 mirror neurons were tested in two conditions. In one, the monkey was shown a fully visible motor act directed toward an object (“full vision” condition). In the other, the monkey saw the same act but with its final critical part hidden (“hidden” condition) (Umiltà et al., 2001). The results showed that more than half of F5 mirror neurons also discharged in the hidden condition. An example is shown in figure 43.5.

These experiments strongly support the notion that the activity of mirror neurons underpins the understanding of motor acts. Even when the motor act comprehension is possible on a nonvisual basis, such as via sound or nonlinguistic

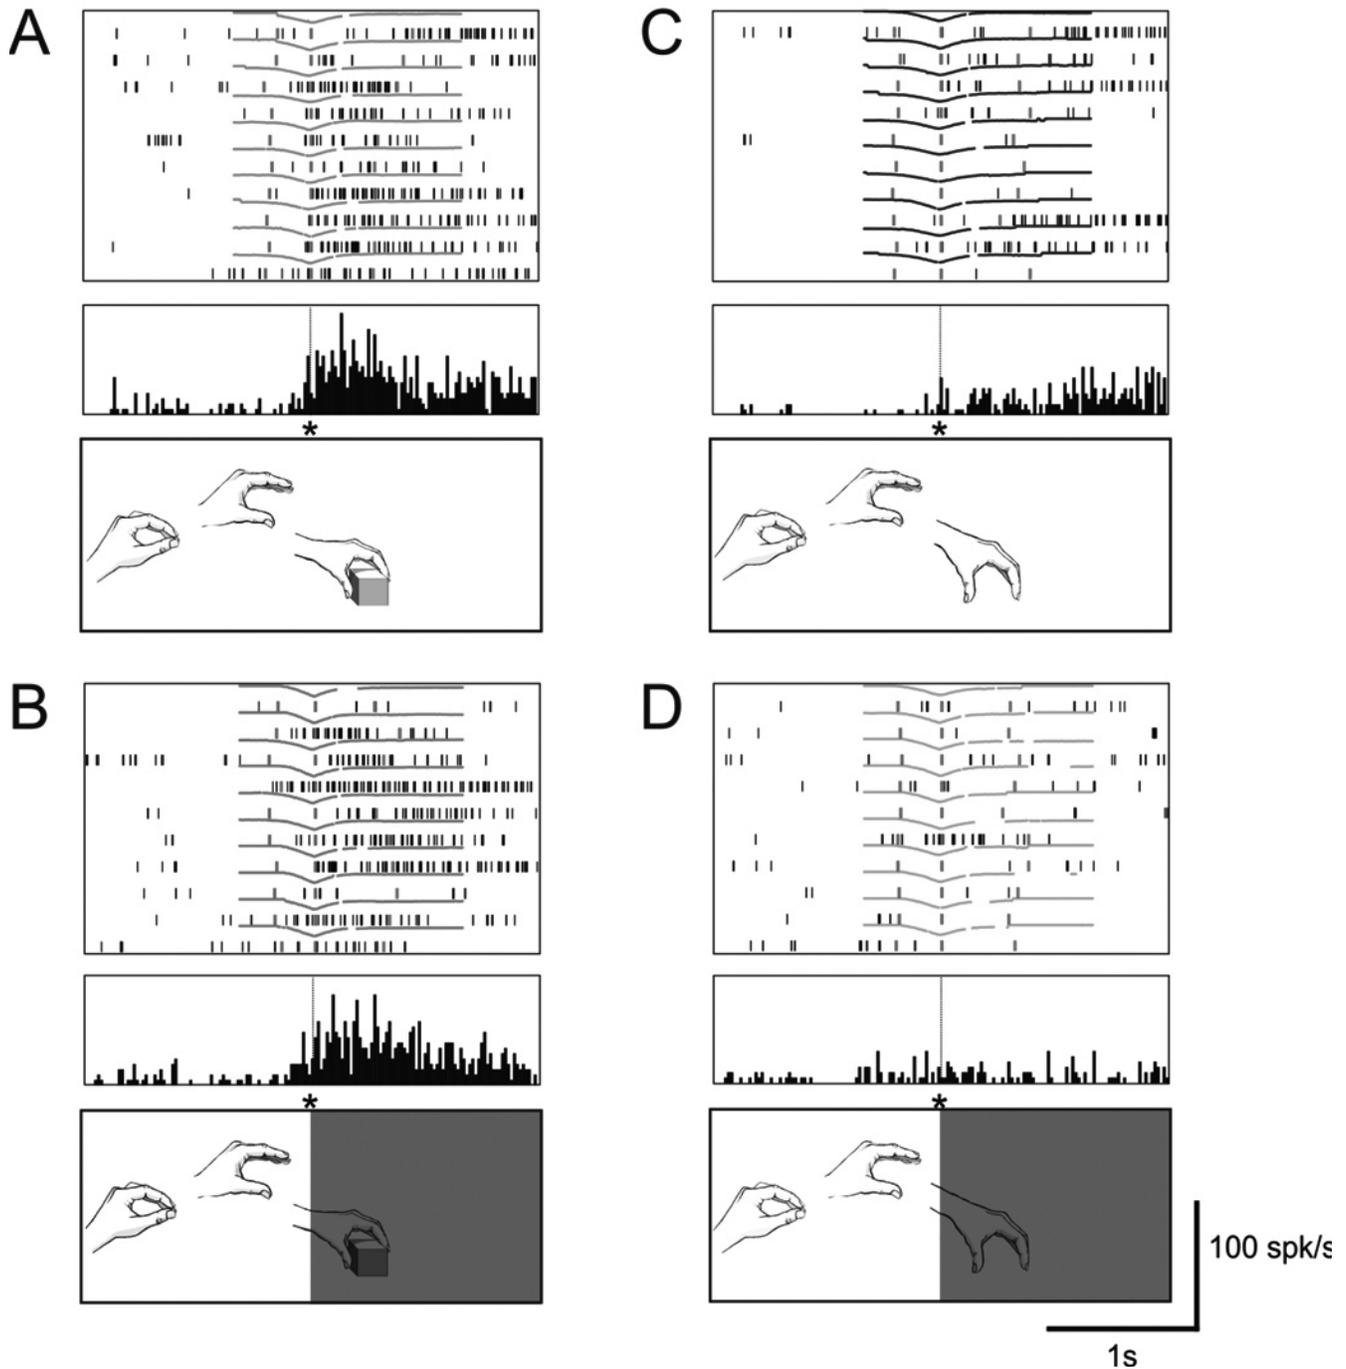

FIGURE 43.5 Example of a mirror neuron responding during observation of grasping in both full vision and “hidden” condition. (*A* and *C*): Observation of goal-directed or mimed grasping, respectively, in full vision. (*B* and *D*): Observation of goal-directed or mimed grasping, respectively, in the hidden condition. In every panel, from top to bottom, rasters and histogram and the schematic drawing of the experimenter motor act are shown. The gray frame in conditions *B* and *D* represents a screen interleaved between the monkey and the experimenter hand in the two hidden conditions.

The asterisk indicates the location of a stationary marker that was attached at the level of the crossing point where the experimenter’s hand disappeared behind the screen in the hidden conditions. The colored line above each raster represents the kinematics of the experimenter’s hand movement; the downward deflection of the line means that the hand is approaching the stationary marker (the minimum corresponding to the moment in which the hand is closest to the marker). Histograms bin width = 20 ms. (Modified from Umiltà et al., 2001.) (See color plate 56.)

mental representation, mirror neurons equally discharge, signaling the goal of the motor act.

Early studies on mirror neurons examined the dorsal-most sector of F5, where hand motor acts are mostly represented. Recently, a study was carried out on the properties of neurons located in the most ventral part of F5, where neuron activity is mostly related to mouth actions (Ferrari, Gallese, Rizzolatti, & Fogassi, 2003). The results showed that two classes of mouth mirror neurons could be distinguished: ingestive and communicative mirror neurons. Ingestive mirror neurons, which represent the majority of mouth mirror neurons, respond to the observation of motor acts related to ingestive functions (e.g., grasping food with the mouth). Virtually all of them show a good correspondence between the effective observed and the effective executed motor act. More intriguing are the properties of the communicative mirror neurons. For them, the most effective observed motor act is a communicative gesture, such as lip smacking. However, most of them strongly discharge also when the monkey actively performs an ingestive motor act. The presence of a motor response during both communicative and ingestive motor acts is rather intriguing. However, it could be explained by ethological observations suggesting that in evolution, monkeys' communicative gestures derived, at least in part, from ingestive motor acts (Van Hoof, 1962, 1967; Maestriperi, 1996).

Intention understanding

Before we discuss the role of mirror neurons in intention understanding, it is important to define the terms *motor act* and *motor action*. *Motor act* describes a movement or, most commonly, a series of movements performed to achieve a goal (e.g., grasping an object). *Motor action* describes a series of motor acts (e.g., reaching, grasping, bringing to the mouth) that allow individuals to fulfill their intention (e.g., eating). When an individual observes a motor act, he or she understands the *what* of the motor act (e.g., grasping an object) but typically is also able to make inferences about *why* the motor act is being performed (e.g., grasping for eating), that is, the intention behind the action of which that motor act is part.

As was described above, grasping neurons in both parietal and premotor cortex discharge with a different intensity according to the final goal of the action in which the grasping act is embedded (action-constrained neurons). Further experiments investigated whether action-constrained neurons also had mirror properties and whether their visual response during grasping observation was influenced by the action goal in which grasping was embedded (Fogassi et al., 2005, 2007). To this purpose, neurons were tested in the same two conditions that were used for studying their motor

properties. Instead of grasping objects, monkeys observed the experimenter performing the two actions (grasping for eating and grasping for placing).

The results showed that the majority of mirror neurons in the two areas were differently activated when the observed motor act belonged to one action or another. Examples are shown in figure 43.6.

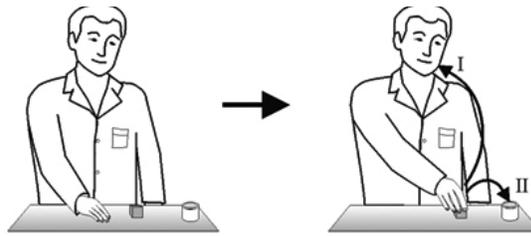

What could be the explanation of this neuron behavior? It is very likely that when an action-constrained grasping neuron is activated by the observation of a grasping motor act inserted into its motor action, its discharge triggers the whole motor chain of the observer underpinning the same action. In this way, the observer activates an internal motor representation of the action that the observed agent intends to do. Thanks to this mechanism, the observer understands the observed agent's intention.

One may ask how action observation can activate the appropriate motor chain when the monkey actually sees only the first motor act of it. A systematic study of this problem has not been done. It is clear, however, from the grasping neuron behavior that an important factor in determining the neuron discharge is the type of stimulus with which the agent interacts. Food, for example, tends to activate eating chains as soon as the monkey sees the experimenter grasping the food. Another factor is the statistical probability of a given action. Thus, for example, in a block of trials in which grasping is always followed by placing, grasping neurons that are tuned for placing become active. It is interesting to note that in such a block of trials, if food, rather than an object, is grasped and placed into a container, grasping-to-eat neurons fire initially, then they stop firing while grasping-to-place neurons become active.

MIRROR-LIKE ACTIVITY Recent data suggest that neurons in dorsal premotor and primary motor cortex discharge during execution and observation of trained arm movements directed toward a target.

In one study (Cisek & Kalaska, 2005), monkeys were trained to move a cursor from a central position to a peripheral position on a screen defined by a color cue. The recorded neurons discharged both when the monkey performed the learned task and when the monkey, being still, observed another party moving the cursor in the correct direction. The discharge typically occurred at the presentation of the target and increased with the cursor movement. Unlike mirror neurons, these neurons did not require the observation of an effector-object interaction. One may postulate, however, that the cursor was an abstract substitute for a moving hand and that the occurrence of the stimulus evoked the mental representation of the hand movement.

In another study (Tkach, Reimer, & Hatsopoulos, 2007) monkeys were trained to move repetitively a cursor to targets

Visual responses of mirror neurons

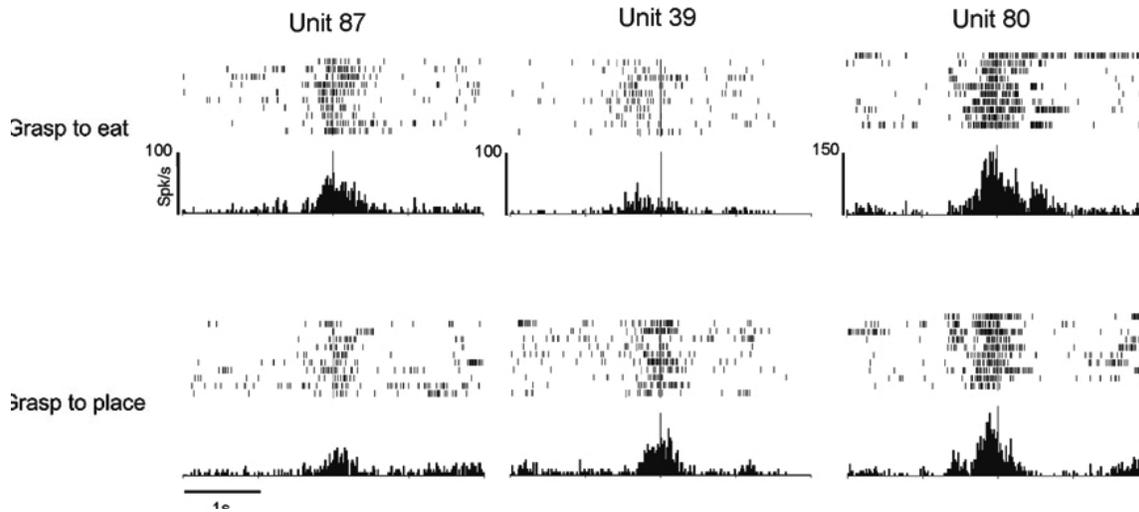

FIGURE 43.6 Examples of visual responses of IPL mirror neurons during the observation of grasping-to-eat and grasping-to-place conditions performed by an experimenter. (A) The paradigm is similar to that used for the motor task shown in figure 43.3, but in this case, the two conditions are performed by the experimenter in front of the monkey, which is simply observing the scene. (B) Activity of three mirror neurons during observation of grasping in the two experimental conditions. Unit 87 discharges are stronger

during observation of grasping to eat than during observation of grasping to place, Unit 39 discharges are stronger during observation of grasping to place. Unit 80 did not show any difference in discharge between the two conditions. Rasters and histograms are aligned with the moment when the experimenter touched the object or food to be grasped. (Modified from Fogassi et al., 2005.) (See color plate 57.)

that appeared at random locations. The experiment consisted of two phases: active movement and observation. In the active movement phase, the monkey controlled the cursor, while in the observation phase, the monkey observed the replayed movements generated in the active phase. The observation phase had three conditions. In the first, both the cursor and the targets were visible; in the second, the monkey saw only the replayed targets; in the third, the monkey saw only the moving cursor but not the targets. The results showed that passive observation of the task determined a neural discharge similar to that found during task execution. The observation of the cursor without targets or of the targets without cursor gave either no responses or responses that were weaker than those found during the observation of both cursor and targets. The authors concluded that the most likely explanation of their findings is that the observation of the movements determined a covert generation of a motor command.

Mirror system in humans

ANATOMY OF THE MIRROR SYSTEM A large number of brain imaging studies showed that parietal and frontal areas that activate during motor acts execution are also active when an individual observes similar motor acts done by others (see Rizzolatti & Craighero, 2004). Most of these studies concerned observation of object-directed *grasping* movements. The regions that are activated in these studies form the grasping human mirror system. The two main nodes of this system are the inferior parietal lobule (IPL) and the ventral premotor cortex (PMv) plus the caudal part of the inferior frontal gyrus (IFG), roughly corresponding to its *pars opercularis*. The localization of human grasping mirror system corresponds to that of the homologous mirror system in the monkey (figure 43.7).

Several experiments addressed the issue of how observed motor acts performed by different effectors are organized in

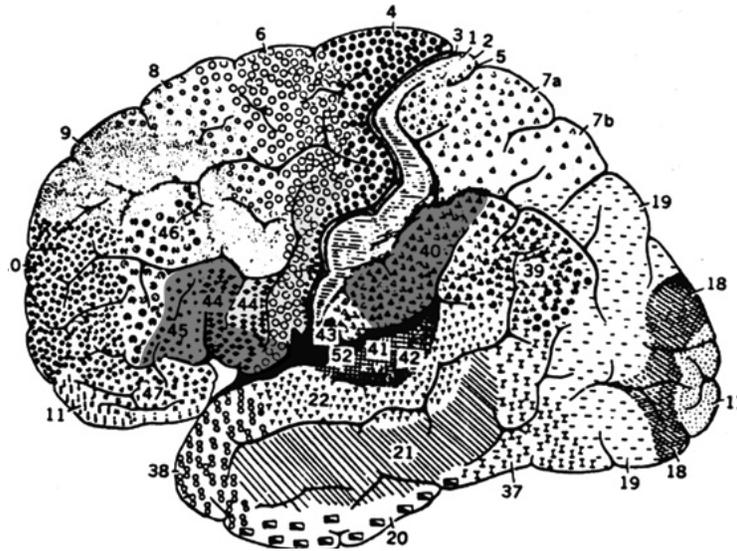

FIGURE 43.7 Lateral view of the human cortex showing the frontal (yellow and blue) and parietal (red) regions constituting the core of the grasping mirror neuron system in humans. Numbers and symbols indicate the different cytoarchitectonic areas according to the parcellation of Brodmann (1909). (See color plate 58.)

the human mirror system by presenting videos of motor acts performed with leg, hand, and mouth (Buccino et al., 2001; Sakreida, Schubotz, Wolfensteller, & von Cramon, 2005; Shmuelof & Zohary, 2006; Wheaton, Carpenter, Mizelle, & Forrester, 2008) or using point-light displays of biological motion of different body parts (Saygin, Wilson, Hagler, Bates, & Sereno, 2004; Ulloa & Pineda, 2007).

As far as the premotor cortex is concerned, the results showed that the observed leg motor acts are represented more dorsally in the ventral premotor cortex (PMv) extending across the superior frontal sulcus into the dorsal premotor cortex (PMd), and the hand motor acts are represented in an intermediate position in PMv, while the mouth motor acts are represented ventrally, extending into the IFG. There was considerable overlap between adjacent representations. While the goal of the observed motor acts in these studies was achieved mostly by distal movements, a recent study investigated the organization of reaching movements, that is, the transport phase of the hand to a particular location in space, eliminating the contribution of grasping movements (Filimon, Nelson, Hagler, & Sereno, 2007). It was found that in both observation and execution, the sector of premotor cortex that was activated was located in the cortex of the superior frontal gyrus (SFG), that is, in PMd. Thus, it appears that observation of motor acts focused on the distal part of the effector activates PMv, while when the focus is on the proximal part, activation mostly concerns PMd.

The activation pattern in the parietal lobe is rather complex. The observation of goal-directed motor acts in which the focus was on distal movements showed activation of the rostral part of the cortex inside and around the intra-parietal sulcus, extending into the convexity of IPL for

mouth motor acts, activation of the caudal part of the same cortex but extending into the superior parietal lobule for the leg motor acts, and activation of an intermediate sector for the hand motor acts (Buccino et al., 2001). In the experiment (Filimon et al., 2007) in which the focus was on observation of the transport phase (reaching movement), the activation was located more dorsally, in the superior parietal lobule extending toward the dorsal bank of the IPS.

In a recent study (Jastorff, Rizzolatti, & Orban, 2007), video clips showing four distal motor acts (grasping, dragging, dropping, and pushing), each performed by using three different effectors (foot, hand, and mouth), were presented to volunteers. The results showed that while in PMv, the activations determined by the observed motor acts were clustered according to the effector used, independently of their positive (grasping and dragging) or negative (dropping and pushing) behavioral valence, in the parietal cortex, the organization followed another principle: The observed motor acts were found to be clustered according to their valence, regardless of whether they were done with the mouth, hand, or foot. The most activated region corresponded to putative human AIP, extending ventrally to the inferior parietal lobule and dorsally to the superior parietal lobule. Motor acts with negative valence were represented dorsally, while those with positive valence ventrally. It can be hypothesized that this parietal organization, by generalizing the motor act valence across effectors, allows a unified understanding of the observed behavior.

In addition to an organization based on the valence of the motor act, the parietal lobe activation also showed a coarse effector-based organization. The strongest activations for foot motor acts were located dorsally, and those for mouth

motor acts were located ventrally, well below AIP. Activations for hand motor acts were the strongest in the center of the responsive region, which also responds to foot acts. It has been suggested (Jastorff et al., 2007) that the valence-related organization is based on a motor scaffold and that the representation of the observed motor acts that are typically performed with the hand becomes active also when they are performed with other effectors.

Another issue that has been recently addressed (Gazzola, Rizzolatti, Wicker, & Keysers, 2007; Orban et al., 2006) is whether the observation of tool use or robotic arms activates the same circuit that becomes active during the observation of motor acts done with natural effectors. The results of these studies showed that the basic parieto-premotor circuit that becomes active during the observation of hand grasping is also active during the observation of tool actions. In addition, however, it was shown (Orban et al., 2006) that the observation of actions performed with tools activates a specific region in the inferior parietal lobule, corresponding to the rostral inferior part of the supramarginal gyrus. The two parietal regions that are activated by the observation of tools and robotic arms could underlie two different ways in which tool use is understood. The sector around the intraparietal sulcus could mediate an association between a tool and the tool use outcome without an understanding of tool functioning. In contrast, the rostral supramarginal gyrus could be involved in the uniquely human capacity of understanding the tool use in terms of its functioning. It is interesting to note that the rostral supra-marginal gyrus is the part of the inferior parietal lobule that is most frequently damaged in patients with ideomotor apraxia (see Leiguarda & Marsden, 2000; Wheaton & Hallett, 2007).

PLASTICITY OF THE MIRROR SYSTEM Is the mirror system modulated by motor experience? There is clear evidence that the observation of motor acts that are richly represented in the observer's motor repertoire determines a stronger activation of the mirror system than does the observation of novel motor behaviors (Casile & Giese, 2006). In particular, in a functional magnetic resonance imaging (fMRI) study, Calvo-Merino, Glaser, Grezes, Passingham, and Haggard (2005) demonstrated that the observation of actions performed by others results in different cortical activations depending upon the specific motor competence of the tested individuals. Participants, who included classical dancers, dancers of Capoeira, and people who had never taken a dancing class, were shown a video of Capoeira dance steps. The sight of the dance steps of Capoeira caused a greater activation of the mirror system in the Capoeira dancers than in either the classical dancers or the beginners. Conversely, a video showing classical dance steps resulted in a much stronger activation of the classical dancers' mirror

system compared to those of the Capoeira dancers and the beginners.

In a further experiment, the same researchers (Calvo-Merino, Grezes, Glaser, Passingham, & Haggard, 2006) tried to understand whether the differences in the activation found in the previous experiment were due to motor or visual familiarity with the observed movements. The results showed that the mirror system was activated more strongly by the sight of the dance steps executed by the dancers of the same sex of the observer, indicating, therefore, that the activation was regulated by motor practice and not by visual experience, given the fact that the latter was the same for both sexes.

The data by Calvo-Merino and colleagues (2005, 2006) were extended by Cross, Hamilton, and Grafton (2006) in a study in which expert dancers learned and rehearsed novel, complex whole-body dance sequences for five weeks. Brain activity was recorded weekly by fMRI as dancers observed and imagined performing different movement sequences. Half of these sequences were rehearsed, and half were unpracticed control movements. Critically, activation of the mirror system was modulated as a function of dancers' motor experience.

These data show that the mirror system codes the observed actions by mapping them onto "corresponding" motor representations of the observer. But how would the mirror system respond to the observation of hand actions if the observer never had hands or arms? Two aplasic individuals, born without arms or hands, were scanned while they observed hand motor acts (Gazzola, van der Worp, et al., 2007). The results showed activations in the parietofrontal circuit of aplasic individuals while they watched hand motor acts. This finding demonstrates the brain's capacity to mirror acts that deviate from the typical motor organization by recruiting brain cortical representations involved in the execution of motor acts that achieve corresponding goals by using different effectors.

THE MIRROR SYSTEM AND INTENTION UNDERSTANDING IN HUMANS Recent experiments showed that besides understanding of motor acts, the mirror system is also involved in understanding the *intention* behind the observed motor acts.

Evidence in this sense has been provided by an fMRI study (Iacoboni et al., 2005). In this study, there were three conditions. In the first one (called "context"), participants saw a scene with objects (a teapot, a mug, a plate with some food on it) arranged as if a person was ready to have breakfast or arranged as if a person had just finished having breakfast; in the second condition (called "action"), participants were shown a hand that grasped a mug without any context; in the third (called "intention"), participants saw the same hand motor act within the two different contexts. The

context suggested the intention of the agent, that is, grasping the cup for drinking or grasping it for cleaning.

The results showed that in both action and intention conditions, there was an activation of the mirror system. The comparison between intention and action conditions showed that the understanding of the intention of the agent determined a marked increase in activity of the right IFG.

Interestingly, the observation of grasping of the cup to drink produced a stronger activation than did the observation of grasping done to clean. This result is similar to findings in monkeys (see above) showing that the number of neurons that code grasping for bringing to the mouth largely exceeds the number of neurons that code grasping for putting an object into a container.

In another fMRI study, based on repetition suppression paradigm, participants were instructed to observe repeated movies showing the same action outcome (such as opening or closing a box) achieved by using the same or different kinematics. The results showed that the right inferior parietal and right inferior frontal cortex responses were suppressed by the observation of the same action outcome, independent of the means used to achieve it. This finding has been interpreted as evidence of the involvement of the mirror system in intention understanding (de Hamilton & Grafton, 2008).

In conclusion, these data show that the intentions behind the actions—at least of basic actions—of others can be recognized through the mirror mechanism. This does not imply, of course, that other, more cognitive ways of “reading minds” do not exist (see Frith & Frith, 2008). However, there is little doubt that the mirror mechanism is one of the most basic and possibly the most basic mechanism for intention understanding.

More recently, an fMRI study investigated the neural basis of human capacity to differentiate between actions that reflected the intention of the agent (intended actions) and actions that did not reflect it (nonintended actions). Participants were shown video clips of a variety of actions done with different effectors, each in a double version: one in which the actor achieved the purpose of his or her action (e.g., pouring the wine) and one in which the actor performed a similar action but failed to reach the goal because of a motor slip or a clumsy movement (e.g., spilling the wine) (Buccino et al., 2007). The results showed that both types of actions activated the mirror system. The direct contrast nonintended versus intended actions showed activation in the right temporoparietal junction, left supramarginal gyrus, and mesial prefrontal cortex. The converse contrast did not show any activation. It was concluded that the capacity to understand when an action is nonintended is based on the activation of attention areas signaling unexpected events in spatial and temporal domains (Corbetta & Shulman, 2002; Coull, 2004; Mitchell, 2008). These results indicate that

when an individual observes an unexpected motor act, such as a motor slip, his cortical machinery, besides signaling the observed motor act, also signals the strangeness of the motor act outcome.

THE MIRROR SYSTEM, MOTOR COGNITION, AND AUTISM
Autistic children display a striking inability to relate themselves to people in ordinary ways. According to Kanner (1943), this represents the fundamental feature of autism. However, in the same seminal paper, Kanner reported that “almost all mothers [. . .] recalled their astonishment at the children’s *failure to assume at any time an anticipatory posture* (Kanner’s italics) preparatory to being picked up.” Unlike typically developing children, autistic children use motor strategies that basically rely on feedback information rather than on feedforward modes of control. Such motor disturbance prevents autistic children from adopting anticipatory postural adjustments (Schmitz, Martineau, Barthélemy, & Assaiante, 2003).

The theoretical relevance of these findings has been clarified by a recent electromyographic (EMG) study (Cattaneo et al., 2008) showing that high-functioning autistic children are unable to organize their own motor acts in intentional motor chains as typically developing children do. Participants in this study were typically developed (TD) and high-functioning autistic children who were required both to execute and to observe two different actions: grasping with the right hand a food item placed on a plate, bringing it into the mouth, and eating it or grasping a piece of paper placed on the same plate and putting it into a box (figure 43.8A). During the execution and observation conditions of both actions, the activity of the mouth-opening mylohyoid muscle (MH) of the participants was recorded by using EMG surface electrodes.

The results showed that during the execution and observation of the eating action, a sharp increase of MH activity was recorded in TD children, starting well before the food was grasped. No increase of MH activity was present during the observation of the placing action. This means that one of the muscles that are instrumental to accomplish the action final goal (opening the mouth to eat a piece of food) is already activated during the initial phases of the action. The motor system anticipates the consequences of the action final goal (to eat), thus directly representing the action intention, both when the action is executed and when the action is observed being done by others. In contrast with TD children, high-functioning autistic children showed a much later activation of the MH muscle during eating action execution and *no activation at all* during eating action observation (figures 43.8B and 43.8C).

These results reveal that children with autism are impaired in chaining sequential motor acts within a reaching-to-grasp-to-eat intentional action, a mechanism

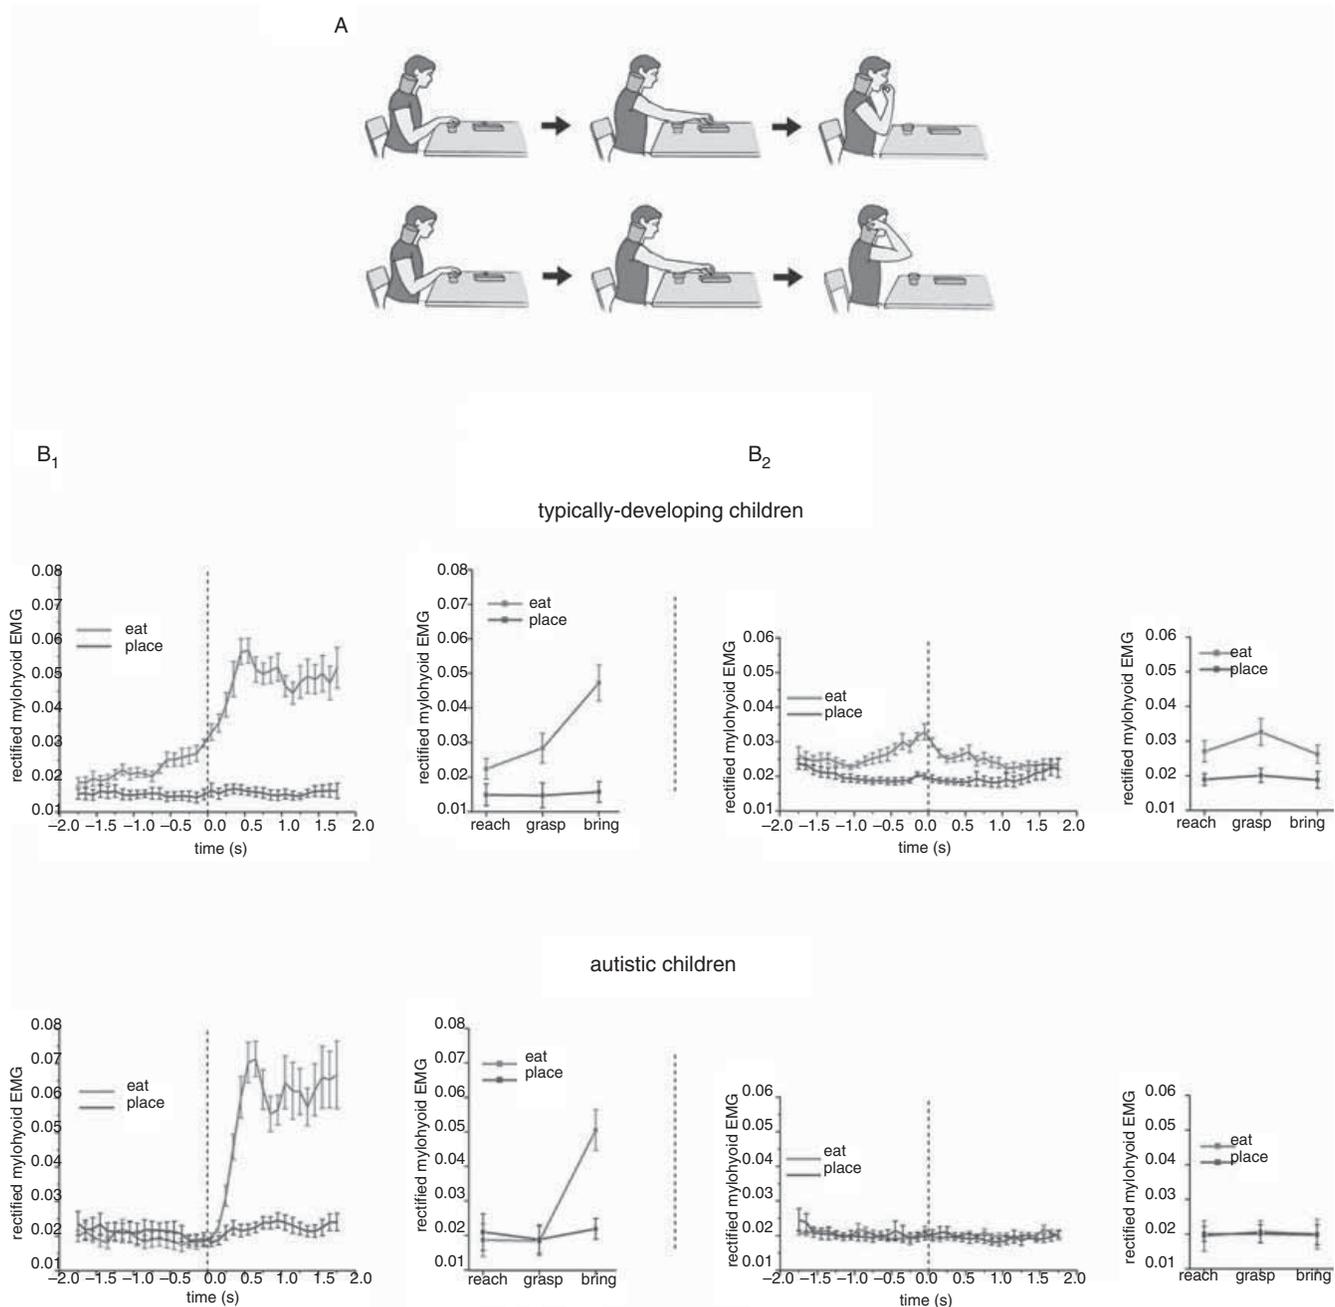

FIGURE 43.8 Differential activation of a mouth-opening muscle during execution and observation of two actions in typically developing and autistic children. (A) Schematic representation of the two actions executed and observed by the two groups of subjects. *Upper part:* The individual reaches for and grasps a piece of food located on a touch-sensitive plate, brings it to the mouth, and eats it. *Lower part:* The individual reaches for and grasps a piece of paper located on the same plate and puts it into a container placed on the shoulder. (B₁) *Left:* Time course of the EMG activity of the mylohyoid muscle during execution of grasping for eating (red) and grasping for placing (blue). Vertical bars indicate the standard error. The

curves are aligned (dashed vertical line) with the moment in which the object is lifted from the touch-sensitive plate. *Right:* Mean EMG activity of the same muscle in three epochs of the two actions. Vertical bars indicate 95% confidence intervals. (B₂) *Left:* Time course of the EMG activity of the mylohyoid muscle during observation of grasping for eating (red) and grasping for placing (blue). Other conventions as in B₁. *Right:* Mean EMG activity of the same muscle in three epochs of the two observed actions. Other conventions as in B₁. (Modified from Cattaneo et al., 2008.) (See color plate 59.)

that most likely reflects the chained organization of the parietal cortex described in the monkey (see above) (Fogassi et al., 2005). This impairment is mirrored in the action observation condition and most likely accounts for the difficulty these children have in *directly understanding* the intention of the observed action when executed by others.

Other recent studies have documented a deep impairment of the core mechanisms of motor cognition in children with autism. Two recent studies show that autistic individuals might be suffering from a dysfunction of their mirror system. Theoret and colleagues (2005) showed that, again unlike healthy controls, children with autism did not show TMS-induced hand muscle facilitation during hand action observation. Oberman and colleagues (2005) showed that children with autism, unlike healthy controls, did not show mu frequency suppression over the sensorimotor cortex during action observation.

Hence, converging evidence from a variety of studies suggests that some of the social cognitive impairments manifested by autistic individuals could be rooted in their incapacity to organize and directly grasp the intrinsic goal-related organization of motor behavior, because of a dysfunctional mirror system.

44 Relative Hierarchies and the Representation of Action

SCOTT T. GRAFTON, L. AZIZ-ZADEH, AND R. B. IVRY

ABSTRACT Hierarchy is a central concept for understanding how complex goal-oriented behaviors are organized. In this chapter we present recent functional and behavioral evidence that supports the existence of a control hierarchy in the human brain for organizing complex motor. It is proposed that the functional hierarchy is not based on strict anatomical connectivity within the motor system. Instead, there are multiple motor planning circuits, each of which can serve a supraordinate role, and this role can be readily interchanged to achieve a much wider range of task outcomes. This can be observed at the level of hand-object interactions, bimanual control, and the integration of semantics into action planning.

Historical perspective: The hierarchy of serial behavior

Within the field of motor control, the problem of how people accomplish complicated tasks has historically been intertwined with the concept of what constitutes a motor program. This in turn depends on solving the problem of serial order, first articulated by Lashley (1951). He sought to understand how the nervous system organized sequential motor elements to achieve a desired motor goal. Bernstein (1996) elaborated on the serial order problem by emphasizing that the control system was flexible, designed to produce actions that were constrained by task demands rather than fixed action patterns. This shift in emphasis brought to the forefront the concept of a goal. We move to accomplish goals.

These early theories were critical in minimizing the role of the simple chaining of reflexes, proposing instead the existence of a motor plan as an alternative. But they also introduced fundamental questions that continue to challenge the field: What is a motor plan? Is it composed of discrete representational elements? Can associative mechanisms that underlie reflex chains be used to solve more complex

problems, including those associated with task planning? Do all plans require goals? How does a task get organized?

One possible mechanism for planning goal-directed sequences of actions is based on hierarchical control. The argument for hierarchical control was elaborated within a cognitive science framework by Keele and colleagues (1990) during the 1980s. Using a set of model tasks such as handwriting and the serial reaction time task, researchers sought to describe the structure of control hierarchies by identifying consistent patterns of variation in the time required to initiate successive components of an action, as well as through studies of motor transfer. These studies showed that many aspects of control reflected constraints that were related to the abstract nature of action representations, separable from the musculoskeletal system. A fundamental distinction derived from this perspective can be made between abstract plans and their implementation, the basic components of a hierarchy.

Another form of hierarchical control within the implementation process itself became evident through studies of naturalistic grasping. Kinematic analysis showed that the transport phase of an arm movement has an exquisite interdependency with processes involved in shaping the hand to grasp an object (Jeannerod, 1984, 1986). The velocity of the transport phase is subordinate to the grasp requirements, with timing that is tightly coupled to maximal hand aperture. At a more abstract level, prior experience and task goals can also influence grasping (Rosenbaum, Meulenbroek, & Vaughan, 2001; Rosenbaum, Vaughan, Barnes, & Jorgensen, 1992). For example, the way in which an object is grasped is constrained by task demands. Given a fixed starting position, the adopted grasping posture will depend on how the tool is to be moved (defined by the center of mass) and used (defined by the tool's functional properties), as well as the comfort of the end-state posture. In this case the selected grip is subordinate to the desired goal for using the tool as well as biomechanical constraints.

Computational models of motor planning have also exploited hierarchical features in action representation. In a model of hierarchical behavior proposed by Cooper and Shallice (2006), a logical tree structure of discrete behaviors is developed to organize an action sequence. To make a cup

of coffee, the act of adding sugar is distinct from the act of adding milk, and each must be scheduled after the coffee has been brewed. This scheduling occurs within a large multi-layered, interactive network, with the top level of the hierarchy providing constraint in terms of its specification of task goal (see figure 44.1A).

In such models, the notion of a hierarchy is explicit, with the layered representation defined as a task schema. In an alternative approach, action planning could be goal-independent, with the hierarchy arising as an emergent property of processes that arises from sequential transitions between different components. For example, Botvinick (2008) has shown that a simple recursive network based on an action layer, a perception layer, and an intermediate layer can learn fairly complex motor actions without the need for top-down task structuring with respect to a goal. Furthermore, sequencing and the formation of motor programs can lead to compilation of complex acts into a smaller set of tasks, as shown in figure 44.1B. The evaluation of these computational models has primarily relied on behavioral studies that involve dependent variables such as variation in planning time and errors of substitution.

Methods of cognitive neuroscience can provide additional means for addressing these issues. The present chapter seeks to incorporate these other forms of evidence to reconsider how the notion of hierarchy and action goals may be conceptualized to aid our understanding of how movement is achieved. To assess these questions, we review a wide range of actions, spanning tool use, bimanual coordination, and, finally, how language influences motor planning and control.

Anatomic versus representational hierarchy

The concept of an action hierarchy has not been limited to the psychological and computational realms; neuroscientists have also been highly influenced by hierarchical notions in theorizing about the organization of the nervous system. Efforts to map different levels of motor planning into distinct neural substrates were motivated in large part by the belief that there existed a strict anatomical hierarchy, at least within lower levels of the nervous system. As one ascends from muscle activity to peripheral nerves and then into spinal cord and ultimately to motor cortex, there is increasing abstraction in the type of information represented (d'Avella & Bizzi, 2005; Giszter, Mussa-Ivaldi, & Bizzi, 1993). It is only natural to assume that there is a continuation of this control hierarchy into premotor and ultimately prefrontal and parietal areas. An example is the sensorimotor hierarchy first proposed by Fuster (Fuster, 1995) and recently implemented by Botvinick (2007) (figure 44.2A). In this model, only the primary motor cortex influences the environment. As a task becomes more complex, increasing reliance is placed on premotor heteromodal sensory circuits and ultimately prefrontal-polymodal sensory circuits. In an extreme version of this model, there is a linear gradient between task complexity and posterior to anterior prefrontal cortex (Badre & D'Esposito, 2007; Botvinick, 2007, 2008).

Early brain imaging studies of action planning were often interpreted as being consistent with an anatomical hierarchical framework (Roland, Larsen, Lassen, & Skinhoj, 1980;

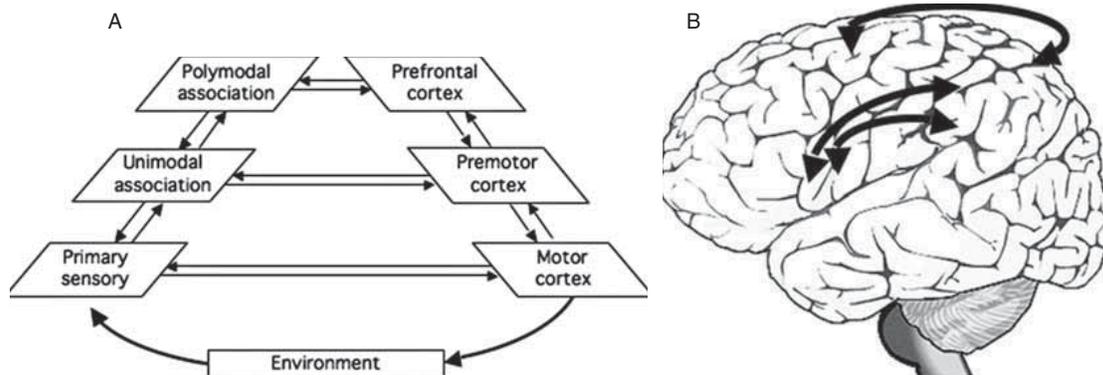

FIGURE 44.2 Examples of anatomic networks. (A) In this model, based on Fuster (1995), sensorimotor loops represent information of increasing abstraction or complexity. Only the motor cortex controls interactions with the environment, and there is strict segregation between unimodal and polymodal sensory areas. (B) In this multiple stream model, there are at least two parietal-prefrontal-premotor streams engaged for goal-oriented behavior.

A dorsal-dorsal stream (upper arrow) is used for learning arbitrary sensorimotor transformations and reaching. A ventral-dorsal stream (middle arrow) is used for object centered actions. A third stream, positioned between inferior parietal lobule and inferior frontal gyrus (lower arrow), has been hypothesized for representing complex actions and tool use. In this model, these circuits operate in tandem, with no fixed hierarchical arrangement.

Roland, Skinhøj, Lassen, & Larsen, 1980). One of these studies used positron emission tomography to measure blood flow and compared activation patterns during real versus imagined movement. Whereas the supplementary motor area (SMA) was active during both real and imagined movement, motor cortex was only weakly activated during imagined movements. This dissociation was interpreted as showing that the SMA provided a more abstract representation of the action plan, one that provided the plan of the action, and motor cortex activation was primarily limited to the actual implementation of that plan. From this view, the SMA has sometimes been referred to as a “supramotor” area.

However, four arguments suggest that caution is required in attempting to identify a direct correspondence between a well-defined anatomical hierarchy and a functional hierarchy. First, many of the descending pathways to the spinal cord originate outside the primary motor cortex, including rich projects from premotor and parietal cortex, as well as the extrapyramidal brain stem pathways (Dum & Strick, 1991, 1996). The diversity of these cortical and subcortical projections underscores the ability of these areas to directly influence movement. In addition to their direct influences on motor commands, these areas likely play a role in establishing the context of an action and the coordination of movement commands with current information about the state of the actor.

A second argument against the presence of a strict anatomical hierarchy within motor regions of the cortex is that most premotor areas have direct inputs onto motor cortex, and no premotor area appears to have a dominant role over another (Dum & Strick, 2005). It has become clear that there are multiple body representations within premotor cortex, and the anatomy fails to indicate some sort of hierarchical structure across these subregions.

The third argument is based on recent evidence that even the lowest levels of this presumed cortical hierarchy are capable of organizing extremely complex serial behavior (Lu & Ashe, 2005; Matsuzaka, Picard, & Strick, 2007). Recent recordings from the primary motor cortex in nonhuman primates demonstrate sequence-specific responses that are tied to the action rather than particular muscles. Similar evidence for learning-dependent changes within motor cortex for complex serial actions has been observed in humans (Grafton, Hazeltine, & Ivry, 1998; Grafton, Salidis, & Willingham, 2001; Karni et al., 1998).

Finally, models that emphasize a strict anatomical hierarchy for motor planning run the risk of requiring a command and control structure with a “decider” at the top; the problem of the homunculus resurfaces in such models. This type of architecture seems difficult to reconcile with the effortless nature with which we perform many of our everyday actions. These are planned unconsciously and adjusted on-line at an extremely rapid rate (Desmurget & Grafton, 2000).

An alternative conceptualization of functional anatomy is motivated by the existence of multiple interactive loops across prefrontal-parietal cortex. For example, the concept of two visual streams for object identification versus action pragmatics has been extended, as is shown graphically in figure 44.2B (Goodale, Milner, Jakobson, & Carey, 1991). There is now extensive anatomical and functional evidence to support at least two and possibly three processing streams within the classic “dorsal” stream related to object-centered action, tool use, and reaching (Johnson & Grafton, 2003; Rizzolatti & Luppino, 2001; Rizzolatti & Matelli, 2003). In addition, there is little anatomical evidence to segregate polymodal sensory from unimodal association cortex as originally proposed by Fuster. Within each parietal-premotor-prefrontal pathway, all forms of sensory information are integrated.

The preceding arguments suggest that insight into the hierarchical nature of action planning and goal representation will not be defined by the existence of an anatomical hierarchy. Instead, an anatomical organization with multiple parallel parietal-prefrontal and premotor pathways supports a multitude of relative hierarchies that can be flexibly recruited as a function of task demands, experience, and context. In this framework, there are dissociable functional anatomic substrates, but these are not constrained by a fixed hierarchy. This shifts the focus of inquiry to understanding representational hierarchies that are highly flexible and goal based.

Goal representation and the on-line control of grasp

Grasping studies traditionally focus on the interplay between grip formation and limb transport to understand the representational organization of these two task components (Haggard & Wing, 1997; Jeannerod, 1997; Jeannerod, Arbib, Rizzolatti, & Sakata, 1995). For grasping, the object itself defines the task goal. The problem then becomes one of sensorimotor transformation, in which object features are decoded to generate hand configurations that are optimally shaped to match the object geometry. Object knowledge involves both physical properties (texture, mass, center of gravity) and utility (how the parts of an object such as a handle and action surfaces are used to accomplish particular goals). Through experience and cumulative knowledge, a library of possible hand-object affordances and utility are constructed.

Neuropsychological and neuroimaging studies have provided evidence of two primary pathways in posterior cortex: the classic “how” and “what” visual streams (Culham et al., 2003; Goodale et al., 1994). Processing distinctions within these pathways can be viewed as supporting pragmatic and conceptual representations for action. Within the dorsal “how” pathway, there is clear evidence that the anterior intraparietal sulcus (aIPS) in humans (area AIP in nonhuman primates) is critical for sensorimotor transformations that relate the visual and/or haptic features of an object to a desired hand shape, with limb transport, body stabilization, and eye movements playing subordinate roles.

This framing in terms of a sensorimotor transformation provides a starting point to understand a functional hierarchy, but it is missing a critical piece: how the goal is related to the sensorimotor transformations. We grasp objects to achieve goals (e.g., pick up a nut) or to solve problems (e.g., use a tool to open the nut). How does an area such as aIPS integrate the low-level details required to control grip aperture with information about an object that includes high-level features that may be defined functionally and in a way that varies with context? This shifts the problem from one of sensorimotor transformation to one of sensorimotor inte-

gration (Wolpert, Ghahramani, & Jordan, 1995; Wolpert, Goodbody, & Husain, 1998).

There are at least two solutions to this problem. One is that areas such as aIPS are akin to low-level visual areas and pass information off to higher cortical areas. This is a classic functional-anatomical hierarchy of ascending representational complexity. For example, the goal level of the action might be represented in ventral premotor cortex, an area that is richly connected to aIPS. In this framework, premotor areas would make the ultimate control decisions. An alternative view is that of an inverted or flexible hierarchy. This emphasizes that information about the task goal can have a direct influence on processing within areas such as aIPS. In this scheme, computations within aIPS use this goal information to constrain sensorimotor integration needed to related motor commands with object information and an internal representation of the body in relationship to the object.

A series of transcranial magnetic stimulation (TMS) studies targeting aIPS during grasping suggest that the latter perspective is more appropriate. In this work, subjects were required to reach and grasp a small $1 \times 1 \times 5$ cm rectangular wooden block located on a computer-controlled torque motor (Tunik, Frey, & Grafton, 2005). The orientation of the block could be changed in less than 30 ms. The subject was required to start with the right hand on a button and, when ready, use the index finger and thumb to grasp the object, aligning these fingers on the vertical axis. To assess on-line updating, the initiation of the grasping movement would trigger the motor to spin the object 90 or 180 degrees. In this manner, the object’s orientation always changed on every trial. However, the planned grasping action would have to be updated when the object rotated 90 degrees, requiring a larger aperture to grasp the 5-cm width. In contrast, when the object rotated 180 degrees, no adjustment was required, since the object’s vertical axis remained at 1 cm diameter.

Single pulses of TMS were delivered to aIPS, timed to the start of the hand movement. The TMS pulses disrupted the subjects’ ability to modify their grip aperture on trials in which the grasp had to be updated but had no effect on trials in which the original grip could be used (figure 44.3). In control conditions in which the TMS pulses were applied to other brain regions (e.g., caudal or mid intraparietal cortex), or 400 ms after movement onset, no behavioral effects were observed.

If reaching and grasping are anatomically dissociable, TMS of aIPS should affect only the control of grip aperture. To test this hypothesis, the same subjects were tested in a critical second experiment. Instead of always grasping the block along the vertical axis, they were now told to always grip the narrow (1-cm) axis. With these instructions, the task goal required that they update the orientation of the forearm and wrist, but the grip aperture remained fixed. In this con-

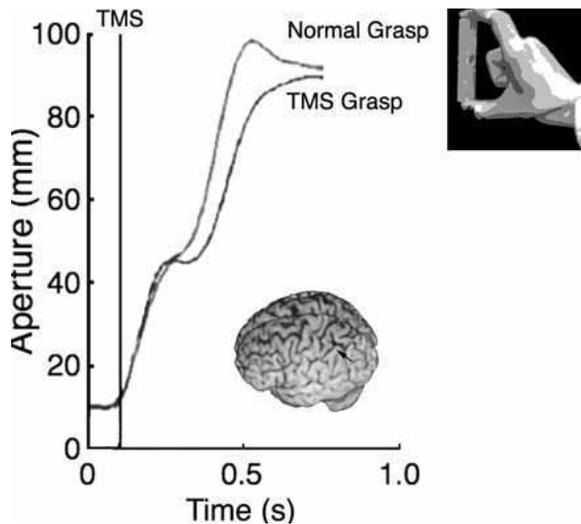

FIGURE 44.3 Effect of a single pulse of TMS during object grasping. The figure plots finger aperture measured when subjects grasp an object that has increased in size, as shown in the insert of the hand. When TMS is applied to the anterior intraparietal sulcus (arrow on brain, insert) at movement onset, there is a delay in the formation of the required grip aperture (lower curve in plot) compared to the no-TMS, control condition (upper curve in plot). (Adapted from Tunik et al., 2005.)

dition, when TMS pulses were applied to aIPS at movement onset, the participants were unable to rotate the arm appropriately to match the new orientation of the object.

Taken together, the results argue against the hypothesis that the TMS is interfering with the adjustment of a particular set of muscles or an elemental process such as grip aperture. A more parsimonious explanation is that this region of the parietal cortex is involved in using information concerning the task constraints to generate a desired hand-object interaction. As such, the TMS appears to disrupt the representation of the goal itself rather than some “downstream” operation that controls some component of that goal.

Note that in the two studies reviewed above, the disruptive effects of TMS were observed on trials in which an action plan had to be updated rapidly. Perhaps aIPS is important for this updating process and not needed when the action has already been planned. To address this, shutter goggles were used to control when visual information about the object was available to the subjects (Rice, Tunik, & Grafton, 2006). The goggles provided a brief 200-ms view of the object but were closed just before reach onset. Thus the subjects were required to reach and grasp the object without vision of the hand or of the object. Critically, TMS to aIPS interfered with grasp kinematics when the pulses were delivered at movement onset but not when it was delivered during the viewing period.

This result argues strongly against the hypothesis that aIPS is essential for planning the requisite sensorimotor transformation solely on the basis of visual information. If

this were the case, disruption should also have been observed when the pulses were applied before movement onset. Instead, aIPS appears to be essential for the on-line integration of visual and proprioceptive information with efference copy signals in order to meet the task goal.

The TMS findings are consistent with the hypothesis that the task goal is embedded in the controllers, even for relatively simple actions such as grasping. Moreover, the constraints associated with the task goal are closely intertwined with processes involved in the sensorimotor integration needed for rapid adjustments of an ongoing movement. At least with respect to the role of aIPS in grasping, there is no evidence for an anatomical dissociation between the representation of a goal and the implementation of movements required to achieve that goal.

Goal representation in bimanual coordination

Studies of bimanual movements have provided another framework for examining how the selection and control of movement are constrained by action goals. Much of this work has involved rhythmic movements, evaluating changes in pattern stability when performers are asked to adopt a range of phase relationships between the two hands (see Schönér & Kelso, 1988). A large body of evidence demonstrates that certain patterns are more stable than others; people are much more adept in adopting antiphase and in-phase patterns of motion than in adopting patterns in which the two hands must adopt more complex phasing patterns. These constraints have been formally described by models in which the limbs are conceptualized as coupled oscillators. An alternative, process-oriented perspective focuses on the manner in which the task goals are represented. In the event-timing model of Spencer, Semjen, Yang, and Ivry (2007), the task is represented as a series of salient temporal events such as the point of contact during finger tapping or maximum flexion or extension during movements performed without such haptic cues. In this model, stability is constrained by the complexity of the temporal representation. Thus, antiphase and in-phase patterns are more stable because the representation of the temporal goals for these patterns is simpler than for more complex phase relationships (Semjen & Ivry, 2001). Moreover, the phase transitions observed from antiphase to in-phase movement when movement frequency increases arise because the latter entails a simpler temporal representation (Spencer et al., 2007).

A similar perspective has been offered to account for bimanual interactions observed in the spatial domain (Ivry, Diedrichsen, Spencer, Hazeltine, & Semjen, 2004). Consider a task in which a person must simultaneously draw two three-sided squares (figure 44.44). Performance is fluid when the patterns are symmetric (e.g., U and U). In contrast, when the patterns are orthogonal (e.g., U and C), severe limitations

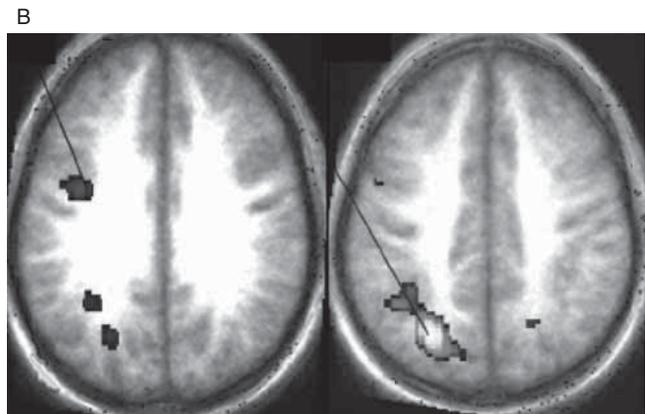

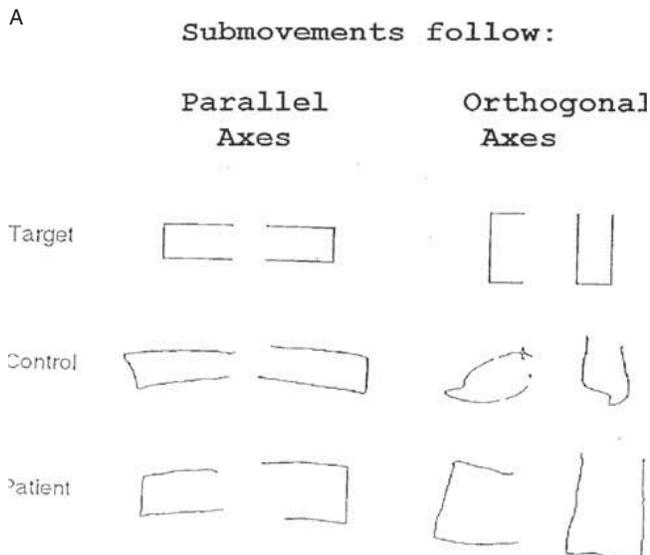

FIGURE 44.4 (A) In this task, the participant must simultaneously draw the shape on the left with the left hand and the shape on the right with the right hand. Representative trajectories produced by a control participant and a callosotomy patient are shown. (B)

Symbolically cued actions produce stronger activation across the left intraparietal sulcus/superior parietal lobule and left premotor cortex than do directly cued actions. (Adapted from Diedrichsen et al., 2006.)

are observed; the time to initiate each segment increases dramatically, and spatial distortions are observed such that the trajectories for the two hands become assimilated (Albert & Ivry, 2009; Franz, Eliasson, Ivry, & Gazzaniga, 1996). These effects can also be observed with simpler patterns; for example, reaction times are much slower when two linear movements are symmetric than when they follow orthogonal trajectories or are of different amplitudes (Heuer, Kleinsorge, Spijkens, & Steglich, 2001). However, these costs are essentially abolished when stimuli appear at the endpoint location, serving as direct cues for the required movements (Diedrichsen, Hazeltine, Kennerley, & Ivry, 2001).

The fact that the constraints are highly dependent on the manner in which the actions are cued indicates that the limitations here are not related to processes that are typically associated with motor programming and execution. Rather, they arise at a more abstract level, one associated with the goal of the action. This may be related to the sensory consequences of the movements (Franz, Zelaznik, Swinnen, & Walter, 2001; Mechsner, Kerzel, Knoblich, & Prinz, 2001) or to the manner in which the movements themselves are conceptualized (e.g., as movements to produce trajectories or movements to locations; see Ivry et al., 2004).

The neural locus of bimanual coordination has been the subject of considerable study. Within a traditional hierarchical perspective, the debate has centered on whether certain neural regions are specialized for coordinating the gestures of the two hands. Much of this work has focused on the supplementary motor area, motivated by anatomical, lesion, and neuroimaging evidence involving sequential or rhythmic movements (e.g., Brinkman, 1984; Sadato, Yonekura,

Waki, Yamada, & Ishii, 1997). Diedrichsen and colleagues (2006) looked at simpler movements, comparing conditions in which reaching movements were either directly cued (e.g., targets specified by the locations of the stimuli) or symbolically cued (e.g., locations specified by letters indicating target locations). The SMA showed no difference between conditions requiring unimanual or bimanual movements. However, a large parietal region extending along the intraparietal sulcus as well as premotor cortex showed greater activation in the symbolic condition than in the direct condition (figure 44.4B). Interestingly, this activation was much stronger in the left hemisphere than in the right hemisphere, and the magnitude of the activation was greater for bimanual movements that were incongruent (e.g., orthogonal directions) than when they were congruent (e.g., parallel conditions).

In terms of the focus of this chapter, these findings speak to three issues. First, contrary to predictions derived from a traditional anatomical-inspired framework, there was no region, including SMA, that appeared to be specifically sensitive to the contrast of unimanual and bimanual movements. Thus, at least for reaching, the evidence fails to support the hypothesis that there exists a neural region that is specialized for bimanual coordination. Second, manipulation of the task goals did not engage new neural regions but rather led to modulation of the magnitude of neural activity. That is, a similar network was recruited for reaching movements in response to direct and symbolic cues, the activation in these areas being greater in the latter conditions. Thus, similar to our review of reaching and grasping, the representation of the task goal and control

operations required to achieve that goal appear to be intimately intertwined.

Third, the symbolic condition did reveal a strong hemispheric asymmetry. Activation was strongly lateralized to the left hemisphere for action goals that required a translation between stimuli and their associated responses. At a functional level, this latter finding suggests some form of hierarchical organization between the two hemispheres, with the left hemisphere playing a dominant role when there is some degree of abstract representation of the action goals.

Action understanding

The hierarchical representation of action has also been addressed in studies of action comprehension. As with studies of perceptual organization, we can ask how people attend to actions and organize their percepts. Do we focus on the goals of an action, perhaps at a cost of becoming aware of the component parts (e.g., the specifics of the gestures)? Or must we process the components in detail to arrive at an understanding of the actor's intentions?

Conventional subtractive methodologies are problematic in functional magnetic resonance imaging (fMRI) studies of hierarchical organization. It is difficult to manipulate how people perform action comprehension tasks, and doing so is likely to affect a host of factors, such as task complexity and the demands on working memory. An alternative approach is to exploit the repetition suppression (RS) phenomenon, a tool that has proven useful across a range of task domains in perception (Grill-Spector & Malach, 2001; Kourtzi & Kanwisher, 2000). RS is also referred to as *fMRI adaptation*. When two successive stimuli are "similar," the BOLD response to the second stimulus is reduced (i.e., a form of adaptation or habituation) compared to conditions in which the second stimulus is novel (i.e., release from adaptation).

The key here is that RS provides a signature of what "similar" means across the brain. For example, in face perception, some brain regions may show an RS effect only when the gender of the face remains the same on successive trials; the same or other regions may show RS only when the same face is presented. As such, RS provides a probe to identify hemodynamic changes within a class of stimuli or a level of a hierarchy rather than between classes. In this way, different levels of representation for the same stimulus can be analyzed independently.

To identify topologies in the human brain corresponding to a motor hierarchy, Hamilton and Grafton (2006) had participants view short video clips of a right arm reaching and grasping either of two objects and then had them transport the selected object to a midline position. Two variables were manipulated. First, one or the other object was grasped. Second, the position of the two objects with respect to the midline was varied. In this way, repetition could be defined

in terms of the trajectory or the object that was grasped. A strong RS effect was observed in the left anterior intraparietal sulcus (aIPS) when the same object was grasped. Importantly, the aIPS was not sensitive to trajectory repetition. Instead, RS effects based on trajectory were limited to the left lateral occipital sulcus and right superior precentral sulcus. This double dissociation provides strong evidence in favor of some type of hierarchy during action observation, with one level sensitive to kinematic-like features of the action (i.e., trajectory) and another sensitive to the goal of the action, defined here in terms of which object is grasped.

In a follow-up experiment, subjects observed movies of an actor reaching out to grasp a wine bottle or a dumbbell; the latter object was placed on end such that its primary axis matched that of the wine bottle (Hamilton & Grafton, 2007). As in the first experiment, the object to be grasped either remained the same or changed from one trial to the next. Independent of this, the form of the grasp was manipulated by having the actors use either a power grip, in which the object was grasped along its thick part, or with a pincer grip, in which the object was grasped along its thin part. The RS effect related to which object was grasped was again localized to the left aIPS (extending into the adjacent IPL) and to a lesser degree within the right aIPS. In contrast, an RS effect based on how the object was grasped was observed in the SMA, middle IPS, inferior and middle occipital regions, and clusters within middle and inferior frontal gyri. These results again suggest a hierarchical organization with some regions sensitive to the form of the grasp and others sensitive to the goal of the action.

In the preceding studies, the goal of the action was defined as the object to be grasped, with the form of the action considered subordinate. However, in most actions, grasping is really the means to an end: We grasp objects such as tools to accomplish some behavioral goal that requires manipulation of that object (Frey, 2008). Thus, the RS experiments described above are not adequate for assessing intentionality in terms of why the actor has selected one object over the other. This issue was addressed in an RS experiment that manipulated the outcome of the actions (Hamilton & Grafton, 2008). For example, a series of video clips were generated in which the actor pushed or pulled a sliding cover that was attached to the top of a wooden box. Depending on the starting position of the lid, the result of this movement either opened or closed the box. A similar manipulation of kinematics and outcome was used with a range of familiar tasks such as turning a stove on or off, tying or untying a string, and drawing or erasing with a pencil.

An RS effect for outcomes was found in the bilateral IPL and the IFG. These effects were not driven by a single action or outcome but were generalized across a wide variety of actions. As in the other RS experiments, these areas were not sensitive to the means through which the actions were

achieved. Rather, repetition of the kinematics (e.g., push or pull) led to a reduced BOLD response in the left middle intraparietal sulcus, left lateral occipital cortex, and left superior temporal sulcus.

Taken together, these three experiments support a model of representational hierarchy that distinguishes action means, kinematics, object-centered behavior, and ultimately, action consequences. The decoding of object-centered action appears to be strongly left lateralized, whereas the decoding of more complex action intentions arising as a consequence of the action engaged bilateral frontal-parietal circuits. The bilateral recruitment that is observed in this latter condition is quite different from the relative hierarchies described in the other sections of this chapter. One explanation focuses on perceptual factors. Complex intentions might require more global perceptual analysis (Ivry & Robertson, 1998). An alternative explanation is that the right hemisphere plays a central role in representing more complex action goals. Most studies of action understanding or production focus on simple object-centered actions rather than complex goals and do not address this hypothesis. This explanation is supported by patient studies. As Hartmann, Goldenberg, Daumüller, and Hermsdörfer (2005, p. 625) recently emphasized, “It takes the whole brain to make a cup of coffee.”

Action semantics

How might language semantics fit into the representational hierarchy of motor control? It seems plausible that a word such as *hammering* could summon the actions associated with this concept. Thus, when one hears the word, an entire action plan would be activated, one composed of various subcomponents: retrieving the required tools, grasping the hammer with one hand and the nail with the other, striking the nail by pounding the hammer. The hypothesis of an interaction between semantic processing and action planning is supported by evidence from various methodologies. For example, adjectives related to object properties have been found to influence movement execution (Gentilucci, Benuzzi, Bertolani, Daprati, & Gangitano, 2000; Gentilucci & Gangitano, 1998; Glover & Dixon, 2002). A subject’s initial grasp kinematics is influenced by seeing the word *large* or *small* printed over the target object. Similarly, initial reach kinematics to an object are altered if the word *far* or *near* is printed adjacent to the object. These findings indicate that semantic processing, even when not explicitly related to the motor task, influences motor planning. As such, they reveal how language provides another representational system through which motor plans are organized and influenced.

The form of these interactions has been the focus of numerous recent investigations. One hypothesis is that language and motor systems constitute two parallel systems (figure 44.5). Task requirements determine which system is

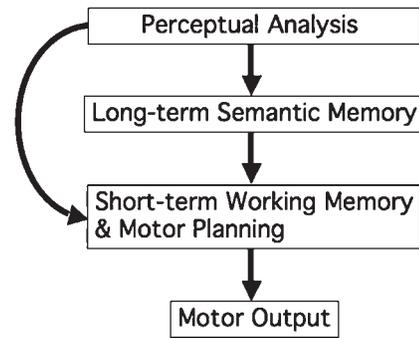

FIGURE 44.5 Two routes, one mediated by semantics, for building up a motor representation. (Adapted from Tessari & Rumiati, 2004.)

used. For example, consider a task in which a person is asked to imitate gestures. If the gestures are meaningless, then it is thought that imitation must occur via a direct visuomotor route. If the gestures are meaningful, however, then imitation could be achieved either by this direct visuomotor route or by accessing long-term semantic memory (Rumiati & Tessari, 2002; Rumiati et al., 2005). Behavioral studies of imitation of meaningful and meaningless gestures (Tessari & Rumiati, 2004) support the theory that actions can be organized by these two systems.

Is processing in these pathways independent, or do the systems share some common neural substrates? A visuomotor route would seem to involve motor-related areas. To what degree does a semantic route use (some of) the same motor-related brain regions? Does hearing the word *hammering* directly activate motor-related brain areas? One way to explore this question is to return to the study of action comprehension. If an action-related semantic area is independent of motor-related areas, then comprehension should remain possible if the motor regions are damaged, at least for meaningful actions. In this view, words related to actions are processed by nonmotor, language-related areas; their effect on motor performance is indirect, perhaps occurring via spreading activation to motor regions. Alternatively, if action semantics is intimately linked with motor-based representations, then lesions of the motor regions should disrupt comprehension. That is, in this view, semantic knowledge cannot be separated from the systems that are involved in producing the actions themselves, a form of embodied cognition (e.g., Gallese & Lakoff, 2005). As such, lesions to these areas will affect both action production and action comprehension.

This question has been asked in a number of neuropsychological studies. Some of this work has focused on patients with apraxia, a disorder defined by impairments in the production of gestures that cannot be attributed to problems in the actual control of the effectors. With regard to their motor output, many of these patients appear to have lost their knowledge of action semantics; for example, they are unable to pantomime familiar gestures or use tools. Ideomotor

apraxia is characterized as a deficit in the sequencing of skilled actions, resulting in temporal and spatial errors. The individual elements of the action, by themselves, might be correctly performed, but the overriding idea of the action as a whole appears to be lost (Heilman, Maher, Greenwald, & Rothi, 1997). There is some evidence however, that this is not simply a disorder of temporal sequencing but might have to do with loss of action semantics. In a seminal paper, Ochipa, Rothi, and Heilman (1989) reported a case study of a left-handed man who exhibited ideational apraxia following damage to the right hemisphere. Paralleling his difficulty in using tools, the patient showed a severe impairment in action knowledge. For example, he was unable to select the object that was best matched with a particular tool (e.g., a nail with a hammer). Thus his problem was not limited to production. Similarly, his deficit could not be attributed to a language comprehension deficit because he could name the tools and readily pointed to the correct object upon command. Instead, it appeared that the patient had an impairment in action semantics (Ochipa et al., 1989), suggesting that, in part, action semantics and motor representations share forms of representation.

Similarly, conceptual apraxia is defined by a loss of conceptual knowledge about tools and objects associated with gestures. However, unlike ideomotor apraxia, the temporal sequencing of an action is preserved. Conceptual apraxia is characterized by two types of problems: impairments of associative knowledge (tool-action associations such as hammer-pound and tool-object associations such as hammer-nail) and impairments of mechanical knowledge such as the properties and advantages of a given tool. Patients with conceptual apraxia exhibit errors when asked to demonstrate the semantic content of an action (e.g., using a scissor-cutting motion for sawing) even though they are not impaired in object recognition (e.g., they can name the saw). Furthermore, the ability to name the tool associated with a given object is often compromised. These patients tend to have difficulty in associating a tool with the linguistic description of its function (e.g., they are unable to pick out the hammer after hearing the word *pounding*) (Goldenberg & Hagmann, 1998; Heilman et al., 1997). Heilman and colleagues (1997) have argued that this form of apraxia is typically limited to patients with left hemisphere damage, consistent with the hypothesis that there is a linguistic component to the deficit. Moreover, these results further support the hypothesis that there is some degree of overlap between action semantics and nonlanguage motor representations.

Imaging studies provide converging evidence that action semantics is tightly coupled to motor regions. Reading words associated with foot, hand, or mouth actions (e.g., *kick*, *pick*, *lick*) activates premotor areas adjacent to or overlapping with areas that are activated when producing actions with the same effectors (Hauk, Johnsrude, & Pulvermuller, 2004).

Tettamanti and his colleagues (2005) found a similar somatotopy in premotor cortex in a sentence comprehension task. Aziz-Zadeh, Wilson, Rizzolatti, and Iacoboni (2006) used an action observation task to localize regions of interest in foot, hand, and mouth regions within premotor cortex. When these participants listened to sentences describing similar actions, these areas were activated in an effector-specific manner. Interestingly, these effects were restricted to the left hemisphere (figure 44.6). This lateralization argues against an account in which the premotor regions are indirectly recruited via imagery given that the video activation patterns had been bilateral. Rather, the left lateralization suggests that premotor cortex is engaged by more abstract linguistic representations.

These data indicate that action semantics and visuomotor representations share common neural substrates. This could explain why, at the behavioral level, interactions between semantics and motor planning are observed. However, we cannot infer causality from patterns of activation in imaging studies; it is unclear whether these premotor activations are essential for action comprehension or reflect some indirect, noncausal recruitment, perhaps via priming from other areas. In the preceding discussion of neurological patients, the locus of the lesions was only crudely specified, generally described in terms of whether the damage was to the left or right hemisphere.

A more direct assessment of the role of motor areas in action comprehension comes from studies in which a more precise specification of the pathology has been described. Action verb comprehension and naming appear to be significantly compromised in patients with motor neuron disease (MND), a neurodegenerative disease with prominent pathology of corticospinal neurons (Bak & Hodges, 1999, 2004; Bak, O'Donovan, Xuereb, Boniface, & Hodges, 2001). Interestingly, these patients do not appear to be impaired in their comprehension and naming of nouns. Postmortem studies indicate that the degeneration in MND patients extends beyond motor and premotor cortex into inferior frontal gyrus (Brodmann areas 44 and 45). Thus, the linguistic problems here might not be directly related to damage to primary and secondary motor regions. Nonetheless, they again demonstrate the neural overlap of regions involved in motor control and action semantics, even when the semantics are accessed linguistically (Bak et al., 2001). Patients with progressive supranuclear palsy (PSP) (Daniele, Giustolisi, Silveri, Colosimo, & Gainotti, 1994) and frontotemporal dementia (Cappa et al., 1998) also show deficits in verb processing, indicating that frontal and frontostriatal brain areas have a role in action semantics.

Perhaps the most comprehensive patient study of action semantics comes from the work of Tranel, Kemmerer, Damasio, Adolphs, and Damasio (2003). Ninety patients with lesions to various brain regions were assessed in their

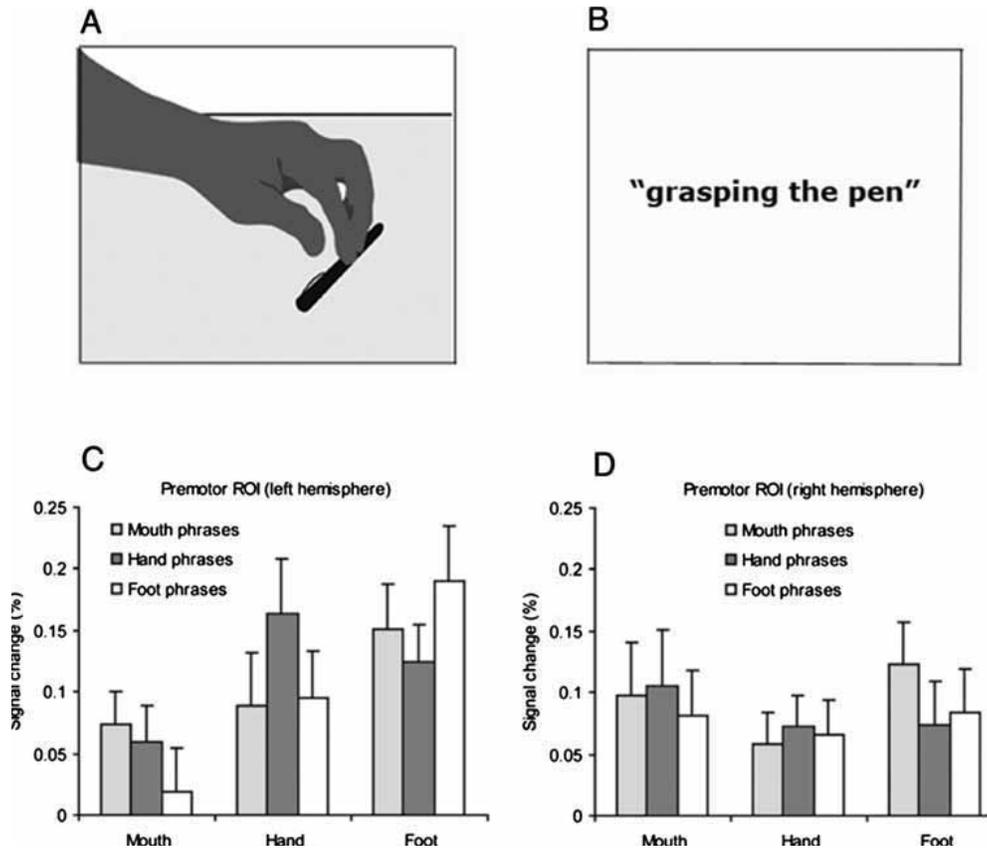

FIGURE 44.6 (A) Observation of movements performed by the hand, mouth, or foot was used to localize regions of interests (ROIs) in the premotor cortex. (B) The same participants read phrases related to hand, mouth, or foot actions. (C) The left hemisphere ROI associated with hand action observation was most active when the participants read phrases described as hand-based actions. The

ROI associated with mouth action observation was most active for mouth-related phrases; similarly, the region defined by foot action observation was most active in reading of foot-based actions. (D) No significant effects were observed in the right hemisphere ROIs. (Adapted from Aziz-Zadeh et al., 2006.)

ability to retrieve action knowledge, using a task in which the participants matched pictures that depicted related actions. Based on a lesion overlap approach, the highest incidence of impairment was associated with damage to the left premotor/prefrontal cortex, the left parietal region, and the white matter underneath the left posterior middle temporal region. A similar dual pattern of deficit was reported in a study in which aphasic patients were tested for their comprehension of visually or verbally presented actions. Patients with lesions of premotor or parietal area were impaired on these tasks, although lesions in premotor areas were more predictive of the observed deficits (Saygin, Wilson, Dronkers, & Bates, 2004).

Taken together, these studies indicate that action comprehension deficits can be observed in patients who have damage to areas associated with planning actions, in particular premotor and parietal regions. Consistent with the arguments raised in our earlier discussion of hierarchies, these results further challenge a traditional view in which motor control and language are segregated into separate modules, with the latter occupying a supraordinate position that can

access the former. Rather, the evidence is more consistent with an embodied cognition framework, one in which our conceptual knowledge of actions is dependent on the systems that are required to produce actions. In the more extreme form, this embodiment would extend to our linguistic knowledge of actions (Feldman, 2006).

Summary

Hierarchy as a word was first used around 1380 to describe the strict relationship between the three layers of angels (seraphim, cherubim, and thrones) ascending toward heaven. Each was subordinate yet dependent on the lower level. In this chapter, we have argued for the existence of a hierarchy in the human brain for organizing complex motor behavior that, like the angels, carries with it distinct functional dependencies. However, unlike the angels, the anatomy of the motor system and the multitude of solutions for achieving complex behaviors suggest that the supraordinate or subordinate roles played by different layers of functional hierarchy can be readily interchanged.

Introduction

DANIEL L. SCHACTER

MEMORY IS SO fundamental to the operation of the brain and mind that students of the topic could be forgiven for feeling that their object of study is perhaps the most central in all of cognitive neuroscience. But what is memory? As I wrote in the introductory section to the memory chapters in the 2005 edition of this book, we cannot yet provide a satisfactory answer to this question, but we do know something worth knowing about what memory is *not*: it is not a single entity or concept. Indeed, as Endel Tulving stated in his introduction to the memory chapters in this volume's first edition, "Memory is many things, even if not everything that has been labeled memory corresponds to what cognitive neuroscientists think of as memory. Memory is a gift of nature, the ability of living organisms to retain and to utilize acquired information. The term is closely related to *learning*, in that memory in biological systems always entails learning (the acquisition of information) and in that learning implies retention (memory) of such information." Tulving also characterized memory as a trick of evolution, a biological abstraction, and a convenient chapter heading for certain kinds of problems that scientists study.

Tulving's observations still make a great deal of sense. For example, the starting point for virtually any scientific analysis of memory involves a decomposition into processes of encoding, storage and consolidation, and retrieval. Furthermore, a prominent theme in cognitive neuroscience for the past two decades has been that memory can be divided into multiple forms or systems—collections of processes that operate on different kinds of information and according to different rules. Forms of memory such as working, episodic, semantic, priming, and procedural memory are all familiar to contemporary researchers.

The idea that memory is not a single thing also extends to memory's imperfections. Memory is not a simple matter

of success or failure. Memory can go awry because of either forgetting or distortion, and each of these types of error can be subdivided into several distinguishable forms. Furthermore, memory interacts in important ways with a number of related processes, including emotion, cognitive control, and planning. A full understanding of memory requires us to address its varied manifestations and complexities. Happily, memory researchers have risen to the challenge by exploring and perhaps beginning to unravel the many complexities of memory.

The seven chapters in this section highlight many facets of memory at different levels of analysis. The starting point for cognitive neuroscience analyses of memory typically begins in the medial temporal lobe. Ever since the groundbreaking observations of Scoville and Milner during the 1950s concerning the severe amnesia observed in patient HM after bilateral resection of the medial temporal lobe for relief of intractable epilepsy, attempting to understand this region's role in memory and learning has constituted a kind of holy grail for memory researchers. It is therefore appropriate that the section begins with Suzuki's chapter concerning the neuroanatomy of the medial temporal lobe (chapter 45). She provides a detailed analysis that focuses in particular on similarities and differences across species in a number of key medial temporal lobe structures, including perirhinal, parahippocampal, and entorhinal cortices. Among the interesting differences observed, Suzuki notes that in monkey perirhinal cortex, unimodal input is dominated by the visual modality, whereas the rat perirhinal cortex receives a wider range of inputs from all sensory modalities. Suzuki delineates possibly important functional consequences of such differences.

In chapter 46, Shrager and Squire focus on work with human amnesic patients to examine spared and impaired functions after medial temporal lobe damage. They report a series of refined experimental studies concerning amnesic patients who have well-characterized lesions in order to address a number of topics that have been central to recent discussions of medial temporal lobe function, including working memory, habit learning, recollection versus familiarity, path integration, remote memory, and conscious awareness. Their observations help to delineate the role of the medial temporal lobe in each of the foregoing aspects of memory and learning.

Nader in chapter 47 focuses on the recently rediscovered phenomenon of reconsolidation, one of the most intensively investigated and hotly debated topics in neuroscience-based memory research during the past decade. It has long been accepted that memory is a time-dependent process, involving a consolidation phase where new memories are initially unstable or labile, and then over time become more stable and resistant to disruption. Reconsolidation refers to the observation that reactivating a seemingly consolidated

memory can, under a number of conditions, return it transiently to a labile state in which it is again subject to disruption. Nader reviews recent experimental evidence, considers various alternative interpretations of the phenomenon, and attempts to link reconsolidation with approaches to memory that emphasize its constructive nature.

In chapter 48, Race, Kuhl, Badre, and Wagner examine the interface between memory and cognitive control processes, which guide thought and action in accordance with current goals. They review fMRI studies concerned with the contributions of specific regions within the frontal lobe to cognitive control over memory, focusing especially on situations in which competition between memories creates interference, and where ineffective retrieval cues yield uncertainty. Their discussion of the theoretical implications of dissociations between specific frontal subregions in several task domains illustrates the impressive specificity of neuroanatomical and functional conclusions that can be drawn on the basis of imaging studies.

Just as the interface between memory and cognitive control has brought a major topic of experimental and theoretical concerns to the surface, so has the interface between memory and emotion. Kensinger in chapter 49 reviews this increasingly impressive body of research, which shows that interactions with emotion can arise at every phase of the memory process, including encoding, consolidation, and retrieval. She considers neuroimaging data that clarify the role of the amygdala in emotional memory and that reveal conditions under which amygdala activity corresponds with increased accuracy of emotional memories. Kensinger also considers how individual differences can influence emotion-memory interactions.

The latter topic constitutes the central focus of Miller's chapter 50, especially in relation to neuroimaging studies of memory functions. Though individual differences in memory have often been overlooked in memory research, Miller argues that for neuroimaging studies especially, group analyses can be incomplete and even misleading. Miller illustrates this point with recent work from his own laboratory, and he also integrates observations concerning individual differences with some key theoretical issues in memory research.

Though the preceding six chapters cover many different facts of memory, they all approach memory as a process that is concerned with recovering information from the past. In the concluding chapter of this part (chapter 51), Schacter, Addis, and Buckner consider a recent and rapidly evolving literature that implicates memory as a key player in allowing individuals to think about and simulate possible happenings in the future. They discuss striking observations from neuroimaging and neuropsychological studies showing cognitive and neural overlap between the processes involved in remembering the past and imagining the future, and relate

these observations to the idea that memory is a fundamentally constructive process, sometimes prone to errors and illusions. They consider the possibility that the flexible use of information from memory to simulate alternative future scenarios constitutes a key function of a constructive memory system.

The chapters in this section reveal expansions in both the depth and breadth of memory research, which bodes well for the future of the enterprise. We cannot know with any certainty what path memory research will follow in the upcoming years, but we can be confident that it will be exciting to find out.

45 Comparative Analysis of the Cortical Afferents, Intrinsic Projections, and Interconnections of the Parahippocampal Region in Monkeys and Rats

WENDY A. SUZUKI

ABSTRACT Detailed neuroanatomical studies that focused on the connections of the medial temporal lobe in monkeys provided critical clues toward identifying the structures important for normal declarative memory. These structures include the hippocampus together with the surrounding and strongly interconnected entorhinal, perirhinal, and parahippocampal cortices. Detailed anatomical descriptions of the connections of the analogous cortical regions in rats suggest both similarities and differences in the connections of these cortical medial temporal lobe areas across species. In this chapter we will review the quantitative anatomical studies describing the cortical inputs, intrinsic projections, and interconnections of the entorhinal, perirhinal, and parahippocampal cortices in monkeys and rats. A detailed understanding of the cross-species similarities and differences in the anatomical organization of these regions can provide valuable insight into understanding the core mnemonic functions of these areas.

The landmark description by Scoville and Milner (1957) of a group of brain-damaged patients including the well-known amnesic patient HM demonstrated for the first time that bilateral damage limited to the region of the medial temporal lobe in humans resulted in a permanent and devastating memory impairment. Later studies showed that patients with medial temporal lobe damage exhibited a memory loss that was selective for fact and event memory (i.e., declarative memory; Eichenbaum & Cohen, 2001; Gabrieli, 1998; Squire, Knowlton, & Musen, 1993; Squire, 1992). While the original report of Scoville and Milner (1957) first identified the region of the medial temporal lobe as key for memory function, a convergence of systematic anatomical and neurobehavioral studies in animal model systems was critical for

identifying which of the structures in the medial temporal lobe, when damaged, were responsible for the severe declarative memory impairment seen in patient HM.

Whereas early experimental lesion (Mishkin, 1978) and neurophysiology studies (O'Keefe & Nadel, 1978) tended to focus on the role of the hippocampus in declarative-like memory, because later studies showed that selective hippocampal lesions in humans (Zola-Morgan, Squire, & Amaral, 1986) resulted in mild memory impairment relative to the impairment seen in patient HM, this finding suggested that brain areas beyond the hippocampus may also be involved. The anatomical studies of Amaral and colleagues (Amaral, Insausti, & Cowan, 1987; Insausti, Amaral, & Cowan, 1987a, 1987b) provided critical insight into which other medial temporal lobe areas might be participating in declarative memory. Specifically, their quantitative neuroanatomical studies showed that the monkey entorhinal cortex, the major source of cortical inputs to the hippocampus, received the vast majority of its cortical projections from the surrounding perirhinal and parahippocampal cortices. Further anatomical studies revealed that the perirhinal and parahippocampal cortices (Suzuki & Amaral, 1994a, 1994b) received a powerful convergence of unimodal and polymodal cortical inputs and in this way served as a critical relay for multimodal information into the hippocampal formation (i.e., hippocampus and entorhinal cortex). Taken together, these anatomical insights were critical in focusing attention on the possible mnemonic role of the entorhinal, perirhinal, and parahippocampal cortices. A convergence of subsequent lesion studies (Leonard, Amaral, Squire, & Zola-Morgan, 1995; Suzuki, Zola-Morgan, Squire, & Amaral, 1993; Meunier, Bachevalier, Mishkin, & Murray, 1993; Zola-Morgan, Squire, Amaral, & Suzuki, 1989; Murray &

WENDY A. SUZUKI Center for Neural Science, New York University, New York, New York

Mishkin, 1986) and neurophysiological studies (Miller, Li, & Desimone, 1993, 1991; Riches, Wilson, & Brown, 1991; Baylis & Rolls, 1987; Brown, Wilson, & Riches, 1987) in monkeys together with findings from brain-damaged patients with detailed MRI localization (Stefanacci, Buffalo, Schmolck, & Squire, 2000; Corkin, Amaral, Gilberto Gonzalez, Johnson, & Hyman, 1997) confirmed the critical contribution of these cortical medial temporal lobe areas to declarative memory.

Parallel neuroanatomical, lesion, and neurophysiological studies in rodents have also made important progress in defining the functional organization of these cortical medial temporal lobe regions. Anatomically, the perirhinal and parahippocampal cortices in monkeys are thought to be homologous to the perirhinal and postrhinal cortices in rats, respectively (Burwell & Witter, 2002; Burwell & Amaral, 1998a; Burwell, Witter, & Amaral, 1995). Neuroanatomical studies revealed that similar to monkeys, these cortical areas in rats also receive a strong convergence of multimodal sensory information (Burwell & Amaral, 1998a; Deacon, Eichenbaum, Rosenberg, & Eckmann, 1983). Lesion and neurophysiology studies, however, have revealed both similarities and differences in the functional organization of these cortical areas across species. Behavioral neurophysiology studies support the idea that like the monkey perirhinal cortex (Miller et al., 1993, 1991; Riches et al., 1991; Baylis & Rolls, 1987; Brown et al., 1987), the rat perirhinal cortex signals visual recognition by responding significantly less upon stimulus repetition (Xiang & Brown, 1998; Brown & Xiang, 1998). However, recent lesion studies focused on the rat perirhinal cortex implicate this region in context memory (Bucci, Sadoris, & Burwell, 2002; Bucci, Phillips, & Burwell, 2000), a function that has not been examined in the monkey perirhinal cortex. Lesion (Malkova & Mishkin, 2003) and physiology studies (Rolls & Xiang, 2005; Cahusac, Miyashita, & Rolls, 1989) focused on the monkey parahippocampal cortex have implicated this region in spatial memory. Lesion studies in rats have implicated the postrhinal cortex in context memory (Bucci et al., 2002, 2000), but findings on tasks of spatial memory have been mixed (Burwell, Bucci, Sanborn, & Jutras, 2004; Liu & Bilkey, 2002). Physiology studies reported positional firing characteristics in rat postrhinal cells that differed from those previously seen in the rodent hippocampus or medial entorhinal cortex (Fyhn, Molden, Witter, Moser, & Moser, 2004; Burwell & Hafeman, 2003; Shapiro, Tanila, & Eichenbaum, 1997).

It is clear from this brief review that while there are similarities in the functional organization of these cortical areas across monkeys and rats, differences are emerging as well. Given the reliance on these animal model systems for understanding human memory function, it is important to accurately identify both the core mnemonic and processing

functions of these areas that are similar across species and the species-specific differences. In particular, the recent discovery of grid cells in the rat medial entorhinal cortex (Hafting, Fyhn, Bonnevie, Moser, & Moser, 2008; Fyhn, Hafting, Treves, Moser, & Moser, 2007; Hafting, Fyhn, Molden, Moser, & Moser, 2005; Fyhn et al., 2004) raises fascinating new questions about the homology of physiological findings across these cortical medial temporal lobe areas in monkeys and rats. Grid cells in the rodent medial entorhinal cortex exhibit a striking pattern of spatially selective firing in that they represent large extents of the physical environment in a gridlike pattern of tessellating equilateral triangles. Could there be gridlike cells in the monkey entorhinal cortex as well? One way to address the general question of the homology of the cortical medial temporal lobe areas across monkeys and rats is to take advantage of the growth over the last 10 years of detailed and quantitative neuroanatomical studies of these cortical areas in both species. There is now a critical mass of such anatomical data that allows more detailed cross-species comparisons of the connections of the cortical areas surrounding the hippocampus. In this chapter we will characterize the flow of cortical information into the perirhinal, parahippocampal, postrhinal, and entorhinal cortices together with the prominent intrinsic projections and interconnections of these areas in both monkeys and rats.

Boundaries and nomenclature of the perirhinal, parahippocampal, postrhinal, and entorhinal cortices: Many controversies and some agreement

THE PARAHIPPOCAMPAL REGION IN MONKEYS The perirhinal, parahippocampal, and entorhinal cortices are often referred to as the *parahippocampal region* (Burwell & Witter, 2002). In monkeys, these areas are situated on the anterior-ventral portion of the medial temporal lobe (figure 45.1A) and surround the amygdala anteriorly and the hippocampus posteriorly. While the boundaries and nomenclature of the monkey entorhinal cortex are generally accepted, substantial controversy currently exists over the nomenclature and precise boundaries of both the perirhinal and parahippocampal cortices. Although a detailed discussion of the source of these controversies is beyond the scope of this chapter, we briefly mention the boundaries that are most disputed in both the monkey and the rat literature.

The monkey perirhinal cortex is situated lateral to the fundus of the rhinal sulcus and extends from the posterior border of the rhinal sulcus on the ventral surface of the temporal lobe to the anterior and dorsal portion of the rhinal sulcus on the temporal pole (figure 45.1A). It is bordered medially by the entorhinal cortex, laterally by visual area TE, and posteriorly by the parahippocampal cortex. The perirhi-

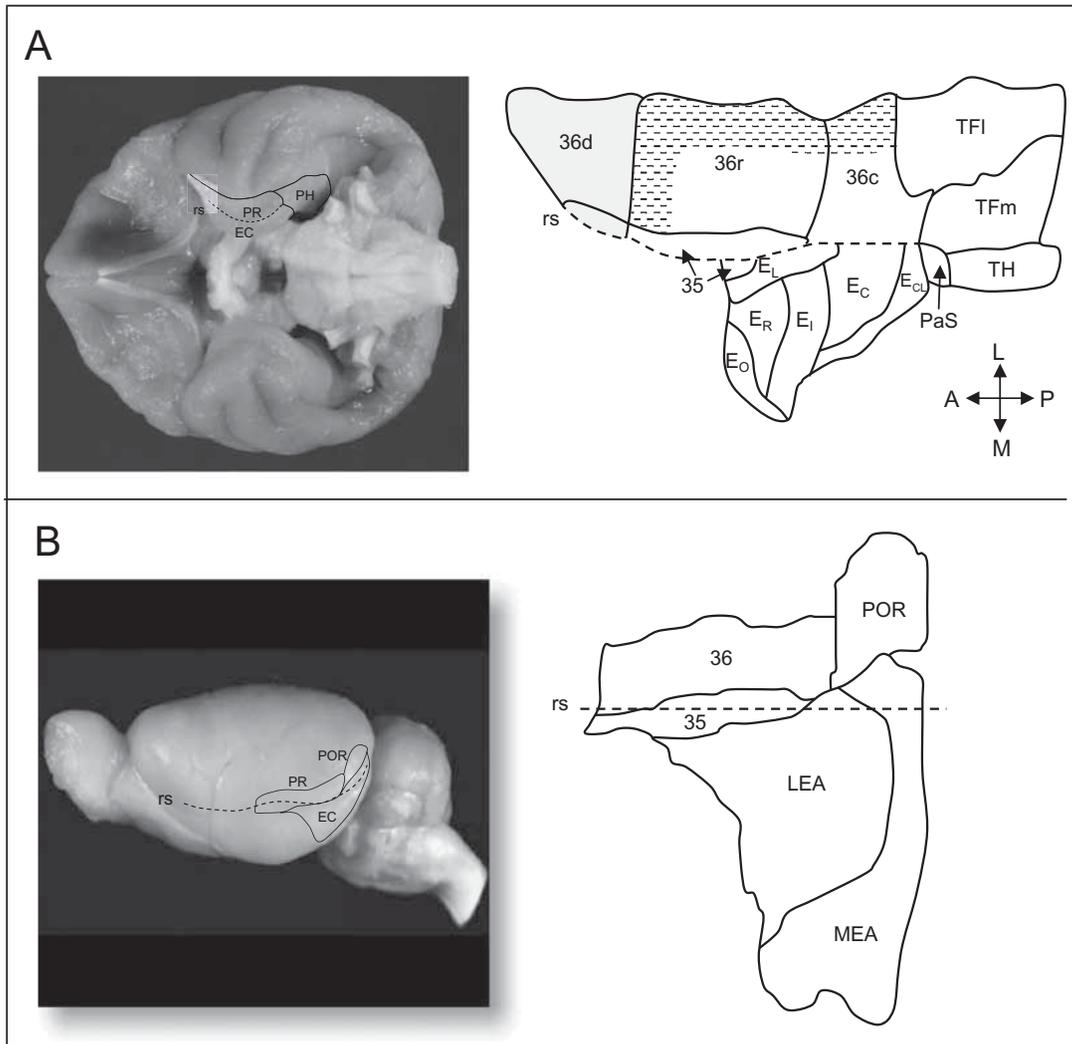

FIGURE 45.1 (A) *Left*: Photograph illustrating the ventral view of the macaque monkey brain showing the locations of the entorhinal (EC), perirhinal (PR), and parahippocampal (PH) cortices surrounding the rhinal sulcus (rs). The shaded region at the level of the dorsal temporal pole corresponds to area 36d. *Right*: An unfolded representation of the same cortical medial temporal lobe areas shown on the left is illustrated along with major subdivisions. The perirhinal cortex is subdivided into areas 35, 36r, and 36c. The parahippocampal cortex includes areas TFI, TFm, and TH. The monkey entorhinal cortex is subdivided into the olfactory (E_O), rostral (E_R), lateral (E_L), intermediate (E_I), caudal (E_C), and caudal limited (E_{CL}) subdivisions. The location of area 36d is indicated on the unfolded map but not included within the boundaries of the perirhinal cortex for this chapter (see text for explanation).

The stippled region within areas 36r and 36c shows the approximate extent and location of the disputed anterior and lateral borders of the perirhinal cortex. We will use the more anterior and lateral boundaries of the perirhinal cortex as described by Suzuki and Amaral (1994b, 2003a). (B) *Left*: Photograph illustrating the lateral view of a rat brain showing the locations of the entorhinal (EC), perirhinal (PR), and postrhinal (POR) cortices. *Right*: An illustration of an unfolded representation of the same cortical areas along with all major subdivisions. As in the monkey, the rat perirhinal cortex is subdivided in areas 35 and 36 while the entorhinal cortex is subdivided into the lateral entorhinal area (LEA) and the medial entorhinal area (MEA). The rat postrhinal cortex has not been subdivided further. Additional abbreviations: PaS, parasubiculum; A, anterior; P, posterior; M, medial; L, lateral.

nal cortex has been further subdivided into area 35, which forms a long and narrow strip of cortex situated in the fundus and lateral bank of the rhinal sulcus, and a larger, more laterally situated area 36. Area 36 has further been subdivided into two major subdivisions (areas 36r and 36c) based on cytoarchitectonic criteria. Two main controversies exist over

the borders of the monkey perirhinal cortex. One concerns whether the cortex of the temporal pole adjacent to the rhinal sulcus should also be considered part of the perirhinal cortex (Saleem, Price, & Haskikawa, 2007; Kondo, Saleem, & Price, 2005, 2003; Suzuki & Amaral, 1994a; Insausti et al., 1987a). The disputed regions, illustrated in the unfolded map in

figure 45.1A, include both area 36d and the anterior stippled region in area 36r that represents the ventral portion of the temporal pole. The second controversy concerns the precise location of the lateral border of area 36 with area TE (Saleem et al., 2007; Kondo et al., 2005, 2003; Suzuki & Amaral, 1994a; Insausti et al., 1987a). This disputed area is shown as the lateral stippled region in areas 36r and 36c in the unfolded map of figure 45.1A. In this chapter, we will focus on the connections of the portion of the perirhinal cortex situated on the ventral surface of the brain, which includes part of the ventral temporal pole that has connections and cytoarchitectonic features similar to the ventral perirhinal areas (Kondo et al., 2005; Suzuki & Amaral, 2003a, 2003b, 1994a), as well as the more laterally situated border of area 36 with area TE as described by Suzuki and Amaral (2003a, 1994a). This includes both areas 36r and 36c illustrated in figure 45.1A. However, we exclude area 36d of Suzuki and Amaral (1994a), since several studies have shown that this region has different connections from the rest of the ventrally situated perirhinal cortex (Saleem, Kondo, & Price, 2008; Kondo et al., 2003; Suzuki & Amaral, 1994a).

The monkey parahippocampal cortex is situated just caudal to both the perirhinal and entorhinal cortices (figure 45.1A). This cortical area is made up of areas TH and TF, and area TF contains two subdivisions defined by cytoarchitectonic features (areas TFm and TFl). Both Blatt, Pandya, & Rosene (2003) and Suzuki and Amaral (2003a, 1994a) place the lateral border of area TF at the level of occipitotemporal sulcus. However, Price and colleagues (Saleem et al., 2007; Kondo et al., 2005) have placed this lateral border approximately 3 mm more medial at approximately the level of Suzuki and Amaral's area TFm. In this review we will use the nomenclature and boundaries for the parahippocampal cortex described by Suzuki and Amaral (2003a, 1994a).

The third component of the parahippocampal region is the entorhinal cortex located in the ventromedial part of the rostral third of the temporal lobe (figure 45.1A). The entorhinal cortex has further been subdivided into six subdivisions based mainly on cytoarchitectonic criteria (Amaral et al., 1987). In general, the monkey entorhinal cortex enjoys the least controversy over the location of its borders, compared to the perirhinal and parahippocampal cortices.

THE PARAHIPPOCAMPAL REGION IN RATS In rats the parahippocampal region occupies a location relative to the rhinal sulcus that is similar to that of monkeys with some subtle differences. Similar to monkeys, the perirhinal cortex in rats comprises areas 35 and 36. These two subdivisions form two strips of cortex associated with the mid- to posterior portions of the rhinal sulcus (figure 45.1B). Area 36 is a wider strip of the cortex that occupies most of the dorsal bank of the rhinal sulcus and part of the laterally

adjacent cortex. Area 35 is situated medially and occupies the ventral bank and fundus of the rhinal sulcus. Similar to the monkey, both the anterior border of the rat perirhinal cortex with the insula and the lateral border with area TEv have both varied widely in the literature (Burwell et al., 1995). Here we will use the borders described by Burwell and colleagues (Burwell, 2001).

In contrast to the perirhinal cortex, which shares substantial cytoarchitectonic features between the rat and monkey brain, the postrhinal cortex in rats and the parahippocampal cortex in monkeys do not share clear cytoarchitectonic features. For this reason, Burwell and colleagues (1995) called the region the postrhinal cortex following the earlier rodent literature (Burwell et al., 1995; Deacon et al., 1983) rather than using the nomenclature used in monkeys (Van Hoesen, Pandya, & Butters, 1975; Van Hoesen & Pandya, 1975a, 1975b). While cytoarchitectonic features are not shared across the rat postrhinal and monkey parahippocampal cortex, as will be described in detail later, they exhibit similarities in their connections that have led to the hypothesis that these two areas are homologous (Burwell, 2000; Burwell & Amaral, 1998a).

In rats, the entorhinal cortex is situated on the ventral and caudal surface of the brain medial to the posterior portion of the rhinal sulcus (figure 45.1B). At anterior levels its lateral border is situated medial to the rhinal sulcus, and at more caudal levels the entorhinal cortex extends laterally past the fundus of the rhinal sulcus. The rat entorhinal cortex has historically been subdivided into a lateral entorhinal area (LEA) and a medial entorhinal area (MEA) based on morphological criteria (Blackstad, 1956; Krieg, 1946a, 1946b).

Connections of the perirhinal, parahippocampal/ postrhinal, and entorhinal cortex: Afferent, intrinsic, and interconnections

THE MONKEY PERIRHINAL CORTEX

Cortical afferents Early anatomical studies first identified the monkey perirhinal cortex as receiving convergent input from areas involved in processing multiple sensory modalities (Martin-Elkins & Horel, 1992; Seltzer & Pandya, 1976; Van Hoesen et al., 1975; Van Hoesen & Pandya, 1975a, 1975b; Jones & Powell, 1970). More recent retrograde and anterograde tract-tracing studies have provided more detailed and quantitative description of these convergent inputs (Saleem et al., 2008; Kondo et al., 2005; Saleem & Tanaka, 1996; Rockland, Saleem, & Tanaka, 1994; Suzuki & Amaral, 1994a). The single most prominent input to perirhinal area 36 arises from the anterior and medial portions of unimodal visual area TE, a major component of the "ventral visual pathway" important for processing object information (Ungerleider & Mishkin, 1982). The same

regions of medial area TE converge on all parts of the area 36. The second strongest input to area 36 arises from area TF of the adjacent parahippocampal cortex with the strongest inputs originating from the anterior two-thirds of area TF and terminating throughout area 36. Only weak projections are seen from area TH. Moderate projections arise from the visual areas of the ventral bank of the superior temporal sulcus (STSV) that terminate anteriorly in the perirhinal cortex. Weak projections from the polymodal areas of the dorsal bank of the STS (STSD) and area 36d also terminate anteriorly in area 36. Weak projections from orbital frontal areas 11, 12, and 13 (Kondo et al., 2005), insular cortex, and anterior cingulate cortex terminate throughout

area 36. In general area 35 receives a pattern of cortical inputs similar to that of area 36, though it receives a relatively stronger input from the dorsal bank of the superior temporal sulcus (see box 45.1).

Intrinsic projections The perirhinal cortex also exhibits prominent intrinsic projections such that each major perirhinal subdivision (36r, 36c, and 35) has prominent interconnections within that subdivision and moderate projections to the other subdivisions (shading in figure 45.2A; Lavenex, Suzuki, & Amaral, 2004). Given the strong convergence of projections from areas TE and the parahippocampal cortex to all levels of the perirhinal cortex, this observation suggests that

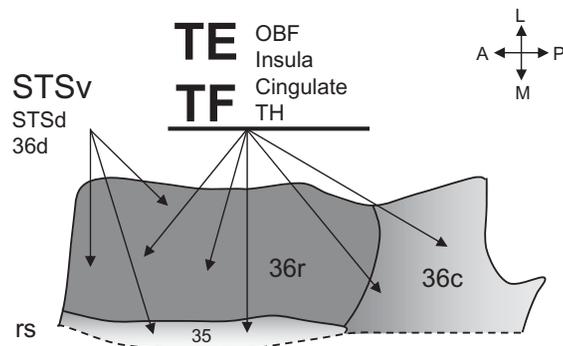

Box 45.1 Calculations of the Relative Strength of Cortical Inputs

To accurately and systematically quantify the relative strength of the cortical inputs shown in figures 45.2–45.4, we used data derived from retrograde labeling studies in both monkeys and rats. For the cortical inputs to the monkey perirhinal and parahippocampal cortices, we used the quantitative retrograde tracer data from table 1 of Suzuki and Amaral (1994a). For the cortical inputs to the monkey entorhinal cortex, we used the retrograde data from table 1 of Insausti, Amaral, and Cowan (1987a). For the relative proportions of cortical inputs to the rat perirhinal and postrhinal cortex, we used retrograde data from Furtak, Wei, Agster, and Burwell (2007), and for the cortical inputs to the rat entorhinal cortex, we used the retrograde data from Kerr, Agster, Furtak, & Burwell (2007). Based on the number or proportion of retrogradely labeled cells reported in these studies, we next defined the strongest afferent projections (shown with the largest lettering in figures 45.2–45.4) as those projections that represented 20% or more of the total retrogradely labeled cells in cortical areas. Medium-sized afferent projections shown with medium-sized lettering represent between 11% and 19% of total cortical labeling, and weak afferent projections shown with the smallest lettering represent 10% or less of the cortical inputs. To complete these calculations, we also recalibrated the retrograde data presented in both Furtak and colleagues (2007) and Kerr and colleagues (2007) in the following way. First, we recalculated the relative proportion of cortical inputs to the rat perirhinal and postrhinal cortices to include inputs from either the perirhinal or postrhinal cortices themselves that were originally included in hippocampal formation inputs, but not in cortical inputs by Furtak and colleagues (2007). Similarly we recalculated the relative strength of cortical inputs to the entorhinal cortex to include inputs from both the perirhinal and postrhinal inputs from the data shown in Kerr and colleagues (2007). For figure 45.5, we performed a similar recalculation to show the relative proportion of all cortical (including perirhinal and postrhinal) and subcortical inputs to the rat LEA and MEA from the data shown in Kerr and colleagues (2007).

B. Rat Perirhinal Cortex

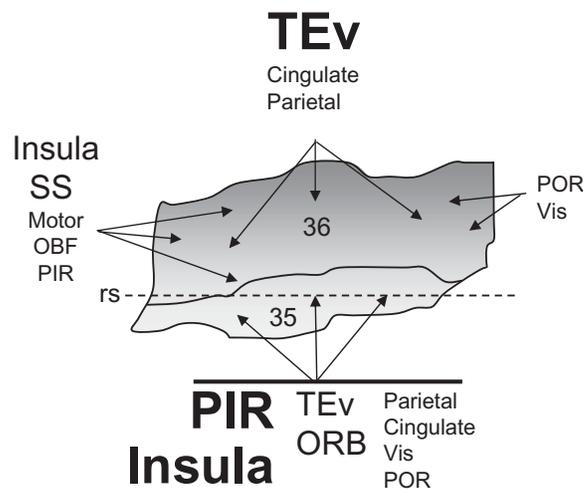

FIGURE 45.2 (A) Schematic representation of the topography and strength of cortical inputs to the monkey perirhinal areas 35, 36r, and 36c. The relative strength of the cortical projections is indicated by the size of the lettering, and the locations of the arrows indicate the relative topography of projections throughout the perirhinal cortex. The pattern of intrinsic projections is illustrated by the shading pattern within areas 35, 36r, and 36c. The strongest inputs arise from visual area TE and the adjacent area TF of the parahippocampal cortex that project to all levels of the perirhinal cortex. As indicated by the shading pattern, area 36r projects most strongly to itself and moderately to 36c and 35 and visa versa. (B) Schematic representation of the topography and strength of cortical inputs to the rat perirhinal cortex. All conventions are the same as in Panel A. Area 36 in rats receives its strongest input from area

TEv (mainly from areas processing auditory and somatosensory information) with moderate inputs from insula and somatosensory areas (SS). Area 35 receives its strongest inputs from the piriform cortex (PIR) and insular cortex with moderate inputs from area TEv and the orbitofrontal areas of the frontal lobe (ORB). While dorsal/lateral regions of area 36, project mainly to more medial/ventral regions of area 36, the medial regions of area 36 project strongly to area 35 (shading). These intrinsic projections, however, are not strongly reciprocal. Additional abbreviations: Motor, motor areas of the frontal lobe; POR, postrhinal cortex; rs, rhinal sulcus; SS, somatosensory areas; STG, superior temporal gyrus; STSd, dorsal bank of the superior temporal sulcus; STSv, ventral bank of the superior temporal sulcus.

this convergent cortical input is further processed throughout large extents of the perirhinal cortex.

THE RAT PERIRHINAL CORTEX

Cortical afferents In contrast to the preponderance of visual object input to the monkey perirhinal cortex, the rat perirhinal cortex is characterized by a strong convergence of inputs from all sensory modalities (Furtak, Wei, Agster, & Burwell, 2007; Burwell & Amaral, 1998a; Deacon et al., 1983). The strongest inputs to area 36 of the perirhinal cortex arise from anterior and ventral temporal association areas known to receive strong projections from somatosensory (anterior TEv) and auditory areas (mid-rostrocaudal levels of TEv), respectively (Burwell & Amaral, 1998a). The projections from area TEv along with weak projections from cingulate and parietal cortex terminate throughout area 36. Weak projections from the postrhinal cortex as well as weak projections from posterior visual areas both terminate most strongly in caudal portions of area 36. Moderate projections are seen from insular cortex and somatosensory cortical areas (Burwell, 2001; Remple, Henry, & Catania, 2003; Shi & Cassell, 1998) that terminate more strongly in rostral portions of area 36. Frontal areas, including both orbitofrontal areas and frontal motor regions together with the piriform cortex, provide weak projections mainly to anterior levels of area 36. In contrast to area 36, area 35 receives its strongest cortical inputs from piriform cortex and insular cortex, with moderate inputs from TEv and orbitofrontal cortex and weak projections from parietal cortex, cingulate cortex, posterior visual areas, and postrhinal cortex. Thus, taken together, the afferent inputs to rat perirhinal areas 35 and 36 are dominated by sensory inputs from the olfactory, somatosensory, and auditory, as well as the visual, modalities (see box 45.1).

Intrinsic projections While the cortical inputs to area 36 of the rat perirhinal cortex tend to exhibit a more prominent rostrocaudal topography, the intrinsic projections of the perirhinal cortex have a clear dorsal-to-ventral gradient (shaded pattern in figure 45.2B; Burwell & Amaral, 1998b). Thus the most dorsal regions of area 36 project mainly to more ventral areas of 36 while the ventral areas of area 36 project strongly to area 35. In contrast, area 35 returns a weaker projection to area 36. Thus area 35 may be the ultimate site of convergence for all sensory modalities within the rat perirhinal cortex.

Summary and comparisons The monkey perirhinal cortex is dominated by high-level visual inputs from area TE as well as prominent polymodal inputs from the parahippocampal cortex. The rat perirhinal cortex, by contrast, receives a much more diverse range of sensory inputs from olfactory, somatosensory, and auditory, as well as visual, modalities. Thus, while monkey perirhinal cortex appears to be special-

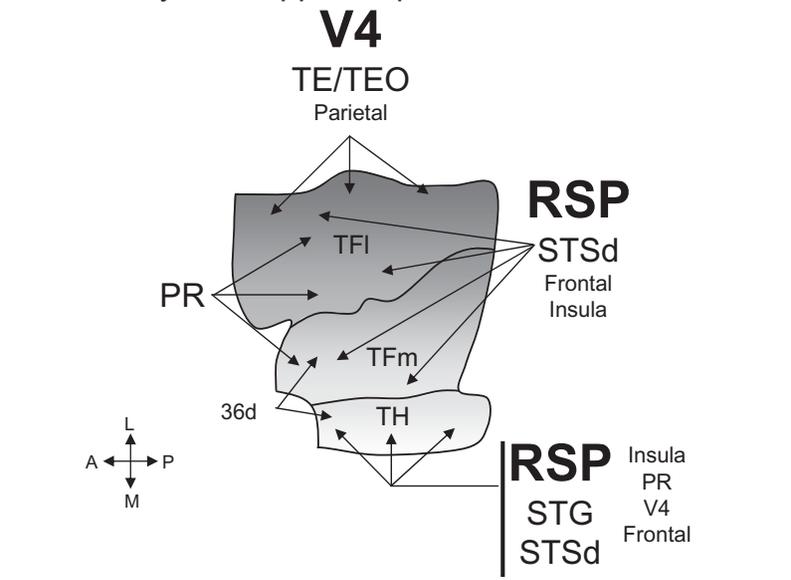

ized in processing visual object information in memory as well as polymodal input from the parahippocampal cortex, the rat perirhinal cortex appears to be poised to integrate information from all sensory modalities in memory.

THE MONKEY PARAHIPPOCAMPAL CORTEX

Cortical afferents Like the perirhinal cortex, area TF of the parahippocampal cortex also receives its strongest single input from visual areas (Blatt et al., 2003; Suzuki & Amaral, 1994a), but the visual areas that project to the parahippocampal cortex (mainly areas V4 and TEO; figure 45.3A) are posterior to the visual areas that project to the perirhinal cortex (i.e., area TE; figure 45.2A). Moreover, these projections exhibit a clear medial lateral topography projecting more strongly to lateral portions of area TF than to medial portions. The next most prominent input to area TF comes from brain areas involved in the so-called ventral visual processing pathway important for analyzing spatial information (the “where” pathway of Ungerleider & Mishkin, 1982). The most prominent of these dorsal stream inputs arise from the retrosplenial cortex, which projects to all levels of area TF. Similarly, moderate projections from area STSd, also considered a dorsal stream area, provide a moderate projection to all levels of area TF. Weak projections are also seen from the posterior parietal cortex, which terminate laterally in area TFl. Moderate projections also originate from area 36c of the perirhinal cortex and weak projections from area 36r that terminate most strongly in anterior portions of area TF while weak projections from area 36d tend to terminate more medially in area TF. Weak projections are also seen from frontal areas including area 46, orbital and medial prefrontal areas (Kondo et al., 2005), and the insular cortex. Area TH exhibits some differences in its cortical inputs relative to the cortical inputs of area TF. The most striking difference is that area TH receives only sparse input from visual area V4, but similar to area TF, it receives prominent projections from the retrosplenial cortex. Another striking difference is the moderate input from auditory association areas of the STG, which appears to constitute the strongest direct auditory projections to any parahippocampal region. Moderate inputs are seen from STSd, and weak inputs arise from insular cortex, the perirhinal cortex (including area 36d), and similar portions of the frontal lobe that project to area TF (see box 45.1).

Intrinsic projection The intrinsic projections of the parahippocampal cortex (illustrated by the shading in figure 45.3A) parallel the medial lateral topography of the inputs to this region. Thus area TFl (lateral portions of area TF) has the strongest connections with itself, moderate interconnections with area TFm, and only weak projections with area TH. Similarly, area TFm projects most strongly with itself, but

A. Monkey Parahippocampal Cortex

B. Rat Postrhinal Cortex

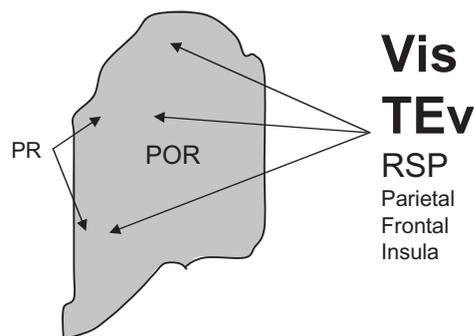

FIGURE 45.3 (A) Cortical inputs of the monkey parahippocampal cortical areas TFI, TFm, and TH. All conventions are the same as in figure 45.2. The strongest inputs to area TF arise from visual areas V4 and the retrosplenial cortex (RSP) with moderate inputs from visual areas TE/TEO and polymodal inputs from the dorsal bank of the superior temporal sulcus (STSd). Area TH receives its strongest single input from the retrosplenial cortex (RSP), with moderate input from the superior temporal gyrus (STG) and the

dorsal bank of the STS (STSd). Intrinsic projections are strongest within each subdivision and progressively weaker to more distantly located subdivisions (shading). (B) The cortical inputs to the rat postrhinal cortex are strongest from primary posterior visual areas (Vis) and area TEv, with moderate inputs from the retrosplenial cortex. No topography of inputs or intrinsic projections is seen. Additional abbreviations: PIR, piriform cortex; SS, somatosensory areas.

moderately with both area TH and area TFI. Finally, like area TFI, area TH projects most strongly with itself, moderately with area TFm, and only weakly with area TFI. Thus, while information arriving only in lateral area TF does not have strong direct interactions with area TH (and vice versa), this information can reach area TH by way of intermediate connections with area TFm.

THE RAT POSTRHINAL CORTEX

Cortical afferents Similar to the monkey parahippocampal cortex, the rat postrhinal cortex is dominated by secondary

visual inputs from both occipital cortex and temporal lobe visual areas (TEv) as well as from dorsal stream areas including the retrosplenial cortex and parietal cortex. Weak projections are seen from frontal and insular cortices. The perirhinal cortex provides a weak projection to anterior regions of the postrhinal cortex, with the strongest projections arising from area 36. No strong topography of projections to the POR cortex was seen, with all afferent regions projecting to most or all of the postrhinal cortex with the exception of the perirhinal cortex, which tended to project to more anterior regions of the postrhinal cortex. Thus, like the parahippocampal cortex in monkeys, the postrhinal

cortex in rats appears to be a strong site of convergence for both visual and visuospatial input (see box 45.1).

Intrinsic projections The postrhinal cortex does not exhibit any strong topography or polarity in its intrinsic projections. Thus all regions of the postrhinal cortex appear to project to all other regions.

Summary and comparison Striking similarities are seen in the patterns of connections of the monkey parahippocampal cortex and the rat postrhinal cortex. Both areas are dominated by visual input from posterior visual areas together with visuospatial input from so-called dorsal stream areas. More specifically, area TF of the parahippocampal cortex has the strongest resemblance to the postrhinal cortex in rats. In contrast, the two regions differ in that the monkey parahippocampal cortex exhibits a striking topography of inputs and intrinsic connections that is not seen in the rat postrhinal cortex.

THE MONKEY ENTORRHINAL CORTEX

Afferents The cortical inputs of the monkey entorhinal cortex were first studied using anterograde degeneration techniques (Van Hoesen et al., 1975; Van Hoesen & Pandya, 1975a, 1975b) and later using WGA-HRP and fluorescent retrograde tracers (Insausti et al., 1987a). These comprehensive studies showed that the entorhinal cortex is the recipient of prominent input from higher-level polymodal association. If one does not include the temporal pole as part of the perirhinal cortex, then the perirhinal and parahippocampal cortices together make up about half of all the cortical input to the monkey entorhinal cortex, with somewhat more than half of that proportion arising from the parahippocampal cortex and the remainder arising from the perirhinal cortex (Table 1 of Insausti et al., 1987a). The cortex of the temporal pole contributes only weak projections to the entorhinal cortex. Moreover, the perirhinal and parahippocampal cortices exhibit a clear topography of projection, with the parahippocampal cortex projecting most prominently to the posterior entorhinal cortex with weaker projections to anterior and lateral regions and the perirhinal cortex projecting most prominently to anterior and lateral portions of the entorhinal cortex with weaker projections more laterally and caudally. Another prominent input comes from the retrosplenial cortex, which, like the parahippocampal cortex, projects most prominently posteriorly in the entorhinal cortex. Weaker projections are seen from the superior temporal gyrus (STG) and STSd, which project posteriorly, and the insular cortex, which projects anteriorly and laterally. Weak projections are also seen from the piriform cortex to the olfactory subdivision of the entorhinal cortex (E_O). Weak inputs from visual area TE have also been described pro-

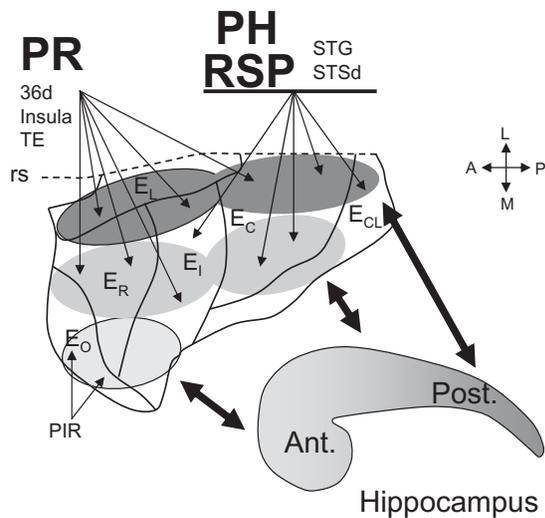

jecting anteriorly and laterally in the entorhinal cortex (Mohedano-Moriano et al., 2008, 2007). Insausti and colleagues (Mohedano-Moriano et al., 2007) have highlighted the lateral band of the monkey entorhinal cortex as receiving the strongest convergence of afferent input from widespread cortical areas (see box 45.1).

Intrinsic projections and connections with the hippocampus Given that the lateral half of the entorhinal cortex receives the strongest convergent input, another important question concerns how that convergent information is processed intrinsically within the entorhinal cortex. Chrobak and Amaral (2007) showed that the intrinsic entorhinal connections in the monkey are organized into rostrocaudally oriented bands where each band extends for about half the anterior-posterior extent of the entorhinal cortex (shaded regions in figure 45.4A). There is also a clear medial lateral topography such that two adjacent bands situated end to end cover the lateral portion of the entorhinal cortex, two more bands situated end to end cover the mid-mediolateral portion of the entorhinal cortex, and a single band covers the most rostral and medial entorhinal cortex at the level of area E_O . Interestingly, the projections from the perirhinal and parahippocampal cortices terminate in multiple bands spanning the mediolateral extent of the entorhinal cortex. Additional studies in the monkeys showed that the three mediolaterally oriented bands in the entorhinal cortex project in a topographic fashion to different anterior-posterior levels of the hippocampus as illustrated in figure 45.4A (Witter, Van Hoesen, & Amaral, 1989). Thus information originating from the perirhinal and parahippocampal cortices is ultimately processed in the posterior half of the hippocampus.

THE RAT ENTORRHINAL CORTEX

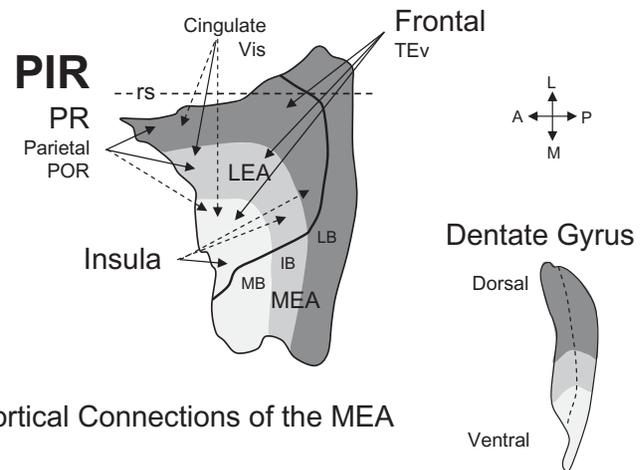

Afferents The rat entorhinal cortex is subdivided into the medial entorhinal area (MEA) and the lateral entorhinal area (LEA), and these two areas have been further separated into lateral, intermediate, and medial bands that project to different septotemporal regions of the dentate gyrus (Dolorfo & Amaral, 1998b). Given this striking and well-described topography, we will summarize the projections to the entorhinal cortex with respect to the different entorhinal subdivisions (MEA and LEA) as well as the different hippocampal projection bands. By far the strongest cortical input to the LEA originates from the piriform cortex, with moderate inputs also arising from the perirhinal cortex, insula, and frontal cortices. Both the piriform and perirhinal cortices project most strongly to the lateral and intermediate bands and more weakly to the medial band. Parietal cortex and the postrhinal cortex provide a weak input to the LEA with the same overall termination pattern as the piriform and perirhinal cortices. The insular input projects most strongly

A. Monkey Entorhinal Cortex

B. Rat Entorhinal Cortex

Cortical Connections of the LEA

Cortical Connections of the MEA

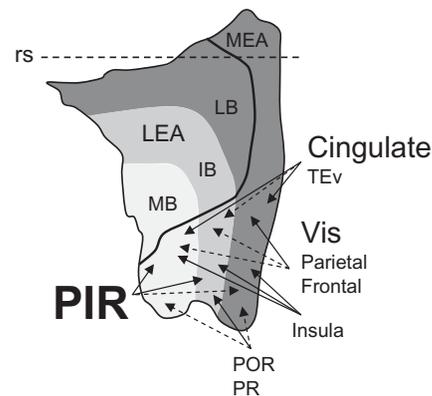

FIGURE 45.4 (A) The cortical inputs of the monkey entorhinal cortex arise predominantly from the parahippocampal (PH) and retrosplenial (RSP) cortices that project posteriorly and laterally as well as from the perirhinal cortex (PR) that projects anteriorly and laterally. The shading illustrates three mediolaterally differentiated bands of intrinsic entorhinal projections. The most lateral and middle mediolateral bands (dark and medial dark shades) also exhibit intrinsic connections that are arranged rostrocaudally. The most medial band (lightest shading) has only a single module. These mediolaterally oriented bands also provide a clear topographic projection to different rostro-caudal levels of the hippocampus such that posterior hippocampus receives inputs from the most lateral bands of the entorhinal cortex, mid anterior-posterior hippocampal areas receive projections from the mid-mediolateral bands, and the most anterior portions of the hippocampus receive inputs from the most medially situated entorhinal band. (B) Top: Illustration of the cortical connections of the lateral entorhinal area (LEA) of the rat. Also illustrated are the

locations of the lateral (LB), intermediate (IB), and medial band (MB) that represent both the pattern of intrinsic projections that are maintained mainly within a single band as well as the topographic projection to different dorsoventral levels of the dentate gyrus (shown schematically at the right). The LEA region receives its strongest cortical input from piriform cortex, with moderate projections from the perirhinal cortex, insula, and frontal cortices. The arrows in this figure illustrate the relative strength of projections to different bands with relatively stronger projections illustrated as solid lines and relatively weaker projections illustrated with dashed lines. Bottom: Illustration of the cortical inputs to the medial entorhinal area (MEA). All conventions are the same as in the top panel. The strongest cortical input to the MEA originates in the piriform cortex (PIR), with moderate projections seen from the cingulate cortex and posterior visual areas (Vis). Note the weak projections from both the perirhinal (PR) and postrhinal (POR) cortices to the MEA. All additional abbreviations are the same as in figures 45.2 and 45.3.

to the medial band, while the frontal and temporal projections terminate similarly in all three bands. Weak projections from cingulate cortex and visual cortex (Vis) project mainly to the intermediate band.

Similar to the LEA, the most prominent cortical projection of the MEA originates in the piriform cortex, terminating mainly in the medial and intermediate bands. Moderate inputs that arise from the cingulate cortex and visual cortex (Vis) mainly target either the lateral and medial or the lateral band, respectively. Weak inputs are seen from ventral temporal area TEV, and parietal, frontal, and insula cortices. Post-rhinal and perirhinal cortices provide only a weak input to the MEA, mainly to the intermediate band (see box 45.1).

Intrinsic connections and connections with the hippocampus Intrinsic projections of the entorhinal cortex tend to remain within one of the roughly rostrocaudally oriented bands of cortex that include both the medial and lateral E_C (i.e., lateral, intermediate, or medial bands—LM, IM, or MB, illustrated in figure 45.4B). This finding suggests the possibility that there may be preferential processing of information destined for particular dorsoventral levels of the hippocampus (Kerr, Agster, Furtak, & Burwell, 2007; Dolorfo & Amaral, 1998a). However, like the monkey, the inputs to the perirhinal cortex often cross bands, suggesting that different combinations of information may be processed in different bands and projected to the hippocampus.

Summary and comparison Perhaps the most striking differences in connectivity between the monkey and rat parahippocampal regions are observed at the level of the entorhinal cortex. While the cortical inputs to the monkey entorhinal cortex are dominated by the strong projections from the parahippocampal and perirhinal cortices, the rat LEA receives only moderate inputs from the perirhinal cortex and weak projections from the postrhinal cortex, whereas the MEA receives weak projections from both the perirhinal and postrhinal cortices. Instead, the rat entorhinal cortex is dominated by inputs from olfactory-related areas as well as inputs from the insula, frontal, and cingulate cortices.

Comment on subcortical inputs Another striking difference to consider when evaluating the functional organization of the entorhinal cortex across species is the relative proportion of cortical inputs relative to subcortical inputs. For example, quantitative data from Kerr and colleagues (2007) showed that a defining feature of the rat LEA is that only about one-half of its total afferent inputs (defined as inputs from cortical and nonhippocampal subcortical structures) originate in the cortical areas shown in figure 45.4B while the remaining half of its afferent projections arise from subcortical regions including olfactory areas, the claustrum, amygdala, and dorsal thalamus. The relative proportion of

subcortical inputs to the rat entorhinal cortex is illustrated in figure 45.5. Similarly, only about half of all afferent inputs to the rat MEA arise from cortical areas. Although a parallel quantification of all cortical and subcortical inputs to the monkey entorhinal cortex has not been done (Insausti et al., 1987a, 1987b), estimations based on the illustrations of Insausti and colleagues (1987b) suggest that subcortical projections make up a much smaller proportion of inputs to the monkey entorhinal cortex compared to the rat entorhinal cortex (figure 45.5). Thus the rat entorhinal cortex not only receives different patterns of cortical inputs but also appears to be influenced much more by its subcortical projections compared to the monkey entorhinal cortex.

Discussion

This comparison of the patterns of cortical inputs, intrinsic projections, and interconnections of the entorhinal, perirhinal/parahippocampal, and postrhinal cortices across both monkeys and rats has revealed both similarities and some striking differences across species (figure 45.5). For example, the perirhinal cortex in both monkeys and rats is characterized by receiving prominent unimodal sensory input. In monkeys this unimodal input is dominated by the visual modality, likely reflecting the predominant role of vision in the primate brain. In contrast, the rat perirhinal cortex receives a much wider range of inputs from all sensory modalities, likely reflecting a species-specific difference in sensory processing. Despite the differences in the range of sensory modalities projecting to the perirhinal cortex in monkeys and rats, damage including the perirhinal cortex in both species is associated with significant deficits in both recognition memory (Mumby, Piterkin, Lecluse, & Lehmann, 2007; Barker, Bird, Alexander, & Warburton, 2007; Mumby & Pinel, 1994; Zola-Morgan, Squire, Clower, & Rempel, 1993; Wood, Mumby, Pinel, & Phillips, 1993; Meunier et al., 1993; Zola-Morgan et al., 1989) and associative memory (Barker & Warburton, 2008; Murray, Gaffan, & Mishkin, 1993; Bunsey & Eichenbaum, 1993). Moreover, perirhinal neurons in both species signal recognition of visual information with a significantly decreased response (Wan, Aggleton, & Brown, 1999; Xiang & Brown, 1998; Brown & Xiang, 1998; Zhu, Brown, & Aggleton, 1995; Miller et al., 1993, 1991; Riches et al., 1991; Baylis & Rolls, 1987; Brown et al., 1987). In addition, it has been well established that monkey perirhinal neurons signal long-term memory for well-learned visual-visual paired associates (Naya, Yoshida, & Miyashita, 2003; Naya, Sakai, & Miyashita, 1996; Sakai & Miyashita, 1991). The patterns of mnemonic activity in the monkey perirhinal cortex suggest the possibility that rat perirhinal neurons may also signal sensory paired associate information as well as recognition memory signals in modalities other than vision (i.e., olfactory, somatosensory, and

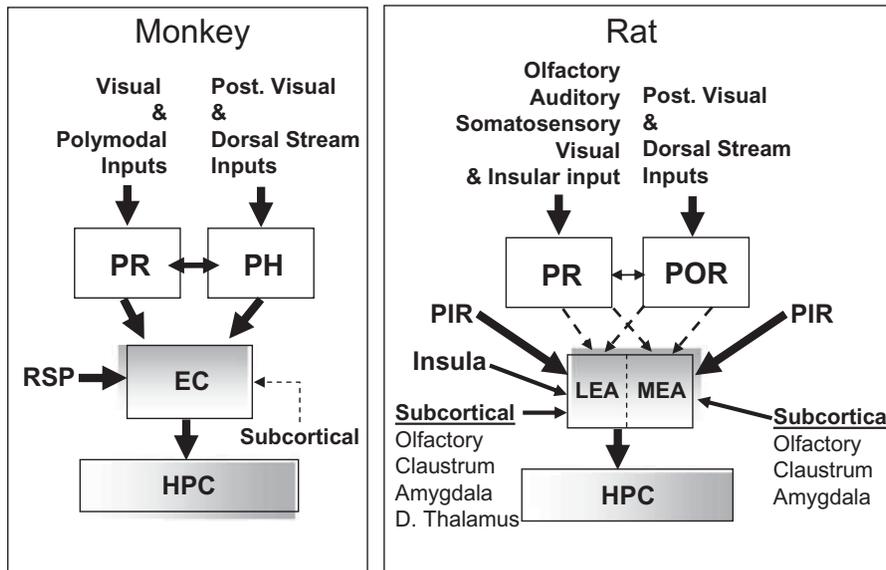

FIGURE 45.5 Schematic illustration of the patterns and relative strength of inputs to the parahippocampal region in monkeys and rats. Similarities are seen in the general patterns of inputs to the perirhinal and parahippocampal/posrhinal cortices in monkeys and rats. However, more striking differences are noted in the patterns of inputs to the entorhinal cortex. To better illustrate one of the key differences, we show the relative strength of the cortical and subcortical projections of the monkey and rat entorhinal cortex, with the relative thickness of the arrows illustrating the rela-

tive strength of projections (see box 45.1 for a description of the calculation of the relative strength of cortical inputs). All quantitative data from the rat entorhinal inputs taken from Kerr et al. (2007). However, the weak projections from subcortical regions to the monkey entorhinal cortex are only estimations since similar quantitative comparisons have not been published. Note that the subcortical inputs to the perirhinal (PR) and parahippocampal (PH) or postrhinal (POR) cortices are not illustrated. Additional abbreviations: D. thalamus, dorsal thalamus; RSP, retrosplenial.

auditory). It will be of interest to compare and contrast the full range of mnemonic signals seen in the monkey and rat perirhinal cortex.

Perhaps the most striking cross-species similarities in cortical afferent inputs are seen in the parahippocampal and postrhinal cortices (figure 45.5). These areas in both monkeys and rats receive prominent visual inputs as well as visuospatial inputs from dorsal stream structures including the retrosplenial and parietal cortices. Consistent with these anatomical inputs, the parahippocampal cortex in both monkeys and humans has most commonly been associated with spatial memory functions (Malkova & Mishkin, 2003; Burgess, Maguire, Spears, & O'Keefe, 2001; Bohbot, Allen, & Nadel, 2000; Johnsrude, Owen, Crane, Milner, & Evans, 1999; Maguire, Frackowiak, & Firth, 1997; Aguirre, Detre, Alsop, & D'Esposito, 1996), and in humans it has also been associated with episodic memory (Squire, Stark, & Clark, 2004; Ranganath et al., 2004; Schacter & Wagner, 1999). A growing body of lesion studies in rats suggests a role of the postrhinal cortex in memory for context (Eacott & Easton, 2007; Burwell et al., 2004; Bucci et al., 2002, 2000). However, reports on the contribution of the postrhinal cortex to spatial memory as measured by water maze tasks have been mixed (Burwell et al., 2004; Liu & Bilkey, 2002). Consistent with these lesion studies in rats, the important role of the human parahippocampal cortex in processing contextual associa-

tions has recently been highlighted in a series of fMRI studies. Bar and colleagues (Bar, Aminoff, & Ishai, 2008; Aminoff, Gronau, & Bar, 2007; Bar & Aminoff, 2003) report that the parahippocampal cortex is activated in response to objects highly associated with particular contexts (i.e., a traffic light) irrespective of whether the context is spatial (i.e., swings associated with a playground) or nonspatial (i.e., birthday cake associated with a birthday party). Based on these findings, this group has proposed a contextual associative theory of parahippocampal function whereby the parahippocampal cortex is thought to mediate contextual associative processing, an important component of both spatial memory and episodic memory. It will be fascinating to test this contextual associative theory of parahippocampal functions in both monkeys and rats. Neuroanatomical data supports the idea that contextual signals could be seen across both the monkey parahippocampal cortex and the rat postrhinal cortex.

While the parahippocampal/postrhinal cortices in monkeys and rats exhibit clear similarities in their cortical inputs, more striking differences are seen in both the pattern and relative strength of cortical inputs to the entorhinal cortex (figure 45.5). For example, monkey entorhinal inputs are dominated by the prominent projections from the perirhinal and parahippocampal cortices together with strong inputs from the retrosplenial cortex. In contrast, the ento-

rhinal cortex in rats receives its strongest cortical inputs from piriform cortex with moderate inputs from the perirhinal cortex (specifically to LEA), insula, frontal cortex, cingulate cortex, and visual cortical areas. Postrhinal cortex only projects weakly to the entorhinal cortex (figure 45.4B). The differences in the patterns of inputs are even more striking if one takes into account that while the monkey entorhinal cortex appears to receive the majority of its inputs from other unimodal and multimodal cortical areas, the rat LEA and MEA receive only about half of all their inputs from cortical structures, with the remaining half arising from subcortical structures (figure 45.5).

Despite the differences in the details of the anatomical connections, there remain intriguing parallels between the rat and monkey entorhinal cortex. For example, it is clear from recent physiological studies focused on the rat entorhinal cortex that cells in LEA and MEA process distinct kinds of information, with the MEA contributing to spatial information, including the striking grid cells specific for the MEA (Hafting et al., 2008; Fyhn et al., 2007; Hafting et al., 2005; Hargreaves, Rao, Lee, & Knierim, 2005; Fyhn et al., 2004). Though recent evidence suggests that cells in LEA are not spatial (Hargreaves et al., 2005), the nature of the input that maximally activates these cells has yet to be identified. The spatial versus nonspatial dissociation in the MEA and LEA in rats parallels the anatomical data in monkeys that the posterior entorhinal cortex receives projections from the strongly visuospatial parahippocampal cortex while the anterior entorhinal cortex receives its strongest projections from the visual-object-processing areas of the perirhinal cortex. These striking topographic projections suggest an anterior-posterior differentiation in object and spatial memory functions, respectively, of the monkey entorhinal cortex (Suzuki & Amaral, 1994b). Indeed, one physiology study attempted to test this anatomical prediction directly by examining responses in the monkey entorhinal cortex during an object version of the delayed-match-to-sample task as well as a spatial version of the same task (Suzuki, Miller, & Desimone, 1997). While neurons throughout the entorhinal cortex signaled memory for both the object and spatial versions of the task, no rostrocaudal topography was found. Because the delayed-match-to-place task required only egocentric and not allocentric spatial memory strategies, this task may not have engaged the particular form of spatial or contextual memory processed by the entorhinal cortex.

The anatomical observations in the monkey entorhinal cortex taken together with the physiological findings from the rat MEA and LEA suggest the possibility that despite the differences in the patterns of inputs, similarities in the functional organization of the entorhinal cortex across species may be present. The entorhinal cortex is one of the least studied medial temporal lobe areas in the monkey, and given the renewed interest in this structure with the discovery of

grid cells in the rat MEA, it will be important to continue to explore the functions of the monkey entorhinal cortex. It will also be critical to define any mnemonic role the grid cells may play in the processing of spatial information. Could there be grid cells in the monkey entorhinal cortex, or will they look more like spatial context cells? How will these entorhinal cells in both monkeys and rats participate in memory? Only further studies will tell.

46 Medial Temporal Lobe Function and Human Memory

Yael Shrager and Larry R. Squire

ABSTRACT The hippocampus and anatomically related structures in the medial temporal lobe support the capacity for conscious recollection (declarative memory). This chapter considers a number of topics that have been prominent in recent discussions of medial temporal lobe function: visual perception, working memory, habit learning, recollection and familiarity, path integration, remote memory, and conscious awareness.

The importance of the medial temporal lobe for memory was established in 1957 when Brenda Milner described the profound effects of medial temporal lobe resection on memory in a patient who became known as HM (Scoville & Milner, 1957; Squire, 2009). Subsequently, animal models of human memory impairment identified the anatomical structures within the medial temporal lobe that are important for understanding HM's memory impairment: the hippocampal region (hippocampus proper, dentate gyrus, and subicular complex) and the perirhinal, entorhinal, and parahippocampal cortices. These structures comprise the medial temporal lobe memory system (Lavenex & Amaral, 2000; Squire & Zola-Morgan, 1991) (figure 46.14).

Medial temporal lobe damage impairs only declarative memory (Schacter & Tulving, 1994; Squire, 1992). Declarative memory refers to the capacity to recollect facts and events. Its contents are thought to be accessible to conscious recollection. The stored representations are flexible and can guide successful performance in a wide range of conditions. Declarative memory can be contrasted with nondeclarative memory, a collection of memory abilities including skills and habits, simple forms of conditioning, priming, and other instances where experience changes how we interact with the world. Nondeclarative memory occurs as modifications within specialized performance systems, and what is learned is expressed through performance rather than recol-

lection. The different forms of nondeclarative memory are supported by specific brain systems outside of the medial temporal lobe memory system (Eichenbaum & Cohen, 2001) (figure 46.1B).

Intact visual perception

Memory-impaired patients with medial temporal lobe damage have consistently exhibited intact intellectual and perceptual functions. Thus the ability to acquire new memories appears to be a distinct cerebral function, independent of other perceptual and cognitive functions. This fundamental principle of brain organization has been revisited recently, as there has been interest in the possibility that medial temporal lobe structures might be involved in visual perception in addition to memory. Initially the focus was on perirhinal cortex. Whereas some experimental studies with monkeys underscored the role of perirhinal cortex in memory and not visual perception (Buffalo et al., 1999; Hampton & Murray, 2002), others have implicated a role for the perirhinal cortex in visual perception (Buckley, Booth, Rolls, & Gaffan, 2001; Buckley & Gaffan, 1998; Bussey & Saksida, 2002; Bussey, Saksida, & Murray, 2003; Murray & Bussey, 1999). Yet it is difficult to test experimental animals for the ability to identify visual stimuli independent of the ability to learn about them, and it has been pointed out that impairments in monkeys that have been attributed to a perceptual deficit could have resulted from impaired learning (Hampton, 2005).

A distinction between perception and learning can be drawn easily in studies of humans because humans can be instructed about the requirements of the task. A number of studies of patients with medial temporal lobe lesions have found intact perceptual abilities (Holdstock, Gaffan, & Mayes, 2000; Levy, Shrager, & Squire, 2005; Stark & Squire, 2000). Yet some work in humans found that a group of memory-impaired patients with damage reportedly involving either the hippocampus, or the hippocampus plus additional medial temporal lobe structures, were impaired on tests of perceptual abilities that involved difficult-to-discriminate faces, objects, and scenes (Lee, Buckley, et al., 2005; Lee, Bussey, et al., 2005). This newer work, which involved rather complex visual stimuli, raised the

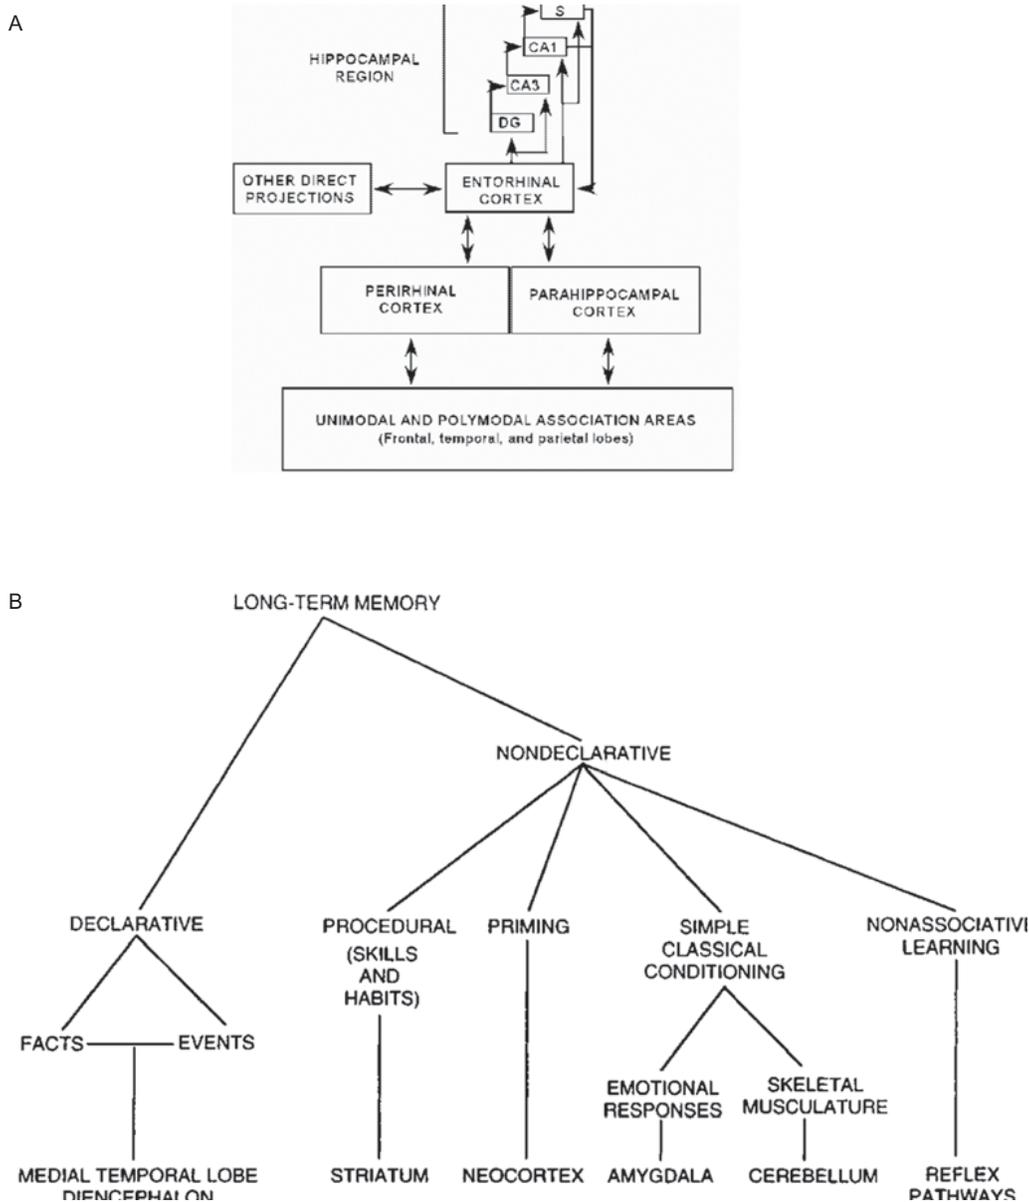

FIGURE 46.1 (A) A schematic view of the medial temporal lobe memory system for declarative memory, which is composed of the hippocampal region together with the perirhinal, entorhinal, and parahippocampal cortices. (From Manns & Squire, 2002.) The hippocampal region is composed of the dentate gyrus (DG), the CA fields, and the subiculum (S). (B) A taxonomy of mammalian long-

term memory systems. The taxonomy lists the brain structures thought to be especially important for each form of declarative and nondeclarative memory. In addition to its central role in emotional learning, the amygdala is able to modulate the strength of both declarative and nondeclarative memory. (From Squire & Knowlton, 2000.)

possibility that appropriate tests can reveal perceptual deficits that had not been detected by conventional tests of visual perception (Lee, Barense, & Graham, 2005). These new findings therefore challenge the long-standing idea that memory impairment can occur as a circumscribed disorder.

Some issues arise in interpreting these studies. First, one wonders if additional damage outside of the medial temporal lobe could underlie the visual perceptual deficits (discussed in the following paragraphs). Second, in these particular studies, the stimuli were created by morphing together two

distinct source images, so that the stimuli presented on consecutive trials were derived from the same pair of source images and were therefore quite similar to one another. Accordingly, the question arises whether memory for previous trials could benefit test performance. To test visual perception without testing memory ability, it would be advantageous to use unique stimuli on each trial.

These issues were explored in a recent study of six memory-impaired patients with well-characterized lesions (Shrager, Gold, Hopkins, & Squire, 2006). Two of these

patients (EP and GP) are severely amnesic and have large bilateral lesions of the medial temporal lobe resulting from herpes simplex encephalitis. Both patients have extensive, virtually complete bilateral damage to the hippocampus, amygdala, entorhinal cortex, and perirhinal cortex, as well as the majority of the parahippocampal cortex. Four of the patients have damage thought to be limited to the hippocampus.

The six patients and eight matched controls were tested with morphed grayscale images from three categories (faces, objects, and scenes), similar to those used in the earlier work that reported impairment (Lee, Bussey, et al., 2005). The morphed images were created by gradually morphing one distinct grayscale image into another (e.g., one hat into a different hat or a lemon into a tennis ball) across a 100-step series.

In one experiment, three images were presented on each trial (figure 46.2A). Two morphed images were presented below one of the distinct images from which the morphed images were derived, and participants were asked to indicate which of the two morphed images was more similar to the distinct image. Critically, on each trial, each pair of morphed images was derived from a unique pair of distinct images. Thus participants could not benefit from their memory of images they had seen in previous trials. All patients performed as well as controls in all three stimulus categories (faces, objects, and scenes).

On each trial in another experiment, a target image, chosen from the 100-step morphed-image series, was presented at the top of the screen (figure 46.2B). In addition, a single image from the same series was presented below the target image. Participants were asked to match the lower image to the target by scrolling through the ordered series of 100 morphed images, viewing only one image at a time, and to select the image that was identical to the target. Performance was scored as the number of image steps between the image that was selected and the target image (thus lower scores indicate better performance). All patients performed as well as controls in all three stimulus categories.

Aside from the possible importance of trial-unique stimuli, it is possible that difference in the patient groups might explain the discrepancy between the findings of Shrager and colleagues (2006) and the findings of Lee and colleagues (Lee, Buckley, et al., 2005; Lee, Bussey, et al., 2005), as well as related findings (Graham et al., 2006). The lesions in the patients studied by Lee and colleagues (Lee, Buckley, et al., 2005; Lee, Bussey, et al., 2005) were characterized by visual ratings of magnetic resonance images (the ratings were made on a 4- or 5-point scale). These ratings, based on visual inspection, are not the same as quantitative brain measurements. Also, the ratings given for each patient were based on a single coronal section for each structure of interest in the medial and lateral temporal lobe, leaving a considerable

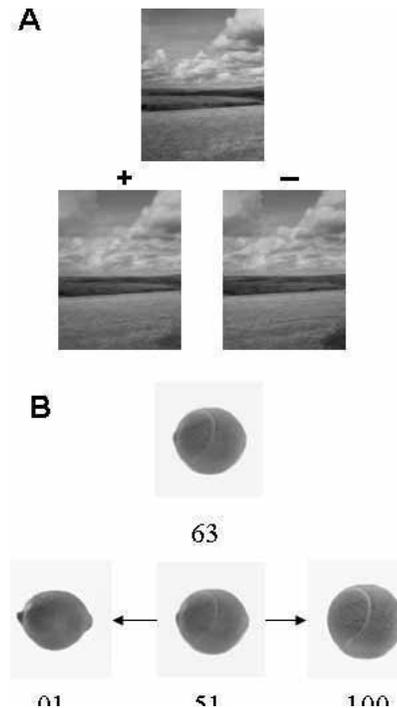

FIGURE 46.2 (A) Trial-unique visual discrimination. On each of 120 unique trials, two morphed images were presented below a single distinct image. Participants were asked to choose the lower image (here identified by a +) that appeared more similar to the upper image. (B) Visual matching. On each of 45 unique trials, a target image was presented above a single image. Both images were derived from a unique pair of distinct images (01 and 100). In the case illustrated, the target image is image number 63 in the 100-image series, and the bottom image is image number 51 from the same series. Participants were asked to scroll through the ordered series of 100 images to find the image that matched the target image. (From Shrager, Gold, Hopkins, & Squire, 2006.)

amount of tissue unexamined. Furthermore, even by these assessments, the damage in some patients extended beyond the brain structures that defined the groups. Without thorough, quantitative assessment of the lesions, the possibility remains that there is additional damage in the patients and that such damage might underlie the visual perceptual deficits that were observed.

In contrast, the lesions of the patients in Shrager and colleagues (2006) were rigorously measured using quantitative volumetric analysis of magnetic resonance images (Bayley, Gold, Hopkins, & Squire, 2005; Gold & Squire, 2005). For each patient, approximately 60 sections were measured in 1-mm intervals rostrocaudally through the medial and lateral temporal lobes. The measurements were taken in every section in which a structure of interest was present. In addition, volumes were calculated for the insular cortex, the fusiform gyrus, and the frontal, parietal, and occipital lobes.

Over the past 40 years, numerous studies of memory-impaired patients with lesions of the medial temporal lobe

have found visual perceptual function to be intact (Corkin, 1984; Levy et al., 2005; Milner, Corkin, & Teuber, 1968; Stark & Squire, 2000). It was this early work that led to the principle that memory can be severely impaired without impairing other intellectual or perceptual functions. More recently, visual perception has been challenged with newer, more difficult tasks than had been used previously. This new work provides additional support for the principle that memory impairment can occur in the absence of impaired visual perception.

Working memory and brain systems

Working memory refers to the capacity to maintain temporarily a limited amount of information in mind. This information can then be used to support various cognitive abilities, including learning and reasoning (Baddeley & Hitch, 1974). Amnesic patients with damage to the medial temporal lobe have consistently exhibited intact working memory despite grave impairment in long-term memory (Drachman & Arbit, 1966; Milner, 1972). Thus working memory has been thought to be independent of the medial temporal lobe and has come to be defined as a kind of memory that is spared in patients with medial temporal lobe damage (Atkinson & Shiffrin, 1968; Milner, 1972; Pashler & Carrier, 1996).

These ideas have been challenged recently by the proposal that working memory might sometimes depend on medial temporal lobe structures. Specifically, patients with medial temporal lobe damage were found to be impaired at remembering information across brief time intervals (Hannula, Tranel, & Cohen, 2006; Hartley et al., 2007; Nichols, Kao, Verfaellie, & Gabrieli, 2006; Olson, Moore, Stark, & Chatterjee, 2006; Olson, Page, Moore, Chatterjee, & Verfaellie, 2006). The interpretation that these impairments result from impaired working memory would require a revision of the long-standing principle that working memory is separable from long-term memory and is independent of the medial temporal lobe. Yet it is possible that the impairments might have occurred because the capacity for working memory was exceeded and performance in these cases depended on long-term memory. This possibility draws attention to the fact that there is a circularity in the way that working memory is often defined. Working memory has been characterized as a kind of memory that is spared in amnesia, but amnesia is traditionally characterized as a condition in which working memory is intact. It would be useful to have a method for identifying and measuring working memory that is independent of the performance of amnesic patients.

A recent study used distraction between study and test to measure working memory in controls and also tested the performance of amnesic patients (Shrager, Levy, Hopkins, & Squire, 2008). Amnesic patients with medial temporal lobe damage (EP, GP, and six patients with damage limited

to the hippocampus) and controls were tested across short delays in four different tasks. Next, the effect of distraction on control performance was tested in the same tasks. The reasoning was as follows: If amnesic patients perform well on tasks when they can operate within working-memory capacity (i.e., by active maintenance), then controls given the same tasks should be impaired when distraction is interposed between study and test because distraction should disrupt the active maintenance process. Conversely, if amnesic patients perform poorly when their working-memory capacity is exceeded, then controls given the same tasks should be minimally affected by distraction between study and test (because performance is now supported more by long-term memory than by active maintenance).

Memory was first tested for names and faces in the patients and their controls. Participants studied either three names presented one at a time or a single face. After a 14-second delay, memory was tested with a single probe stimulus, and participants indicated whether the probe stimulus (a name in the names test and a face in the faces test) had just been presented in the study phase. The patients performed as well as controls in the names test (patients scored 94.4%, and controls scored 94.5% correct), and they were impaired in the faces test (patients scored 93.2%, and controls scored 98.0% correct) (figure 46.3A).

The question of interest was whether the impairment in the faces test resulted from a working-memory deficit or a long-term-memory deficit. Accordingly, the effect of distraction on control performance was tested in both the names and faces tests. Controls were again asked to study either three names or a single face. During the delay, on half the trials, controls were distracted. Control performance was impaired by distraction in the names condition (96.4% versus 87.5% correct) but not in the faces condition (96.4% correct for the no-distraction condition versus 95.3% correct for the distraction condition) (figure 46.3B). Performance on the distracter (counting) tasks was comparable in the names and faces tests.

These results revealed a correspondence between the performance of amnesic patients and the effect of distraction on controls. Distraction impaired controls on the names test, presumably because the distraction interfered with an active maintenance process that is based on rehearsal. Distraction did not affect performance on the faces test, presumably because the information is difficult to maintain actively (rehearse) and must depend on long-term memory shortly after the information is presented (Warrington & Taylor, 1973). We suggest that amnesic patients were intact when task performance was supported by rehearsal (working memory for names) but were impaired when rehearsal was less effective and performance had to depend on long-term memory (in the case of faces). The same finding was obtained in a related set of experiments that tested memory for objects

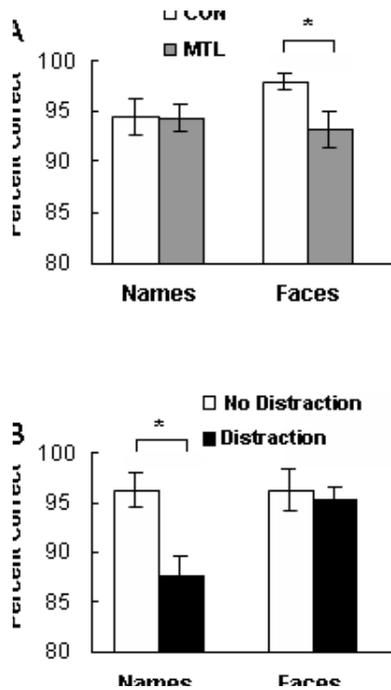

FIGURE 46.3 (A) Percent correct scores for controls (CON) and patients with medial temporal lobe lesions (MTL) when asked to remember either three surnames or a single face for 14 seconds. (B) Percent correct scores for controls on trials with and without distraction when asked to remember three surnames or a single face for 14 seconds. Error bars indicate standard error. Asterisks indicate $p < 0.05$. (From Shrager, Levy, Hopkins, & Squire, 2008.)

and object locations (a form of relational memory) (Shrager, Levy, et al., 2008). Together, the findings support a brain-based distinction between working memory and long-term memory, as well as the idea that working memory is independent of medial temporal lobe structures.

Habit learning

Some tasks are acquired by humans as declarative knowledge through memorization but nevertheless can be acquired nondeclaratively by experimental animals. On such tasks, amnesic patients with medial temporal lobe lesions perform poorly, whereas monkeys with medial temporal lobe lesions acquire the task at the rate of unoperated monkeys. These findings raise the question whether patients with profound amnesia, with no capacity for declarative memory, could acquire such a task nondeclaratively in the way that the monkey learns it. If so, is the learning done consciously or unconsciously? Or is it the case that, in humans, one memory system cannot readily substitute for another? Perhaps in humans, some forms of nondeclarative memory are not well developed, or perhaps a capacity for nondeclarative learning is easily overridden by the tendency to engage a conscious declarative memory strategy.

One example of a task that is approached differently by humans and nonhuman primates is concurrent discrimination learning, a standard task for studying mammalian memory for more than 50 years. In a common version of this task, eight pairs of objects are presented five times each day, one pair at a time in a mixed order, totaling 40 trials each day. One object in each pair is always correct, and a choice of the correct object results in a reward. Humans readily learn this task after one or two days of training, scoring about 90% correct. The task ordinarily depends on declarative memory, as indicated by the fact that task performance is correlated with the ability to describe the objects and by the fact that amnesic patients perform quite poorly (Hood, Postle, & Corkin, 1999; Squire, Zola-Morgan, & Chen, 1988).

In contrast to the findings in humans, monkeys learned the same concurrent discrimination task gradually, across several hundred trials. Furthermore, monkeys with medial temporal lobe lesions learned this task and a similar version of the same task at normal rates (Buffalo, Stefanacci, Squire, & Zola, 1998; Malamut, Sanders, & Mishkin, 1984; Teng, Stefanacci, Squire, & Zola, 2000). For monkeys, learning proceeded by trial and error (sometimes termed habit learning), and learning was impaired by basal ganglia lesions (Fernandez-Ruiz, Wang, Aigner, & Mishkin, 2001; Teng et al., 2000). Habit memory is proposed to involve slowly acquired associations between stimuli and responses that develop outside of awareness and that are rigidly organized, with the result that what is learned is not readily expressed unless the task is presented just as it was during training.

A recent study asked whether severely amnesic patients can learn this task and, if so, whether the learning has the characteristics of nondeclarative (unconscious) memory. Two patients with large medial temporal lobe lesions, EP and GP, and four controls successfully learned the concurrent discrimination task (eight pairs, five presentations of each pair per session) (Bayley, Frascino, & Squire, 2005). Two sessions were scheduled each week. The controls learned the task quickly during three testing sessions (figure 46.4A). In contrast, EP and GP learned gradually during 36 and 28 sessions, respectively, and reached a performance level of 85.0% and 92.5% correct (figure 46.4B,C).

The learning exhibited by the patients across weeks was not accompanied by declarative knowledge of the task. Thus neither patient recognized that he had been tested in previous sessions, and neither patient could describe the testing procedure. An additional condition tested whether the knowledge that had been acquired was rigidly organized, as is thought to occur for habit learning, or whether it could be used flexibly. Three to six days after the conclusion of formal training, participants were given a sorting task. They were presented with all 16 objects mixed together (the eight pairs they had learned) and were asked to sort them into two

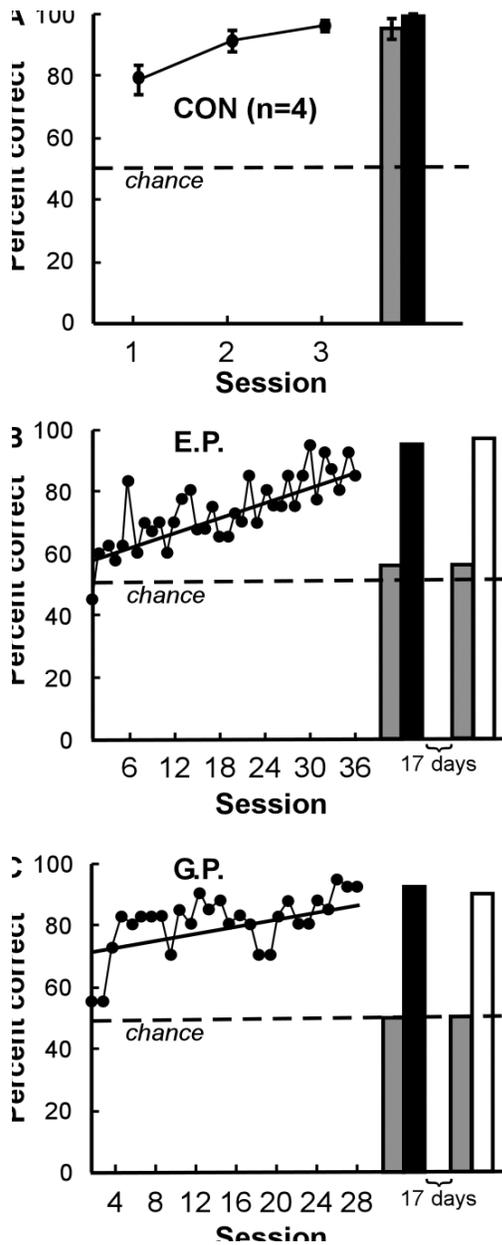

FIGURE 46.4 Performance on the concurrent discrimination task. (A) Controls learned the task easily within three sessions and performed well on the sorting task 3–6 days later (gray bar). The black bar shows performance immediately afterward when participants were asked to verbalize their choices rather than reach for objects. Results are means plus and minus standard error. (B,C) EP (B) and GP (C) gradually learned the object pairs across 14–18 weeks. Five days later, each patient failed the sorting task (gray bars) but then, immediately afterward, performed well in the standard task format while verbalizing his responses (black bars). Seventeen days later, both patients again failed the sorting task (gray bars) but performed above 90% when the test was given exactly as in original training (white bars). (From Bayley, Frascino, & Squire, 2005.)

groups: one containing the correct objects and another containing the incorrect objects. Controls succeeded, scoring 95.3% correct, while the patients failed altogether (EP scored 56.3%, and GP scored 50.0% correct; chance = 50%) (figure 46.4B,C). Thus the learned information could not be used flexibly. Both patients were able to perform well when asked to verbalize their responses instead of reaching for the objects, but the objects needed to be presented as pairs in order for performance to succeed (figure 46.4B,C). Seventeen days later, EP and GP failed the sorting task again and then succeeded once more when the task was presented in its original format (figure 46.4B,C).

These findings demonstrated a robust capacity for habit learning that can operate outside awareness and independently of declarative memory and the medial temporal lobe. The knowledge acquired by both patients was rigidly organized and most accessible when the task was structured just as it was during training. These results provide a particularly compelling example of the distinction between declarative (and conscious) and nondeclarative (and unconscious) learning systems.

Recollection and familiarity

One of the most widely studied examples of declarative memory is recognition memory, the capacity to judge an item as having been encountered previously. Recognition memory is thought to consist of two component processes, recollection and familiarity (Mandler, 1980). Recollection involves remembering specific details about the episode in which an item was encountered, whereas familiarity involves simply knowing that an item was presented without any recollection of the original episode.

There has been considerable interest in finding an anatomical basis of the distinction between recollection and familiarity. One suggestion is that the hippocampus is especially important for recollection, whereas the adjacent medial temporal lobe cortex supports familiarity (Brown & Aggleton, 2001; Eichenbaum, Yonelinas, & Ranganath, 2007; Fortin, Wright, & Eichenbaum, 2004; Yonelinas et al., 2002). In contrast, it has also been suggested that the hippocampus is important for both recollection and familiarity (Manns, Hopkins, Reed, Kitchener, & Squire, 2003; Squire, Wixted, & Clark, 2007; Wixted & Squire, 2004).

A recent series of experiments applied signal detection techniques to address these anatomical questions about recollection and familiarity. The receiver operating characteristic (ROC) is a plot of the hit rate versus the false alarm rate across different decision criteria. In order to obtain pairs of hit and false alarm rates at different decision criteria, one can ask participants to provide confidence ratings for their yes/no recognition decisions. A pair of hit and false alarm rates is computed for each level of confidence, and the paired

values are plotted across the confidence levels to construct an ROC.

The ROC of normal individuals has been compared to the ROC of memory-impaired patients (Yonelinas, Kroll, Dobbins, Lazzara, & Knight, 1998; Yonelinas et al., 2002) and rats with hippocampal lesions (for rats, decision criteria are manipulated by other methods) (Fortin et al., 2004). These ROCs were curvilinear, as is typical, but they differed in their degree of symmetry. As is usually the case, the ROC of controls was asymmetrical, but the ROC of patients and rats with hippocampal lesions was symmetrical (figure 46.5). These data have sometimes been interpreted according to a high-threshold/signal detection model (Yonelinas et al., 1998), which takes the degree of asymmetry in an ROC to reflect the degree to which the recollection process contributes to recognition memory performance. Specifically, a symmetrical ROC indicates that recollection was absent and that recognition memory was based only on familiarity, whereas an asymmetrical ROC indicates that recollection also occurred to some extent. Thus, by the high-threshold/signal detection model, the finding that memory-impaired patients, as well as rats with hippocampal lesions, produce a symmetrical ROC suggests that the recollection process is impaired.

Although the ROC curves of patients and their controls (and lesioned rats and their controls) did differ qualitatively with respect to symmetry, they also differed quantitatively. The patients and the lesioned rats had weaker memories than their respective controls. Indeed, the standard signal detection model of recognition memory (Macmillan & Creelman, 2005) explains the difference between asymmetrical and symmetrical ROCs as a difference in memory strength. An asymmetrical ROC reflects high memory strength, and a symmetrical ROC reflects lower memory strength (Glanzer, Kim, Hilford, & Adams, 1999). If the symmetry of the ROC is related to memory strength, then the difference in symmetry between controls and memory-impaired patients (or lesioned rats) might simply reflect the difference between strong and weak memories, rather than a qualitative difference between the underlying component processes of recognition memory.

This idea was tested in a study of controls and memory-impaired patients with circumscribed hippocampal lesions (Wais, Wixted, Hopkins, & Squire, 2006). The question of interest was how the shape of the ROC changes as a function of memory strength for patients with hippocampal lesions and how the performance of patients compares with the performance of controls. If recollection is selectively impaired in the patients, then the ROC should be symmetrical regardless of memory strength. Alternatively, if the hippocampus does not selectively support recollection, then the patients with hippocampal lesions should produce asymmetrical ROCs like the controls once differences in memory strength are accounted for.

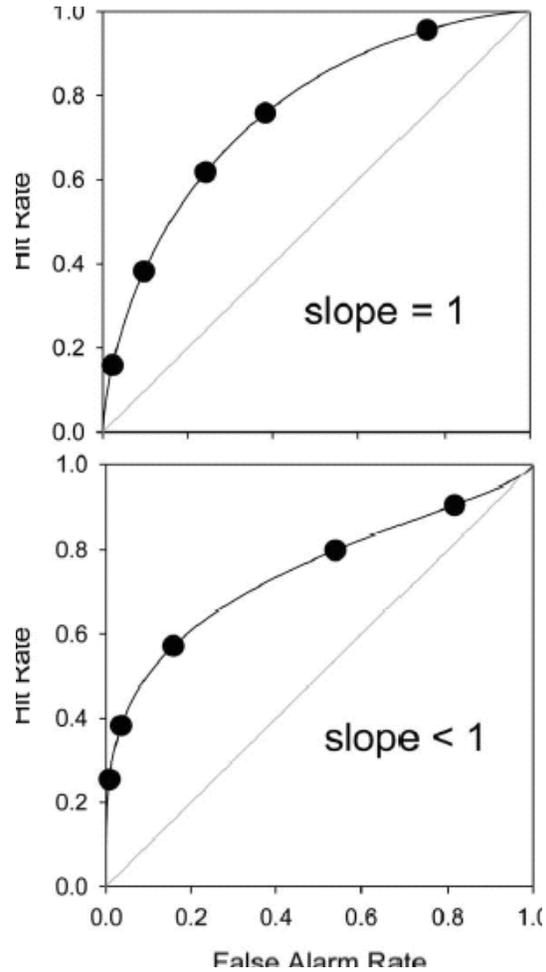

FIGURE 46.5 Hypothetical ROC data illustrating symmetrical and asymmetrical ROC curves. The degree of asymmetry evident in an ROC is typically quantified by a “slope” parameter obtained by fitting the standard signal detection model (Macmillan & Creelman, 2005) to the data. A slope of 1.0 denotes a symmetrical ROC, whereas a slope less than 1.0 denotes an asymmetrical ROC. The high-threshold/signal detection model (Yonelinas, Kroll, Dobbins, Lazzara, & Knight, 1998) would yield a recollection parameter estimate of 0 for the symmetrical ROC (*top panel*) and an estimate greater than 0 for the asymmetrical ROC (*bottom panel*). (From Wais, Wixted, Hopkins, & Squire, 2006.)

Six patients with damage thought to be limited to the hippocampus participated. Participants first studied 50 words. After a three-minute interval, 50 target words were intermixed with 50 foil words, and participants assigned a confidence rating to each word from 1 (“definitely new”) to 6 (“definitely old”). As expected, the patients performed more poorly than controls (H-50 versus C-50, figure 46.6). Patients were then given a second, easier recognition-memory test involving only 10 words (plus four untested filler words, two at the beginning and two at the end of the list). On this test, patient performance improved to a level similar to that of controls (H-10 versus C-10, figure 46.6).

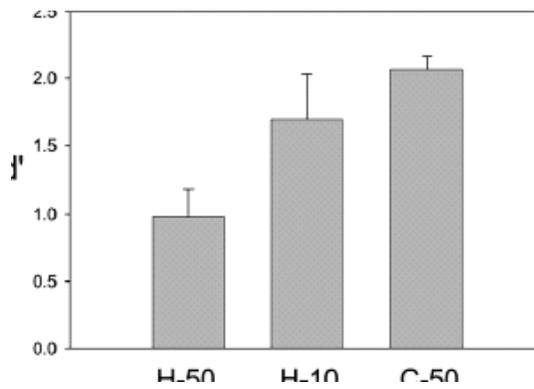

FIGURE 46.6 Recognition memory performance of hippocampal patients and controls. Patients were tested with 50-item lists (H-50 condition) or 10-item lists (H-10 condition). Controls were tested with 50-item lists (C-50 condition). The retention interval was 3 minutes. The mean score of the controls (C-50) was greater than that of the patients in the H-50 condition, but similar to the score obtained by the patients in the H-10 condition. The score in the H-10 condition was also greater than the score in the H-50 condition. Error bars represent standard errors. (From Wais, Wixted, Hopkins, & Squire, 2006.)

The ROCs for the patients and controls were all curvilinear (figure 46.7). The ROC from the H-50 condition was symmetrical, but the ROCs from the H-10 and the C-50 conditions were asymmetrical to a similar extent. Thus the ROC of the hippocampal patients was symmetric when memory was weak but asymmetric when memory was strong (H-50 versus H-10, respectively). Moreover, when memory performance was similar for patients and controls (the H-10 and C-50 conditions), the degree of asymmetry in the ROC was similar as well.

To derive theoretical estimates of recollection and familiarity, the ROC data were first fitted by the high-threshold/signal detection model. In the H-50 condition, the recollection parameter estimate was equal to zero, and in the C-50 condition it was greater than zero (0.23). Similarly, the familiarity parameter estimate was lower in the H-50 condition than in the C-50 condition (0.83 versus 1.64). Importantly, in the H-10 condition, the parameter estimates for both recollection and familiarity were similar to the estimates for the C-50 condition (recollection estimate of 0.22 and 0.23 for H-10 and C-50, respectively, and familiarity estimate of 1.21 and 1.64 for H-10 and C-50, respectively, $p = 0.11$). Thus, according to the high-threshold/signal detection model, the recollection process is present in both patients and controls. Furthermore, when memory performance was matched between patients and controls (H-10 and C-50), the nearly identical recollection estimates (0.22 and 0.23) offered no evidence of a selective deficit in recollection after hippocampal lesions.

In contrast to the high-threshold/signal detection model, the traditional signal detection model (Macmillan &

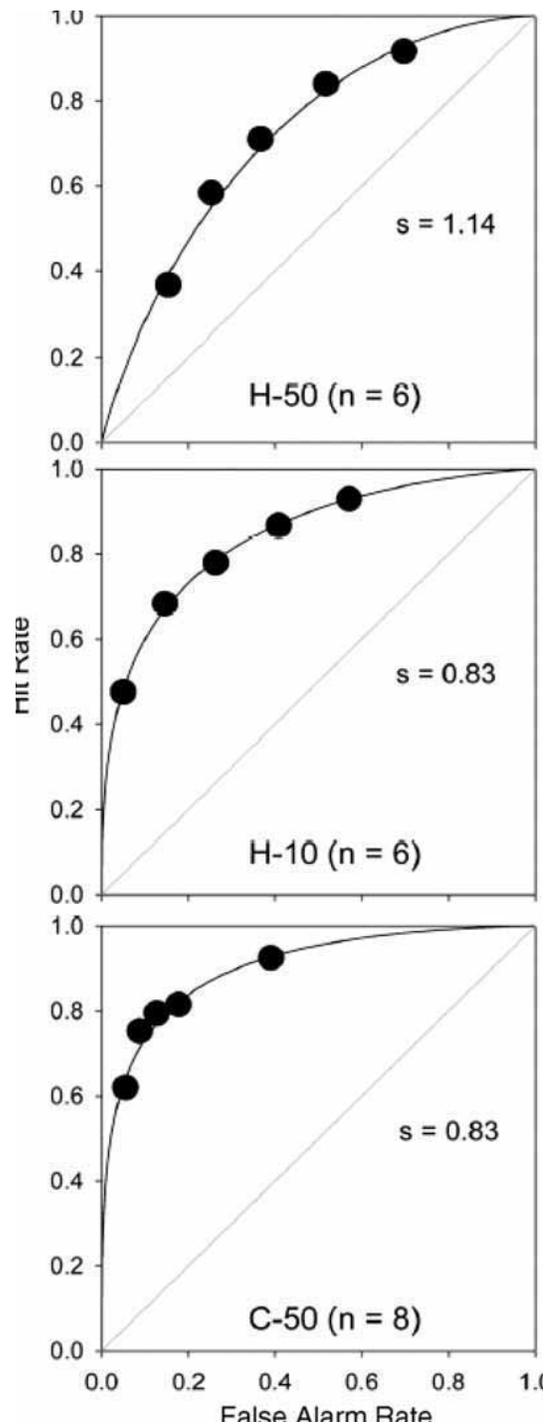

FIGURE 46.7 ROC data produced by the hippocampal patients and controls. The top panel shows the data for hippocampal patients in the 50-item condition, the middle panel shows the data for hippocampal patients in the 10-item condition, and the bottom panel shows the data for controls in the 50-item condition. The H-50 ROC was symmetric (slope = 1.14). The H-10 ROC and the C-50 ROC were both asymmetric (slope = 0.83 for both groups) and also more asymmetric than the ROC of the H-50 group. (From Wais, Wixted, Hopkins, & Squire, 2006.)

Creelman, 2005) does not dictate how recollection and familiarity combine to produce an ROC curve. The fact that patients and controls exhibited similar ROCs as a function of memory strength nevertheless suggests that the component processes of recognition are both operative in the patients. If the asymmetry of the ROC curve is taken as an indicator of recollection, then these results challenge the idea that the hippocampus subserves a recollection process and that hippocampal patients do not have this process. The findings are not an argument against the utility of the constructs of recollection and familiarity. Rather, they challenge the idea that recollection and familiarity can be dichotomized and assigned to separate brain structures in the medial temporal lobe (Squire et al., 2007).

Path integration

During the past several decades, there have been two influential traditions about the function of the hippocampus, entorhinal cortex, and related medial temporal lobe structures. One tradition emphasizes the importance of these structures for memory (Scoville & Milner, 1957; Squire, Stark, & Clark, 2004). The other emphasizes their importance for spatial cognition (Etienne & Jeffery, 2004; McNaughton, Battaglia, Jensen, Moser, & Moser, 2006; O'Keefe & Nadel, 1978; Whitlock, Sutherland, Witter, Moser, & Moser, 2008). An important part of spatial cognition is path integration, the ability to use internal cues during movement (i.e., self-motion cues) to keep track of a reference location. Because many tasks of spatial cognition, including path integration, require memory, these two traditions are compatible with each other to a large extent.

The view that medial temporal lobe structures are important for memory makes a key distinction between short-term (or working) memory and long-term memory (see the section on working memory in this chapter). Patients with damage to the medial temporal lobe, including damage to the hippocampus or entorhinal cortex, are thought to have intact working memory, and they perform poorly only when demands are made on long-term memory. This idea is meant to apply even to tasks that require spatial cognition, such as path integration.

In contrast, the view that the hippocampus and entorhinal cortex are important for path integration often includes the suggestion that the path integrator is located in these structures (Etienne & Jeffery, 2004; McNaughton et al., 2006). By this view, patients with damage to the hippocampus and entorhinal cortex should be impaired at path integration, and this impairment should occur regardless of whether demands are made on long-term memory.

These ideas were tested by asking whether the hippocampus and entorhinal cortex are essential for path integration even when the task can be managed within working memory

(Shrager, Kirwan, & Squire, 2008). Two patients with large medial temporal lobe lesions (EP and GP), three patients with hippocampal lesions, and seven controls were tested for their path integration ability. In the first condition (standard), participants wore a blindfold and earphones to reduce external cues, and they were led in a laboratory space along 16 different paths that averaged 4.3 meters in length and involved either 1 or 2 turns. At the end of each path, participants stepped onto a platform (5 cm above the floor and equipped with handlebars for stability) and were asked to point to their start location. An error measure was then computed as the difference between the participant's pointing direction and the correct direction. Participants were encouraged to actively maintain the path in mind as they walked, so that performance might be supported by working memory (mean trial duration was 33.4 seconds).

The patients performed as accurately as controls (mean pointing direction for patients, -4° ; controls, $+4^\circ$) (figure 46.8A). Furthermore, the variability in performance across the 16 trials was similar for both groups (patients, 31.3; controls, 30.5) (figure 46.8D). Debriefings of the two most severely memory-impaired patients (EP and GP) and four controls indicated that subjects tried to keep track of their position in space as they moved, continually updating their position relative to the start point.

Path integration was further challenged in two additional conditions. In one condition, participants were blindfolded and led in the laboratory along 16 paths involving 3 turns (compared to 1 or 2 turns in the standard condition; mean trial duration, 26.0 seconds). In another condition, participants were blindfolded and led in an outdoor space along 8 paths that were nearly four times as long (15 meters) as the paths in the standard condition. Mean trial duration in this case was 29.7 seconds. In both conditions, the patients pointed to their start location as accurately as controls, and they also exhibited variability similar to that of controls (for 3 turns, controls, $+6^\circ$, variability, 32.2; patients, -7° , variability, 31.7; for the longer paths, controls, $+9^\circ$, variability, 35.0; patients, -15° , variability, 27.2). In a fourth condition, participants were led along 8 paths in the laboratory environment (4 involving 1 turn, 4 involving 2 turns, for a path length averaging 4.2 m). At the end of each path, participants estimated their distance from the start location (instead of pointing). Some paths ended far from the start point, and some ended near the start point. Again, the patients were as accurate as controls (both groups averaged 0.7 m error for distances that averaged 2.8 m).

A separate condition served as a key control to ensure that participants were in fact path integrating, that is, relying on internal cues rather than on external cues that were beyond experimental control. Blindfolded participants were led in the laboratory environment along 16 paths and, at the end of each path, stepped onto the platform and held onto the

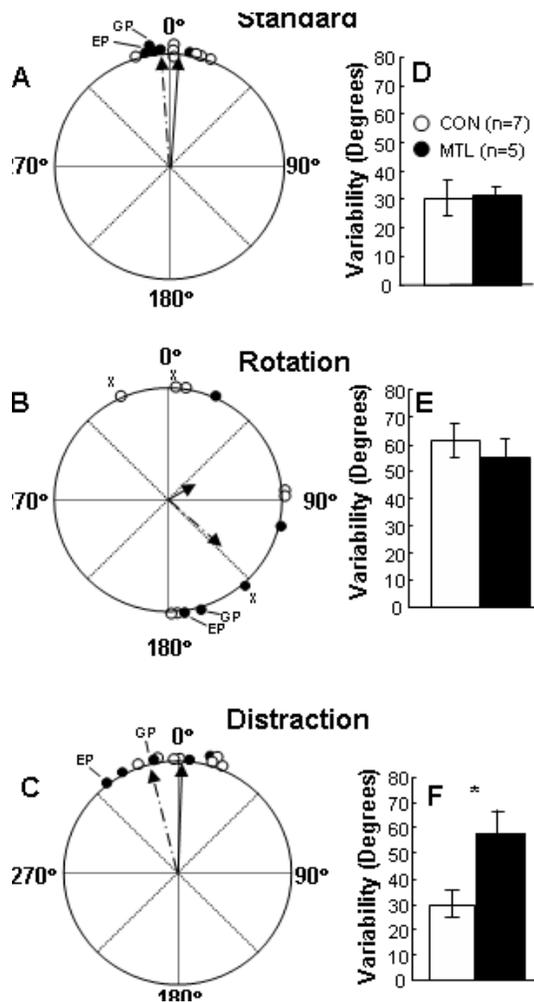

FIGURE 46.8 Circular means of each participant's 16 pointing directions in the standard, rotation, and distraction conditions for patients with damage to the medial temporal lobe (MTL, filled circles) and controls (CON, unfilled circles). 0° indicates the correct direction. Group pointing directions are also indicated (solid arrow, CON; broken arrow, MTL). Shorter arrows denote greater variability (dispersion) in the group's pointing direction (following Moore's test for nonuniformity, Batschelet, 1981). In *B*, *X* indicates individuals who did not exhibit a significant pointing direction. The standard deviation of pointing directions around each participant's circular mean was calculated, and the individual standard deviations were then averaged for each group (*D*, *E*, *F*). Asterisk (*) indicates $p < 0.05$, CON versus MTL groups. Brackets indicate standard error. (From Shrager, Kirwan, & Squire, 2008.)

handlebars. The platform was then slowly rotated by remote control through 190°, after which participants tried to point to their start location. Pilot experiments indicated that, after the rotation, participants had difficulty knowing how far they had been turned. Accordingly, one would expect that, if participants were in fact relying on path integration (internal cues) to point to their start location, they should have difficulty in the rotation condition. Mean trial duration was the same as in the original, standard condition (32.4 seconds). The result was that performance of both patients and

controls was substantially compromised. Neither group exhibited a significant pointing direction (i.e., pointing across participants was random), and variability increased (patients, 54.9; controls, 61.5) (figure 46.8*B*, *E*).

In a final condition, path integration was tested when demands on long-term memory were increased by increasing the duration of each trial and by introducing distraction during the delay (mean trial duration, 1 minute 10 seconds). The controls performed as well in the distraction condition as in the standard condition. Their mean pointing direction was +1° (compared to +4° in the standard condition), and variability was 30.1 (compared to 30.5 in the standard condition) (figure 46.8*C*, *F*). In contrast, the patients had difficulty in the distraction condition. Their mean pointing direction was -14° (numerically worse than their pointing direction in the standard condition, -4°), and variability was 57.1 (significantly worse than in the standard condition, 31.3, and significantly worse than controls in the distraction condition, 30.1) (figure 46.8*C*, *F*).

These results indicate that patients with lesions of the medial temporal lobe can path integrate as well as controls when the task can be managed within working memory. When demands on long-term memory were increased, the patients were impaired. These findings suggest that medial temporal lobe structures are not unique, essential sites where computations needed for path integration are carried out. These computations likely occur upstream of the medial temporal lobe, perhaps in parietal cortex. The medial temporal lobe then operates on this information, much as it operates on information from other sensory modalities, in order to transform on-line perceptual information into long-term memory.

Remote memory

Damage to the hippocampus and related medial temporal lobe structures not only impairs new learning capacity but also impairs memory for information acquired before the damage occurred (retrograde amnesia). Early clinical descriptions of retrograde amnesia led to the proposal that recently acquired memories are typically more impaired than remotely acquired memories (Ribot, 1881), and a large experimental literature has supported this idea (Frankland & Bontempi, 2005; Squire & Bayley, 2007). Yet questions remain about whether medial temporal lobe damage can sometimes cause extensive and ungraded retrograde memory loss and about the status of remote autobiographical memory.

Some have concluded that retrograde amnesia is temporally ungraded and that recent and remote memories are similarly impaired across the life span (Sanders & Warrington, 1971; Warrington, 1996). Others have concluded that retrograde amnesia is temporally limited and related to the extent and locus of the damage (Eichenbaum,

Dudchenko, Wood, Shapiro, & Tanila, 1999; Squire et al., 2004). There are two reasons why this issue has been difficult to settle. First, memory has not always been assessed at early enough time periods to permit a firm conclusion that memory loss is ungraded. Second, the relationship between the extent of retrograde memory loss and the extent of medial temporal lobe damage has not always been clearly identified.

A recent study tested memory for past news events in two patients with large medial temporal lobe lesions (EP and GP), six patients with limited hippocampal lesions, and matched controls (Bayley, Hopkins, & Squire, 2006). The test involved up to 300 questions about news events that had occurred from early life to the current year. The patients with hippocampal lesions performed poorly during the period of anterograde amnesia (after the onset of amnesia) and exhibited temporally limited retrograde amnesia covering a period of about 5 years before the onset of amnesia (figure 46.9). For more remote time periods, the patients performed as well as controls.

EP and GP also performed poorly during their period of anterograde amnesia and in addition exhibited extensive retrograde amnesia covering many years before the onset of amnesia (figure 46.10). Nevertheless, both patients performed better when the questions covered the most remote time periods. GP performed within 1.1 standard deviations of controls in the time period 21 to 25 years before amnesia (when he would have been 17 to 21 years old), and he performed as well as controls in the time period 26 to 30 years before amnesia. EP reached normal levels of performance when the questions covered the period 46 to 50 years before amnesia (when he would have been 20 to 24 years old).

With respect to autobiographical memory, it has been proposed (usually in single-case studies) that medial temporal lobe damage, and even limited hippocampal damage, leads to impaired memory for personal events that extends into early life (Cipolotti et al., 2001; Hirano & Noguchi, 1998; Moscovitch, Nadel, Winocur, Gilboa, & Rosenbaum, 2006; Steinworth, Levine, & Corkin, 2005). Findings from group studies, however, suggest that both patients with limited hippocampal lesions and patients with large medial temporal lobe lesions have intact autobiographical memory of early life (Bayley, Gold, et al., 2005; Bayley, Hopkins, & Squire, 2003; Bright et al., 2006; Eslinger, 1998; Rempel-Clover, Zola, Squire, & Amaral, 1996). For example, a study of six patients with limited hippocampal lesions, two patients with large medial temporal lobe lesions, and 25 controls were given 24 cue words, and for each word were asked to recollect a specific event from the first third of their lives that involved the word (Bayley et al., 2003). Narratives were first scored on a 4-point scale (scores of 0 to 3 points) according to how well participants described an event that was specific to time and place. Patients and controls produced a similar number of well-formed (3-point) memories

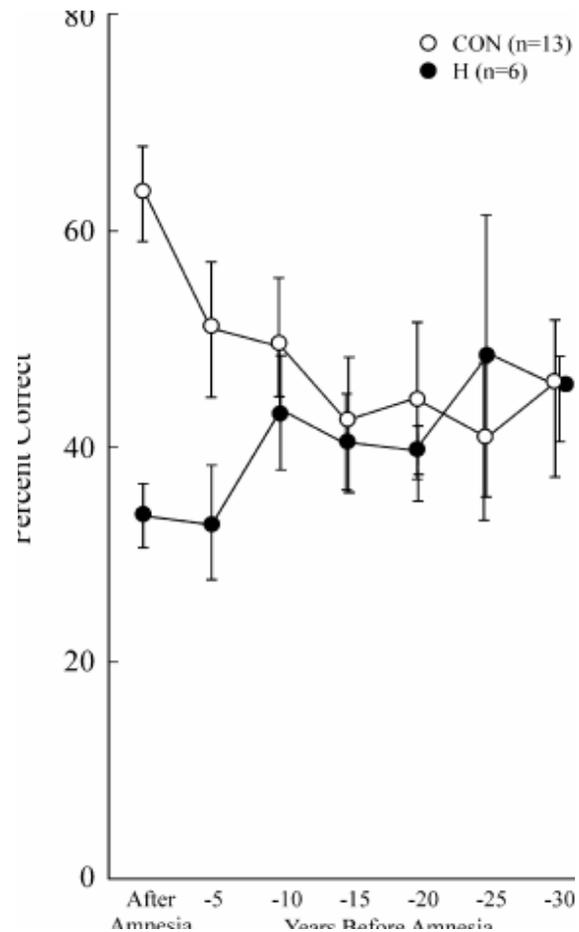

FIGURE 46.9 Recall performance on a test of 279 news events that occurred from 1951 to 2005. The scores for controls (CON) and six patients with damage limited to the hippocampus (H) have been aligned relative to the onset of amnesia so that performance can be shown for the time period after the onset of amnesia and in 5-year intervals for the time preceding the onset of amnesia. The data point at -5 represents 1–5 years before amnesia, the point at -10 represents 6–10 years before amnesia, and so on. Error bars indicate standard error. (From Bayley, Hopkins, & Squire, 2006.)

and were able to produce 3-point memories in response to most of the key words. The narratives were then submitted to a detailed analysis of content. The narratives of patients and controls contained the same number of details and were similar on several other measures as well.

In an effort to maximize the sensitivity with which the assessment of remote memory is carried out, it is also possible to use techniques that ask for a single memory from a given time period (instead of 24 memories, as before) and then probe extensively to obtain as many as 50 details for each memory (the Autobiographical Interview; Levine, Svoboda, Hay, Winocur, & Moscovitch, 2002). This test was given to three patients with damage limited to the hippocampus, two patients with large lesions of the medial temporal lobe, and five controls (Kirwan, Bayley, Galván, & Squire, 2008).

Participants were asked to provide one memory from each of five time periods: childhood (up to age 11 years), teenage years (age 12–17), early adulthood (age 18–35), middle age (age 36–55), and the year before testing. The patients with hippocampal lesions were impaired only at the most recent time period, and the patients with larger medial temporal lobe lesions were impaired at the two most recent time periods (figure 46.11). Both groups of patients performed as well as controls in the three earliest time periods.

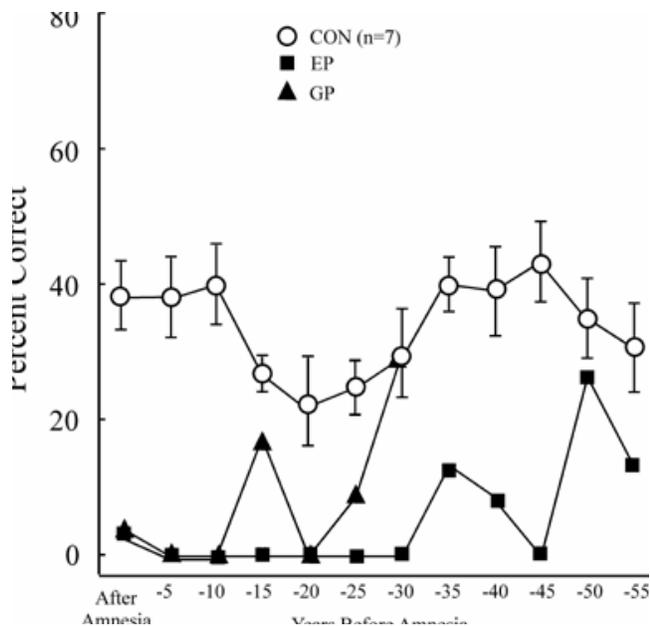

FIGURE 46.10 Recall performance on a test of news events that occurred from 1938 to 2005 (for EP, 300 events) and from 1951 to 2005 (for GP, 279 events). The scores for the two patients with large medial temporal lobe lesions and controls (CON) have been aligned relative to the onset of amnesia (see caption for figure 46.9). Error bars indicate standard error. (From Bayley, Hopkins, & Squire, 2006.)

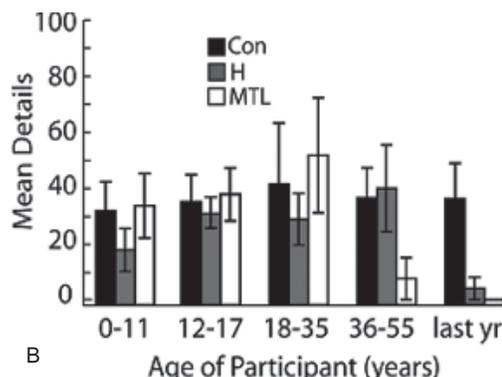

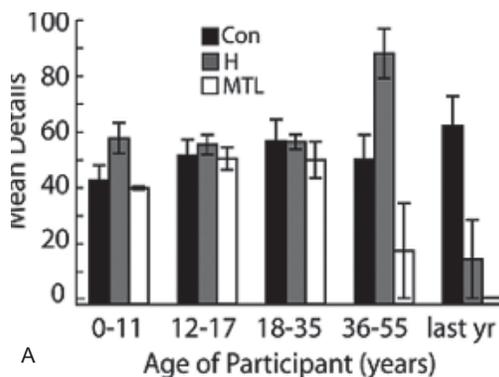

FIGURE 46.11 Total number of (A) episodic and (B) semantic details across time periods. Patients with damage thought to be limited to the hippocampus (H), patients with larger medial temporal lobe lesions (MTL), and controls (Con) were asked to retrieve

Impaired remote autobiographical memory does occur when the brain damage extends beyond the medial temporal lobe. Another study assessed remote autobiographical memory in three patients with medial temporal lobe damage plus significant damage to the neocortex (Bayley, Gold, et al., 2005). As in an earlier study (Bayley et al., 2003), the patients were asked to recall a childhood memory in response to a cue word for each of 24 words. As described previously, patients with damage limited to the medial temporal lobe and their controls produced well-formed memories in response to most of the 24 word cues (21.6 for the patients, 22.9 for the controls). In contrast, the patients with significant neocortical damage outside of the medial temporal lobe were severely impaired and provided a mean of only 4.0 unique, well-formed memories. These patients were able to recall some general information in response to the cue words but had marked difficulty providing memories that were specific to a particular time and place.

Similar findings were obtained with the Autobiographical Memory Interview (AMI; Kopelman, Wilson, & Baddeley, 1989), a standardized test that facilitates comparison of performance across laboratories. In the childhood portion of this test, patients are asked to recall three unique events from their childhood. Patients with medial temporal lobe damage plus significant neocortical damage performed poorly, whereas patients with limited medial temporal lobe damage performed well (Bayley, Gold, et al., 2005; figure 46.12). These findings suggest that patients who fail the AMI (Childhood Portion), or who otherwise have difficulty recollecting events from their early life, have damage outside the medial temporal lobe.

Awareness and memory

Declarative memory has ordinarily been viewed as memory that is accompanied by knowledge or awareness of what

one autobiographical memory from each of five time periods. Error bars indicate standard error. (From Kirwan, Bayley, Galván, & Squire, 2008.)

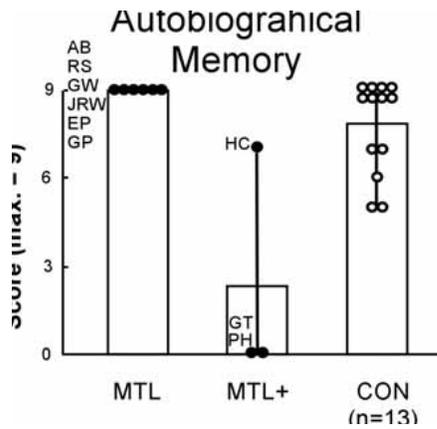

FIGURE 46.12 Performance on the Childhood Portion of the Autobiographical Memory Interview (maximum score, 9). Each participant's score is represented by a circle, and patients are identified by initials. MTL, patients with medial temporal lobe lesions; MTL+, patients with medial temporal lobe lesions and additional lesions in neocortex; CON, controls. (From Bayley, Gold, Hopkins, & Squire, 2005.)

has been learned, and the availability of learned material to awareness has been considered one of its key features (Eichenbaum, 1997; Gabrieli, 1998; Squire, 1992; Tulving & Schacter, 1990). In some cases, when behavior is changed by experience, it is unclear what kind of memory is being expressed. Consider the case of eye movements. When individuals view novel scenes, familiar scenes, or familiar scenes in which a change has been introduced, eye movements differ depending on the viewing history of each scene. What kind of memory is indexed by eye movements, and is this kind of memory accessible to awareness?

Two studies addressed this issue by asking what kind of memory is operating when eye movements change as the result of experience (Smith, Hopkins, & Squire, 2006; Smith & Squire, 2008). Amnesic patients and controls viewed scenes that were either novel, repeated, or manipulated. For manipulated scenes, an element was either added to or removed from a previously presented scene. The first finding was that the patients were impaired at remembering whether a scene was new or old and also whether a scene had been manipulated or not. The second finding was that control subjects, but not amnesic patients, examined scenes differently depending on whether the scenes were new or old. Specifically, during a 5-second viewing period, controls made fewer fixations and sampled fewer regions when scenes were repeated than when they were novel. Importantly, these effects occurred only when individuals were aware that a scene was novel or repeated. The third finding was that, when scenes were manipulated, healthy participants made more fixations in the manipulated region, spent more time looking at the manipulated region, and made more transitions into and out of the manipulated region than in corre-

sponding, unmanipulated regions in the repeated scenes. Again, these effects occurred only when individuals were aware of the manipulation. Participants who were unaware that a scene had been changed looked at it in the same way that they looked at repeated scenes (figure 46.13). The fourth finding was that these effects occurred even when the scenes were presented without any indication that memory was being tested or that individuals should try to detect which scenes were new, old, or manipulated.

Thus there was no indication that eye movements reveal an unaware (unconscious) form of memory. Instead, eye movements reflected declarative (conscious) memory. These findings support the principle that hippocampus-dependent memory is accessible to awareness. Recent studies of transitive inference (Smith & Squire, 2005) and eyeblink conditioning (Smith, Clark, Manns, & Squire, 2005) are consistent with this idea. See Smith, Hopkins, and Squire (2006) for discussion of two studies that reached different conclusions (Greene, Spellman, Dusek, Eichenbaum, & Levy, 2001; Ryan, Althoff, Whitlow, & Cohen, 2000).

Summary

This chapter reviewed a number of recent findings pertinent to the organization of memory and the function of the medial temporal lobe. These findings indicated that (1) visual perception is independent of the medial temporal lobe; (2) working memory can be identified independently of the performance of amnesic patients, and when this identification is accomplished, working memory is found to be independent of the medial temporal lobe; (3) humans have a robust capacity for habit learning that operates outside of awareness and is independent of the medial temporal lobe; (4) path integration, a form of spatial cognition, is independent of the hippocampus and entorhinal cortex when information can be maintained within working memory, but path integration depends on these structures when demands are made on long-term memory; (5) the hippocampus is required for recognition memory, regardless of whether decisions are based on recollection or familiarity; (6) the medial temporal lobe plays a time-limited role in declarative memory such that very remote memory, including remote autobiographical memory, is intact after medial temporal lobe damage; and (7) the kind of declarative memory that is dependent on the hippocampus is accessible as conscious, aware knowledge of what has been learned.

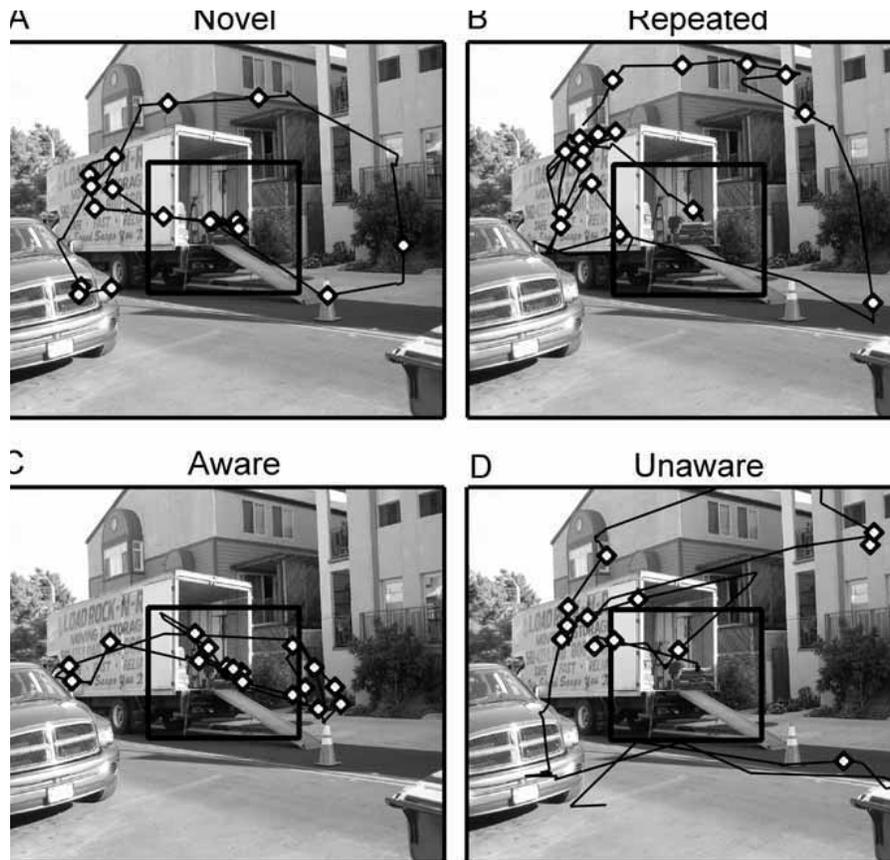

FIGURE 46.13 Eye movement traces (black lines) and fixations (diamonds) for four different individuals who viewed this image for 5 seconds. (A) An individual for whom this image was novel. (B) An individual for whom this image was familiar. (C) An individual for whom the image was familiar but altered (a man is no longer in the back of the truck) and who was aware of the change. (D) An individual for whom the image was familiar but

altered and who was unaware of the change. Aware individuals spent more time looking at the altered region of the image than unaware individuals or individuals who had never seen the version with the man in the truck. In each panel, the critical region is identified by a black square, but the square did not appear during testing. (From Smith, Hopkins, & Squire, 2006.)

47 Reconsolidation: A Possible Bridge between Cognitive and Neuroscientific Views of Memory

KARIM NADER

ABSTRACT The field of reconsolidation is one of the fastest growing fields in memory research. Students of memory find themselves in an extremely exciting period because memory research is beginning to be revealed at the neurobiological level as a fundamentally dynamic process. A neurobiological model of memory is emerging that can accommodate the dynamic nature of memory revealed in a long tradition of cognitive-oriented studies of human memory (Bartlett, 1932). This chapter will briefly address the history of consolidation and reconsolidation. It will describe the basis for which a reconsolidation phenomenon is thought to exist and address some central issues and unresolved problems of memory reconsolidation.

When students are asked to give analogies of how the brain processes memories, they often suggest that memories are like pictures stored in a filing cabinet. Remembering is suggested to consist of pulling the correct files from the brain for examination and then filing them again, unchanged, back into the storage banks of the brain. Memory—that is, the recall of previously stored memory contents—is thus simply faithful readout, just like opening a data file on a computer. Depending on the tradition in which the student was trained, this analogy is half wrong, but different parts of the analogy might be wrong in different traditions.

The cognitive tradition views memory as a reconstructive process, in which memories and their content are subject to change. This view was first developed by Bartlett in his seminal book *Remembering* (1932). He suggested that each (episodic) memory recall represents essentially a re-creation, based on one's current assumptions and beliefs about the world (schemata). A large body of work now supports this initial claim, indicating that under several conditions, memories can be easily corrupted (Loftus, 1997; Schacter, 1999). False memory paradigms can instill false memories within minutes, and subjects who are sensitive to these effects are often amazed and sometimes alarmed by how easily their memories can be manipulated without their consciously

noticing the modifications. These and similar demonstrations established that remembering is not akin to a passive readout of a stored file; rather it is a reconstructive process in which new information is combined with current and previous experiences.

The physiological tradition, along with what is now referred to as systems neuroscience, somewhat limits the scope of the effects of malleability documented in cognitive psychology. Memory models developed in physiological psychology suggest that memories may only be substantially manipulated during a transient period of instability that follows their initial acquisition. It is assumed that memories initially exist in an unstable (labile) state and then become stable (consolidated) over time. This assumption explains why, if you are trying to remember a phone number and you are distracted within a few minutes of learning the phone number, you will likely forget the number in part or totally because the memory for the number was still in an unstable state when the interference occurred. If the same distraction were to happen 24 hours after the initial learning, chances are that the memory for the phone number would not be affected by the same distracter. Again, distracters are only effective shortly after new learning as only then is memory in an unstable state, whereas, after a few hours have passed, memory would have been stored, or “wired,” into the brain, resistant to distracters. In other words, once memory is stabilized, it becomes fixed and cannot be changed as easily as it can shortly after learning (McGaugh, 2000). The processes involved in memory “fixation” have been the main focus in a highly successful research program in the physiological tradition. How do memories become fixed over time in the brain? What are the cellular and molecular mechanisms mediating this transformation from a labile to a consolidated state?

It is obvious that there are only small areas of overlap between these two traditions. On the one hand, cognitive psychology reminds us that our memories are not snapshots of the past but elaborate reconstructions. On the other hand, many physiologists and neuroscientists study the mechanisms

KARIM NADER Psychology Department, McGill University, Montreal, Quebec

of memory as a unidirectional process of fixation. Both views are based on a broad basis of empirical evidence—so how can they be reconciled? The recent rediscovery of reconsolidation—the phenomenon that seemingly consolidated, that is, stable, memories can return for a short time to a labile state after they have been reactivated—may begin to create points of overlap between the two traditions.

Consolidation theory

One of the defining features of memory is that it is a time-dependent process. New memories initially exist in an unstable state (called a labile state) and then over time become more stable, entering a state in which they are resistant to disruptions (Ebbinghaus, 1885; Müller & Pilzecker, 1900; Ribot, 1881). The transformation of memory from an unstable to a stable state is what theories of consolidation try to explain. As in any field in which scientists strive to create reductive models of a phenomenon, terminology is often applied in various levels of analysis, leading to some confusion when used in a different context. “Consolidation” is no exception. The term is used in a variety of ways that differ depending on levels of analysis (e.g., McGaugh, 2000; Spear & Mueller, 1984; Squire, 1992). Thus it would be helpful to explicitly differentiate between two ways in which the term is commonly used today. *Systems* consolidation posits that hippocampus-dependent memory becomes, over years in humans or weeks in rodents, hippocampus-independent (Scoville & Milner, 1957; Squire & Alvarez, 1995). *Cellular* (or synaptic) consolidation refers to a universal property of neurons, namely, the time-dependent stabilization of changes in synaptic efficacy, which represent the neural substrate of memory, within hours following acquisition (Dudai, 2004; Kandel, 2001).

Empirical evidence for a cellular consolidation process is derived from three lines of evidence. First, performance can be impaired if brain or neuronal function is compromised with manipulations such as electroconvulsive shock or protein synthesis inhibitors (Duncan, 1949; Flexner, Flexner, & Stellar, 1965). Second, performance can be impaired by new competing learning (Müller & Pilzecker, 1900). Third, performance can be enhanced by a variety of drugs that in general terms “stimulate” brain function (McGaugh & Krivanek, 1970). In order for any of these manipulations to be effective they must be administered shortly after new learning but not after a delay of minutes to hours after learning. Data from these lines of evidence forms the foundation of contemporary consolidation theory (Glickman, 1961; McGaugh, 1966). It became increasingly clear that memory is not stored immediately in the brain but that this process takes time and changes some aspects of the participating neurons. The initial labile state became synonymous with short-term memory (STM), and when the memory was resis-

tant to challenge, it was referred to as being consolidated, or “fixed,” and thus became long-term memory (LTM). It is important to note that “labile” is conceptually differentiated from the strength of the memory; that is, it is not implied that a labile memory is somehow weaker than a stable one. For example, behavioral responding when the memory is labile (STM) is often comparable to when the memory is in a consolidated state (LTM) (see figure 47.1). One implication of consolidation theory is that consolidation is unidirectional. Once a memory is “fixed” in the brain, it will remain as such (Glickman, 1961; McGaugh, 1966).

In typical experiments studying consolidation, animals are initially trained on a new task, and then a treatment is administered that affects a molecule or molecular pathway deemed critical for consolidation. Powerful predictions can be made about when a behavioral effect should be seen by exploiting the time-dependent nature of memory-consolidation processes. If the treatment specifically impairs consolidation, then it is expected that the behavioral impairment should reflect the time-dependent nature of consolidation: an impairment (or improvement, depending on the kind of treatment administered) should only be seen when the intervention occurred within the few hours memory was in the labile state, that is, STM, but not after it had entered LTM. Thus the operational definition of consolidation impairment is spared STM but impaired LTM (Dudai, 2004; McGaugh, 2000). It is difficult to imagine an alternative model that would predict a time-dependent impairment with these temporal characteristics. Alternative explanations of the time-dependent vulnerability of memory to interference, such as changes in memory strength, in retrievability, or in the content of the memory, predict that treatment effects should have immediate repercussions; that is, STM should be affected already, which is not the case. For these reasons, the consolidation model almost reached the status of a fact.

Studies using modern neurobiological tools at the genetic, molecular, cellular, and systems levels have led to the same basic result pattern—intact STM and impaired LTM. These approaches demonstrated across species and learning systems that, in order for a memory trace to become consolidated, new proteins and RNA must be produced (Kandel, 2001). Departing from the axiom that the unit of memory is a change in the strength of a synapse (Hebb, 1949), the underlying assumption of these investigations is that new proteins contribute to synapse strengthening by either increases in postsynaptic excitatory receptors (Malinow & Malenka, 2002), new synapse formation (Bailey & Kandel, 1993), or the increase in release of presynaptic neurotransmitters (T. V. Bliss & Collingridge, 1993) that stabilize the memory trace over longer time periods. Two of the main mechanisms of these changes are long-term potentiation and long-term depression (T. V. P. Bliss & Lomo, 1973; Martin, Grimwood, & Morris, 2000). These cellular changes, like

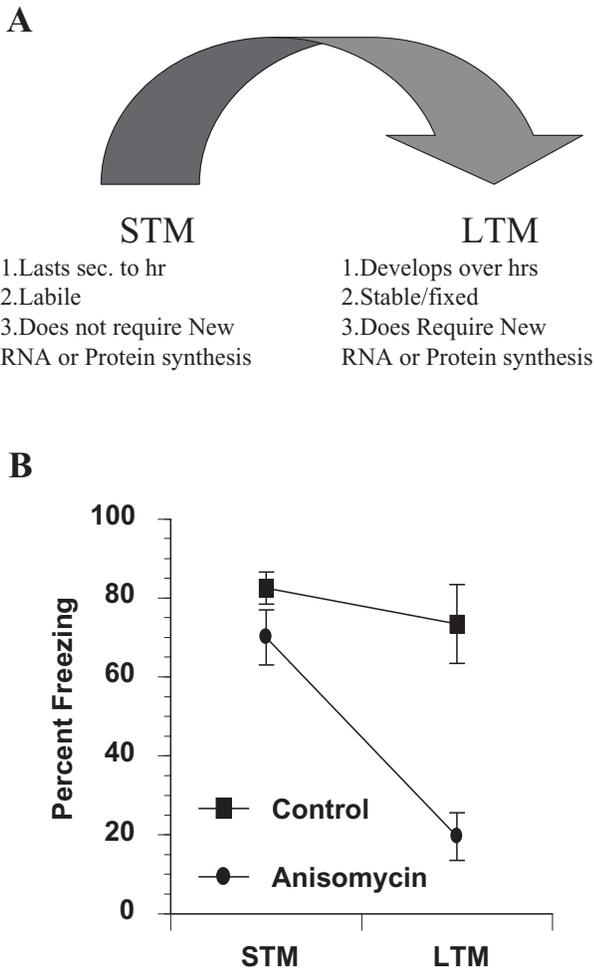

FIGURE 47.1 (A) A schematic of synaptic consolidation theory. Short-term memories (STM) are considered to be unstable or labile. They are thought to last on the order of minutes to hours. The currently dominant view is that STM expression does not require any new RNA or protein synthesis. Long-term memories are thought to develop over a few hours. They require new protein and RNA synthesis in order to become stable. (B) Data from Schafe, Nader, Blair, and LeDoux (2001) demonstrating that posttraining infusions of the protein synthesis inhibitor anisomycin into the basolateral amygdala blocks consolidation of auditory fear conditioning. Note that the data meet the operational definition of a consolidation blockade, intact STM and impaired LTM.

memory, have different phases: an early phase that is sensitive to inhibition of protein synthesis and a later phase that is not (Goelet, Castellucci, Schacher, & Kandel, 1986).

Reconsolidation

In 1968, Misanin, Miller, and Lewis conducted a clever experiment to test the assumption of unidirectionality, one of the main tenets of consolidation theory, which suggests that once memory is consolidated, it remains fixed in the brain. The authors first demonstrated that 24 hours after training the memory had become insensitive to

electroconvulsive shock (ECS), which impaired memory when applied shortly after training, suggesting that the memory was consolidated about one day after learning. However, if they presented the animals 24 hours after training with a reminder just prior to ECS, amnesia would follow (Misanin et al., 1968). According to consolidation theory, as the memory had already become insensitive to ECS, and thus consolidated, it should also remain so following memory retrieval. The authors suggested that transformation of a memory from an unstable to a stable state occurred not only for new memories but also for consolidated memories after they had been recalled. This effect, which was originally called “cue-induced amnesia,” led to a large number of studies. As with many (new) phenomena, the effect was not replicated in some paradigms (Dawson & McGaugh, 1969; Gold & King, 1972; Squire, Slater, & Chace, 1976). Nevertheless, it was found across a range of species and amnesic treatments (Lewis, 1979; Spear & Mueller, 1984), suggesting that the negative findings may point to certain conditions under which the phenomenon does not occur.

The initial studies suggested that reactivation of a memory induced a state of lability such that memory again had to be stabilized over time. Using the standards of consolidation theory and applying them to cue-induced amnesia, reactivation induces a time window during which performance can be affected by one of three different manipulations. First, performance can be impaired if brain or neuronal function is compromised (Misanin et al., 1968). Second, performance can be impaired by new competing learning (Gordon, 1977a). Third, performance can be enhanced by stimulants (Gordon, 1977b). When administered shortly after the reminder but not after a delay of minutes or hours, these manipulations affect performance. In addition, the manipulations are not effective when the memory is not reactivated (Misanin et al., 1968). Thus reactivation of a consolidated memory induces another state of transient lability that affords a process of time-dependent memory stabilization.

For a variety of reasons, however, cue-induced amnesia never became part of the dominant physiological tradition of memory. Some of the original scientists who demonstrated the effect (Land, Bunsey, & Riccio, 2000; Przybylski & Sara, 1997) and others (Rodriguez, Rodriguez, Phillips, & Martinez, 1993) continued to periodically publish reconsolidation results, but these results were met with indifference by the field, which had settled on consolidation theory as the defining paradigm of memory research.

Reviving Reconsolidation

Initially unaware of the early literature on “cue-induced amnesia,” we completed a series of experiments that were aimed at testing whether reactivation of consolidated

memories would cause them to return to a labile state from which they had to be restabilized. We found that the role of protein synthesis in consolidation is *recapitulated* during reconsolidation (Nader, Schafe, & LeDoux, 2000a). These experiments used a fear-conditioning paradigm, for which the circuitry mediating learning is relatively well established (LeDoux, 2000). The most commonly used protein synthesis inhibitor, anisomycin, was *infused directly* into the lateral and basal nucleus of the amygdala (LBA), which is a site believed to mediate the learning and consolidation of fear-conditioned memories (LeDoux, 2000; Maren, 2001; Schafe & LeDoux, 2000). Specifically, infusions of anisomycin immediately after training had no effect on an STM retention test 4 hours after training but impaired performance on an LTM test at 24 hours after training (Schafe & LeDoux, 2000) (figure 47.1B). This finding suggests that the auditory fear memory is consolidated in the LBA.

Using this same logic to test for reconsolidation, rats were infused with anisomycin into the LBA immediately after reactivation and tested 4 hours later (postreactivation STM, PR-STM) and again at 24 hours after reactivation (postreactivation LTM, PR-LTM). These were analogues to STM and LTM tests, respectively. We predicted that if reactivation of a consolidated memory initiated a second time-dependent memory process, then anisomycin infusions into the LBA should have no effect on PR-STM but should impair PR-LTM performance. This was the pattern of results that we found (figure 47.2B; Nader et al., 2000a). Furthermore, in the absence of memory reactivation, the same anisomycin injections did not induce amnesia, indicating that the memory was consolidated at that time. Based on these and other findings, we concluded that reactivation of a consolidated memory initiates a second time-dependent memory process that requires protein synthesis in the amygdala in order to be restabilized. The restabilization process is now called reconsolidation. The term was used at least as early as 1973 (Spear, 1973) and has been used in more recent times by Przybylski and Sara (1997) and Rodriguez and colleagues (1993). Again it is important to point out that making a memory “labile” is not consistent with it being weakened in any way, as suggested, for example, by Rudy, Biedenkapp, Moineau, and Bolding (2006), who argue that lability requires that memories be eliminated and then put back into the brain. This position is clearly at odds with the data and the proposed explanations of the phenomenon (Nader et al.).

Our findings have again led to a large number of studies, and again the evidence is much the same as after the original description of the phenomenon by Misanin and colleagues (1968). A time-dependent behavioral impairment has now been demonstrated across a variety of tasks (figure 47.3), such as object recognition (Kelly, Laroche, & Davis, 2003), incentive learning (Sangha, Scheibestock, & Lukowiak, 2003), inhibitory avoidance (Anokhin, Tiunova, & Rose, 2002),

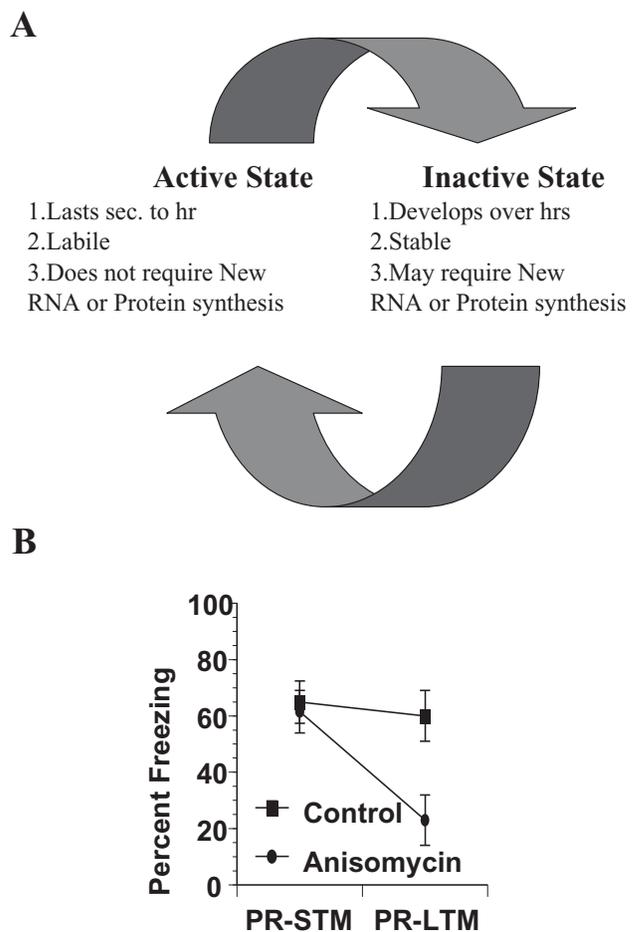

FIGURE 47.2 (A) A schematic of Donald Lewis’s theory of memory processing. Active memories (AM) are considered to be unstable or labile. They are thought to last on the order of minutes to hours. Currently the evidence suggests that its expression does not require any new RNA or protein synthesis. Inactive memories (IM) are thought to develop over a few hours. Currently the data suggest that they require new protein and RNA synthesis in order to become stable. (B) Data from Nader, Schafe, and LeDoux (2000a) demonstrating that postreactivation infusions of the protein synthesis inhibitor anisomycin into the basolateral amygdala blocks reconsolidation of auditory fear conditioning. Note that the data meet the operational definition of a consolidation blockade, intact PR-STM and impaired PR-LTM.

motor sequence learning (Walker, Brakefield, Hobson, & Stickgold, 2003), appetitive conditioning (Wang, Ostlund, Nader, & Balleine, 2005), episodic memories (Forcato et al., 2007; Hupbach, Gomez, Hardt, & Nadel, 2007), and memories of drug reward (Lee, Di Ciano, Thomas, & Everitt, 2005; C. Miller & Marshall, 2005). A variety of different amnesic treatments have been shown to be effective in blocking reconsolidation, such as targeted protein (Nader et al., 2000a) or RNA synthesis inhibition (Duvarci, Nader, & LeDoux, 2008; Sangha et al., 2003), pharmacological inhibition of kinase activity (Kelly et al.), protein knockout mice (Bozon, Davis, & Laroche, 2003), inducible knockout mice (Kida et al., 2002),

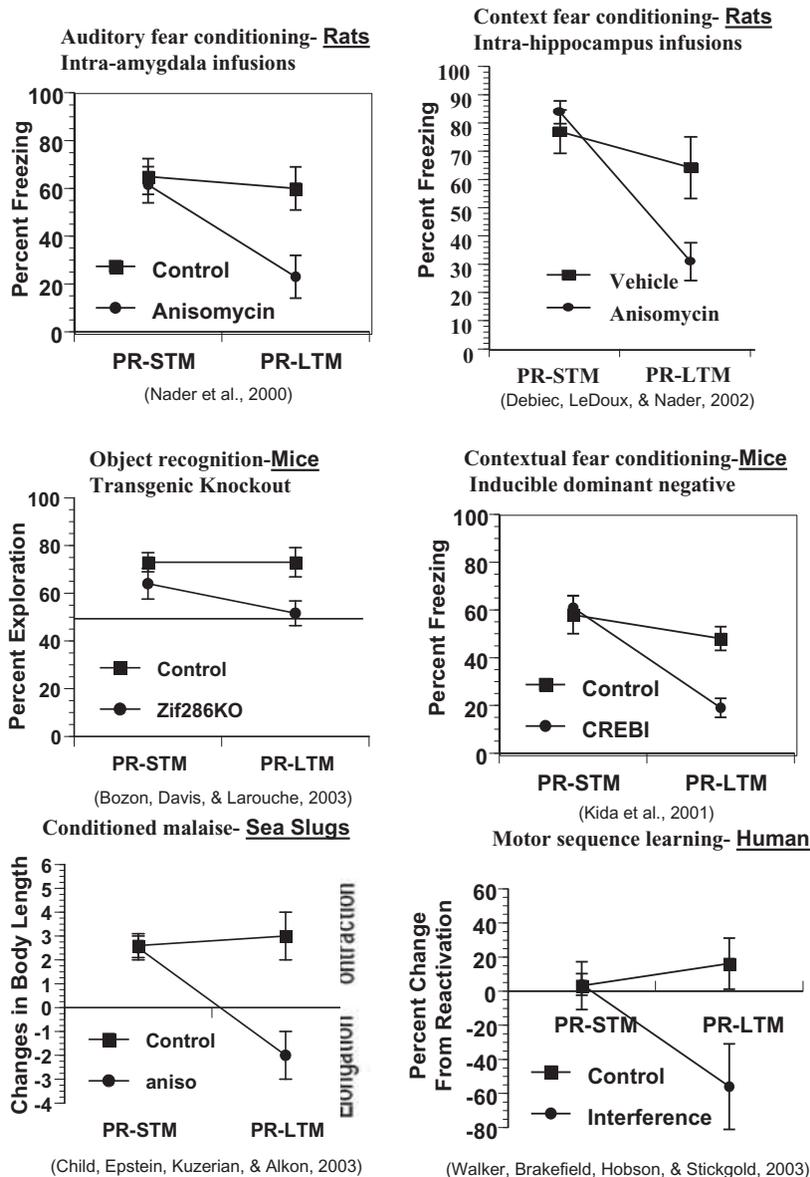

FIGURE 47.3 Representative data from some of the studies reporting a reconsolidation impairment. Notice that they all show intact postreactivation STM (PR-STM) and impaired

postreactivation LTM (PR-LTM). Labels above each graph refer to the paradigm and the nature of the amnesia treatment. Below each are the citations for the data.

beta-adrenergic antagonists (Przybylski & Sara, 1997), and simply an interference by new learning (Forcato et al.; Hupbach et al.; Walker et al., 2003). In addition, reconsolidation has been reported across a broad spectrum of species, such as snails (Sangha et al., 2003), sea slugs (Child, Epstein, Kuzirian, & Alkon, 2003), crabs (Pedreira, Perez-Cuesta, & Maldonado, 2002), chicks (Anokhin et al.), mice (Kida et al.), rats (Nader et al., 2000a), and most importantly humans (Brunet et al., 2008; Forcato et al.; Hupbach et al.; Walker et al.). While most of the aforementioned studies have focused on blockade of reconsolidation, there is also evidence that reconsolidation can be enhanced by postreactivation increases in kinase activity (Tronson, Wiseman, Olausson, & Taylor, 2006).

CONSTRAINTS ON RECONSOLIDATION The data set shows that reconsolidation can be found across a large number of paradigms and species, suggesting that reconsolidation is a fundamental phenomenon. However, it is apparently not ubiquitous, as some have failed to demonstrate it in the late phase of instrumental conditioning or memory of context (Biedenkapp & Rudy, 2004; Hernandez, Sadeghian, & Kelley, 2002). This fact would indicate that perhaps not all memories undergo reconsolidation. Furthermore, there is a large amount of exciting work demonstrating that the ability of a memory to undergo reconsolidation can be influenced by certain experimental parameters. For example, some older memories may be more resistant to reconsolidation (Eisenberg & Dudai,

2004; Milekic & Alberini, 2002; Suzuki et al., 2004). In these studies, the authors report that the ability of postreconsolidation treatments to induce amnesia decreases with time between training and reactivation. This finding would suggest that old memories may not undergo reconsolidation.

Another suggested constraint on reconsolidation is that if the reminder is sufficiently robust to induce extinction of the memory, extinction prevents the memory from undergoing reconsolidation in many paradigms (Eisenberg, Kobil, Berman, & Dudai, 2003; Pedreira & Maldonado, 2003; Sangha, Scheibstock, Morrow, et al., 2003; Suzuki et al., 2004).

In collaboration with Joseph LeDoux's group, we wanted to test whether it mattered if a memory was directly or indirectly reactivated in order to undergo reconsolidation. Reductionists often talk about memories as if they exist in isolation; scientists test consolidation of "this" or "that" memory, training animals in a variety of tasks and treating the learning as if this were the only thing animals ever experience. Therefore, from a mnemonic perspective, the experimental animal's arrival in the lab is ground zero. From then onward, the animals are welcome to have memories. In the real world, of course, memories are richly associated with other memories (Tulving, 2002). We wanted to test whether the manner in which a memory was reactivated, directly or indirectly, influenced a memory's ability to undergo reconsolidation. We found that memories that were directly reactivated underwent reconsolidation; however, memories that were indirectly reactivated did not (figure 47.4) (Debiec, Doyere, Nader, & LeDoux, 2006). This constraint has yet to be tested in other paradigms, so it remains unclear whether it will generalize to other tasks and memory systems.

For all of the suggested constraints on reconsolidation there are published exceptions to the rule. For example, extinction of an auditory fear memory does not prevent the memory from undergoing reconsolidation in the amygdala (Duvarci, Mamou, & Nader, 2006). In honeybees, extinction of an appetitive response was necessary to *induce* the memory to undergo reconsolidation (Stollhoff, Menzel, & Eisenhardt, 2005). For age of memories, a large number of studies have shown that even very old memories can undergo reconsolidation (Brunet et al., 2008; Debiec, LeDoux, & Nader, 2002; Lee et al., 2005). Indeed, in one important study, patients with posttraumatic stress disorder had reconsolidation of their traumatic memories reactivated and targeted with a beta antagonist. We reported that the strength of the traumatic memory decreased even though the average time between trauma and treatment was approximately 11 years (Brunet et al.). It is still too early to know why age and extinction prevent only some memories from undergoing reconsolidation. However, the conditions that constrain when a memory undergoes reconsolidation are a very exciting and dynamic area of current research.

ALTERNATIVE INTERPRETATIONS Given the richness of the data on reconsolidation mentioned previously, including the original findings, alternative interpretations do not readily explain the data set. In addition, because reconsolidation has been defined using the standards of consolidation, nonspecific interpretations are also applicable to the field of consolidation, challenging the latter in the same way as they purportedly challenge the former. The two main alternative interpretations, suggesting that the reconsolidation impairment represents nonspecific effects (including lesion) or that it represents a retrieval impairment, will be discussed in this section. For an extensive review of the issues surrounding reconsolidation, including state-dependent learning and facilitated extinction, see Nader (2003), Nader and Hardt (2009), and Nader and Wang (2006).

Recently it has been suggested that reconsolidation impairments represent nonspecific effects or lesions due to apoptosis (Rudy et al., 2006). In general, this interpretation has difficulty explaining the entire set of reconsolidation results. One has to assume that in all studies that show evidence for reconsolidation, lesions or nonspecific effects are responsible, despite the use of different amnesic treatments, tasks, and species, including new learning and inducible dominant negative CREB mutant mice.

In particular, there are three lines of evidence that make this interpretation of our data unlikely. First, anisomycin-treated animals show intact PR-STM, suggesting that no functional lesion is present 4 hours after reactivation and amnesic agent treatment. However, it is still possible that the behavioral impairments were due to a lesion that developed between the 4-hour PR-STM and 24-hour PR-LTM test. Speaking against this possibility is that anisomycin infusions 6 hours after reactivation had no effect on PR-LTM (Nader et al., 2000a). If anisomycin had produced a functional lesion, then the delayed infusion should also have caused an impairment during the PR-LTM test; however, that was not seen (Nader, Schafe, & LeDoux, 2000b). Second, a similar behavioral impairment is found when amnesic agents are used that target different points in the molecular cascade thought to be important for memory stabilization, such as an inhibitor of the extracellular signal-regulated kinase-mitogen-activated protein kinase (ERK-MAPK) U0126 (Duvarci, Nader, & LeDoux, 2005) and RNA synthesis inhibitors (alpha-amanatin and DRB) (Duvarci et al., 2008).

The question of whether experimental amnesia, induced by blocking novel or reactivated memories, represents an impairment of the consolidation (storage) process or an impairment in retrieval of an otherwise sufficiently consolidated memory has never been resolved (Gold & King, 1974; R. Miller & Springer, 1974). There were a number of reasons for this stalemate. One was that both views of amnesia could explain any results produced within the dominant paradigm used to study the nature of amnesia, the recovery-

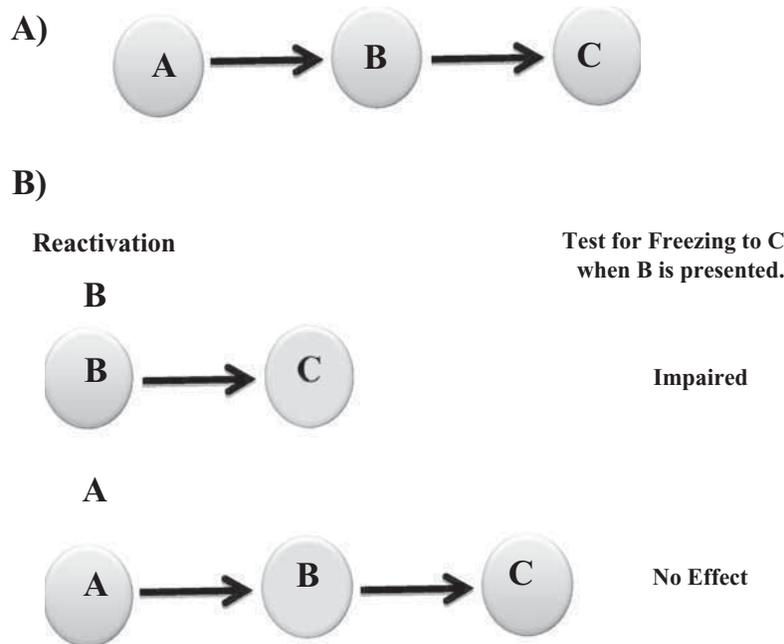

FIGURE 47.4 (A) Cartoon of the chain of associations created to test whether being reactivated in an indirect manner changed a memory's propensity to undergo reconsolidation (Doyere, Debiec, Monfils, Schafe, & LeDoux, 2007). (B) Presenting B during the reactivation *directly* elicits the $B \rightarrow C$ association that undergoes reconsolidation. Amnesic treatments would then induce an impair-

ment in responding if B was presented on test. Indirect reactivation of the same association by presenting A during reactivation causes the directly reactivated $A \rightarrow B$ memory to undergo reconsolidation but not the indirectly reactivated association, $B \rightarrow C$. Therefore, amnesic agents had no effect on responding to B.

from-amnesia paradigm. Furthermore, within this paradigm the consolidation-impairment view of amnesia only makes negative predictions, which do not prove that a memory is not present (Nader & Wang, 2006; Squire, 2006). For this reason, even at the present time, there are completely opposed views on the nature of experimental amnesia (for examples of the discordance on the issue see the special section in *Learning and Memory*, 13[5], 2006).

Consequently, we cannot address whether amnesia induced by postreactivation treatments is due to impairing reconsolidation or retrieval processes. However, what we can do is compare this amnesia to amnesia for new memories and apply the accepted standards in the field of consolidation to conclude that the former deficit is due to impaired memory storage. At the behavioral level, amnesia for new memories (Anokhin et al., 2002; Lattal & Abel, 2004; Quartermain & McEwen, 1970; Squire & Barondes, 1972) and reactivated memories (Anokhin et al.; Lattal & Abel; Quartermain & McEwen, 1970; Squire & Barondes, 1972) are similar, as they can both show recovery. Recovery from amnesia, however, can be consistent with both storage and retrieval-impairment views of amnesia (Nader & Wang, 2006; Squire, 2006).

Because the recovery-from-amnesia paradigm did not resolve the issue, the field has also examined whether the molecular and cellular changes that occur during the post-training stabilization, or consolidation, period are lost in amnesic animals (Squire, 2006). For example, in aplysia the

consolidation of long-term facilitation is accompanied by an increase in synapse number (Bailey & Kandel, 1993). However, in amnesic preparations, in which a memory deficit was induced by inhibiting CREB phosphorylation, increase in synapse number is not observed (Bailey & Kandel, 1993). Such data are considered exclusively as evidence supporting the view that amnesia represents impairment of memory storage (Squire, 2006). While this is certainly a very positive step to advancing the issue, there are still theories of memory processing at the behavioral level (Lewis, 1979; R. Miller & Marlin, 1984; Spear, 1973) that may provide alternative interpretations of this kind of data that remain consistent with the behavioral impairment being a retrieval failure (Nader & Wang, 2006).

A few scientists have begun to examine what happens to established molecular and cellular correlates of LTM when reconsolidation is blocked. Importantly, long-term potentiation in its late phase (L-LTP) can undergo a reconsolidation-like process (Fonseca, Nagerl, & Bonhoeffer, 2006). In addition, learning-induced increases in field potentials in the amygdala are decreased when reconsolidation is blocked for that memory (Doyere, Debiec, Monfils, Schafe, & LeDoux, 2007). Molecular correlates of LTM have also been shown to return toward baseline levels when reconsolidation is blocked (C. Miller & Marshall, 2005; Rose & Rankin, 2006; Valjent et al., 2006), as if the brain area targeted by the amnesic agent reduced the plasticity in those circuits. Within

the physiological tradition, reversal of cellular and molecular signatures of LTM is the accepted standard for concluding that amnesia is a storage impairment (Squire, 2006). Therefore these studies must imply that reconsolidation deficits are due to impairments in memory restorage.

As briefly mentioned previously, a number of alternative interpretations have been proposed for the reconsolidation effect, including nonspecific effects such as lesions (Rudy et al., 2006), transient retrieval impairment (Cahill, McGaugh, & Weinberger, 2001; McGaugh, 2004; Squire, 2006), facilitated extinction (Fischer, Sananbenesi, Schrick, Spiess, & Radulovic, 2004; Myers & Davis, 2002), internal reinforcement (Eisenhardt & Menzel, 2007), and state-dependent learning (Millin, Moody, & Riccio, 2001). As reconsolidation has been found across such a wide range of species and amnesic effects, and both behavioral impairments and *enhancements* have been reported, these nonspecific interpretations have difficulty explaining all findings (Alberini, 2005; Nader, 2003). Indeed, none of these alternative interpretations predict time-dependent behavioral effects. They predict impairments in *both* PR-STM and PR-LTM, and none would predict enhancements in performance. Furthermore, we know that there are constraining conditions that can sometimes determine whether amnesia would be induced. For example, post-reactivation infusions of anisomycin impair the performance of recent but not remote memories (Suzuki et al., 2004), but nonspecific interpretations predict that under all conditions amnesia would be observed. Last, it is important to restate that the reconsolidation interpretation is derived from the standard definitions developed in the consolidation field. Therefore any alternative interpretation of the reconsolidation impairment will generalize to the evidence on which the conclusion for the existence of a consolidation process rests.

Demonstrations of the reconsolidation effect, as Lewis initially pointed out, cannot be explained by consolidation theories. According to consolidation theories, the lability of a memory ceases once it enters LTM. Reconsolidation studies clearly show that reactivation of a consolidated memory can induce another time-dependent stabilization process. Lewis proposed a new model of memory processing that can incorporate findings of both consolidation and reconsolidation. He suggested that a memory can exist in two states—an active or an inactive state (Lewis, 1979). Active memories comprise either new memories or previously consolidated and now reactivated memories. Over time, memories in the active state stabilize to an inactive state. A future reminder may then return the memory again to an active state.

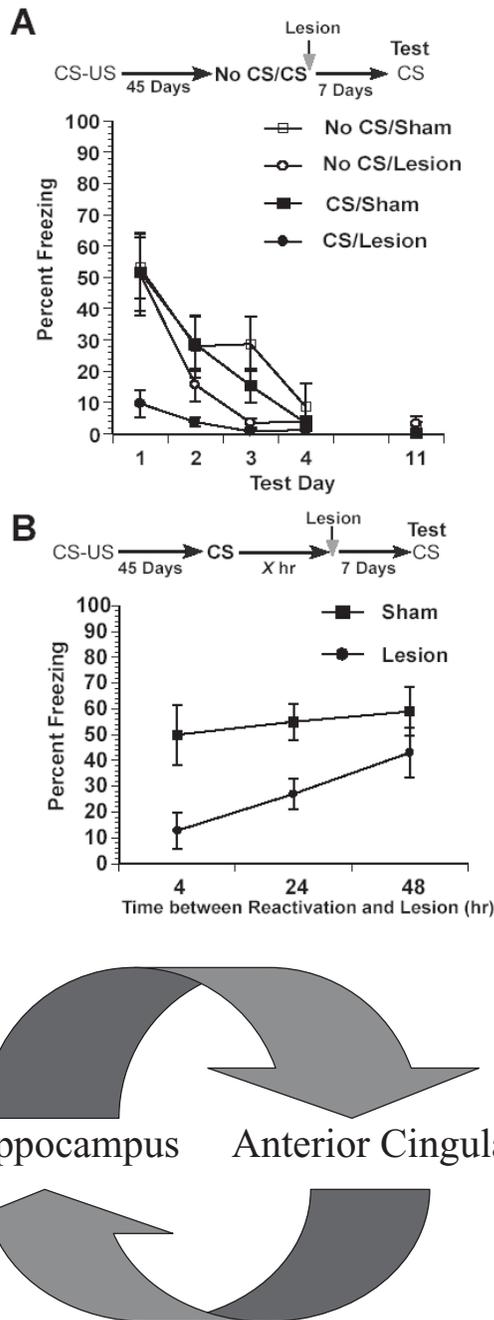

SYSTEMS RECONSOLIDATION When speaking about consolidation and the hippocampus, a time-dependent memory-transformation process—systems consolidation—is implied that is assumed to last weeks (rodents) and years (humans) (Dudai & Morris, 2000). First described by Scoville

and Milner (1957), the hypothesis states that the hippocampus plays a transient role in memory processing, such that recent memories are hippocampus-dependent while remote memories are not (Anagnostaras, Gale, & Fanselow, 2001; Eichenbaum, Otto, & Cohen, 1994; McClelland, McNaughton, & O'Reilly, 1995; Squire & Alvarez, 1995). Whether the hippocampus stays involved or stops being involved in remote memories has become the subject of a lively debate in recent years, and, as an alternative to the standard view articulated in systems consolidation, multiple-trace theory was proposed (Nadel, Samsonovich, Ryan, & Moscovitch, 2000). However, given the fact that systems consolidation still remains the dominant view, especially in the physiological tradition of memory research, the results concerning reconsolidation will be discussed only within this framework.

The first suggestion that something akin to systems reconsolidation (a remote memory that returns to being hippocampus-dependent with memory reactivation) could occur was a study by Riccio's group (Land, Bunsey, & Riccio, 2000). Using an avoidance task, they demonstrated that lesions of the hippocampus affected behavior 1 but not 30 days after training. However, lesions administered after 30 days became effective if the memory was reactivated before. This finding demonstrated that memory reactivation could cause the memory to become hippocampus-dependent again. However, because their task required the hippocampus for retrieval and not acquisition, it did not directly speak to the issue of systems reconsolidation.

We have demonstrated that hippocampus-dependent memories undergo both cellular and systems reconsolidation (Debiec et al., 2002) (figure 47.5). Our study used a contextual fear-conditioning paradigm in conjunction with either targeted infusions of the protein-synthesis inhibitor anisomycin into the dorsal hippocampus or lesions of this structure. Consistent with previous findings, lesions of the hippocampus 45 days after conditioning had no effect on the subsequent expression of contextual fear conditioning (Anagnostaras, Maren, & Fanselow, 1999; Kim & Fanselow, 1992). However, if the memory was reactivated for as little as 90 seconds prior to the same lesion, amnesia was observed and did not recover either with multiple testing protocols or spontaneously with time. Therefore memory reactivation of a remote memory can return it to a hippocampus-dependent state. Interestingly, this reactivated remote trace remained hippocampus-dependent for only two days. Thus, while the duration of systems consolidation (first retrograde amnesic gradient) is on the order of weeks (Anagnostaras et al., 1999; Kim & Fanselow, 1992) (up to 45 days in the present study), systems reconsolidation (second retrograde amnesic gradient) is on the order of days (here, two days). Further, a third gradient of comparable duration to the second was reported (Debiec et al., 2002).

The idea of systems reconsolidation has recently been supported by physiological findings demonstrating that

theta-phase synchronization between the lateral amygdala and the CA1 area of the hippocampus, which is lost for remote memories, returns the day after the reactivation of a remote memory (Narayanan, Seidenbecher, Sangha, Stork, & Pape, 2007). The authors suggest that this finding is evidence that reactivation of a remote memory returns it to a hippocampus-dependent state in which it again critically interacts with the lateral amygdala. In addition, some behavioral findings consistent with systems reconsolidation have been reported. It has been shown that contextual fear memories increase in their generalization to other contexts with age (Winocur, Moscovitch, & Sekeres, 2007). For young memories, animals

FIGURE 47.5 Systems reconsolidation in the hippocampus. Data from a contextual fear-conditioning paradigm demonstrating systems reconsolidation. Training (CS-US) consisted of 8 shock presentations in a conditioning chamber. (A) 45 days after conditioning, electrolytic lesions of the dorsal hippocampus (lesion) immediately after memory reactivation (CS) produced a significant impairment. Conversely, the same lesions had no effect when the reactivation session (no CS) was omitted, demonstrating that 45 days after conditioning the memory is independent of the hippocampus. Thus reactivation of a hippocampus-independent memory returns it to being hippocampus-dependent, an example of systems reconsolidation. (B) Reactivation of the remote memory returned it to being dependent on the hippocampus for less than 2 days. (C) Memory model of the hippocampus demonstrating both-systems reconsolidation. Over time the neocortex (possibly the anterior cingulate) becomes competent to mediate a simple response and might no longer need the hippocampus, at which point it is a remote memory (top arrow). Reactivation of the remote memory causes the cortical trace, which remains in the cortex, to require hippocampus feedback (bottom arrow) over the next 2 days. (From Debiec, LeDoux, & Nader, 2002.)

were able to discriminate between a context associated with a foot-shock and a second distinct nonshock context by freezing more in the shock context. However, for remote memories, animals froze equally between the shocked and nonshocked contexts. The authors suggest that this result is more consistent with a transformation view of memory processing by the hippocampus, as opposed to a consolidation view. One implication of this finding is that when contextual memories are hippocampus-dependent, they permit discrimination of shocked and nonshocked contexts. Over time, when these memories putatively become independent of the hippocampus, animals lose the ability to discriminate between the two contexts. One study has shown that when remote memories are reactivated for 1 minute, then differential context-specific freezing is reinstated (Wiltgen & Silva, 2007). The authors suggest that this differential freezing may be due to systems reconsolidation that occurred when the memory returned to a hippocampus-dependent state. Converging evidence is being accumulated for systems consolidation.

COGNITIVE IMPLICATIONS OF RECONSOLIDATION The traditional physiological view of memory processing viewed memory as becoming wired into the brain over time and then remaining fixed (McGaugh, 1966). This “wiring” is typically discussed as being mediated by increases in postsynaptic receptors (Malinow & Malenka, 2002), growth of new synapses (Bailey & Chen, 1983), or the increase in release of neurotransmitters (T. V. Bliss & Collingridge, 1993). This physiological view is at odds with the cognitive tradition of memory, which views memory as being a *reconstructive* dynamic process. How then can memory be dynamic when it is wired into the brain? Part of the appeal of reconsolidation is that it provides a plausible

neurobiological mechanism for explaining some of the dynamic properties of memory. Indeed, based on the early studies on reconsolidation, Elizabeth Loftus suggested that cue-induced amnesia might be a mechanism underlying some false memories (Loftus & Yuille, 1984).

Perhaps the most straightforward predictions one can make for cognitive neuroscience is that if a specific impairment of reconsolidation is observed in humans, then intact PR-STM and impaired PR-LTM retention should be observed. In addition, any brain area activation that is associated with the presence of the memory should show return toward baseline only for the PR-LTM test. In contrast, the normal PR-STM test should be associated with activation. The amnesic agents could be either a pharmacological agent (Brunet et al., 2008), interference by new learning (Forcato et al., 2007; Hupbach et al., 2007; Walker et al., 2003), suppression (Anderson & Green, 2001), or transcranial magnetic stimulation (Duque et al., 2008). Because memory is one of few psychological time-dependent processes on this time scale, the intact PR-STM and impaired PR-LTM are very powerful tools to characterize both deficits of retention and their underlying substrates.

As mentioned earlier, some memories that undergo reconsolidation will do so only under some conditions. For example, age and extinction of some memories can make them more resistant to undergoing reconsolidation. Another interesting venue of research with regard to reconsolidation as a possible mediator of false memory would be to apply the parameters that control the occurrence of reconsolidation to false-memory studies. If reconsolidation must be present in order for false memory to occur, then false memory should only occur under the experimental conditions favorable to the occurrence of reconsolidation (for example, when the memory is young or directly reactivated).

Summary

Reconsolidation is beginning to provide areas of overlap between cognitive and physiological traditions of memory. There can be no question at this point that memories are fundamentally dynamic, as first explicitly demonstrated by Bartlett (1932). They are not snapshots of events that are passively read out; they are *constructive* in nature and always changing (Loftus & Yuille, 1984; Schacter, 1999; Tulving & Thomson, 1973). But there is also no doubt that memories stabilize over time (Glickman, 1961; McGaugh, 1966; Müller & Pilzecker, 1900). Models now exist across levels of analysis to describe the processes engaged during memory storage (Kandel, 2001; McGaugh, 2000). Reconsolidation, which has been shown to occur in species ranging from slugs to humans, is a mechanism that naturally endows neural systems with the property to both make memories more stable and then return them to unstable, malleable states

in which they may be either strengthened, weakened, or changed—exactly the kind of properties one would want in a system to allow memories to change with future use.

48 The Dynamic Interplay between Cognitive Control and Memory

ELIZABETH A. RACE, BRICE A. KUHL, DAVID BADRE, AND ANTHONY D. WAGNER

ABSTRACT Cognitive control refers to the set of processes that guide thought and action in accordance with current goals. In this chapter we consider the manner in which cognitive control mechanisms guide mnemonic processing. First, we consider the architecture of prefrontal cortex (PFC) and review leading theories of how PFC operations support distinct forms of control. Next, we consider two illustrative and well-characterized situations in which PFC control guides mnemonic processing: (1) when competition between memories creates interference, and (2) when ineffective retrieval cues yield uncertainty. Finally, we consider the ways in which prior mnemonic experiences may reduce future interference and uncertainty, thereby easing the demands placed on PFC control mechanisms. Together, these considerations highlight the dynamic interplay between cognitive control and memory.

Cognitive control refers to the set of processes that guide thought and action in accordance with current goals. Central to higher cognitive function, cognitive control allows organisms to represent task demands, flexibly work with memory, and promote context- and goal-relevant information processing in the face of distraction. Control mechanisms are particularly important in unfamiliar situations or changing environments when acquired knowledge provides either insufficient or inappropriate information to satisfy current demands. The prefrontal cortex (PFC) is a fundamental component of the neural circuitry supporting cognitive control. By orchestrating the influence of past experience on present behavior, PFC mechanisms configure neural processing to optimize behavior.

In this chapter we explore the dynamic interaction between control mechanisms and memory, with a specific focus on prefrontal contributions to cognitive control. We begin with a brief description of the neural circuitry supporting cognitive control, focusing on the anatomy and connectivity of subregions within PFC. Next, we discuss current

theories that characterize the mechanisms, functional organization, and regulation of cognitive control. Finally, we review functional neuroimaging and lesion evidence for the interaction between cognitive control and memory, with an emphasis on the interplay between mnemonic uncertainty, interference, and PFC-mediated control functions.

PFC anatomy and connectivity

This chapter will focus on the function of four main subregions within PFC that have been implicated in cognitive control: ventrolateral, dorsolateral, frontopolar, and medial PFC (figure 48.1). Ventrolateral PFC (VLPFC) corresponds to the inferior frontal gyrus, encompassing pars orbitalis (area 47/12 in Petrides & Pandya, 2002), pars triangularis (~Brodmann's area [BA] 45), and pars opercularis (~BA 44). Following Badre and Wagner (2007), we refer to pars orbitalis as anterior VLPFC and pars triangularis as mid-VLPFC (note that these two regions have been collectively termed mid-VLPFC by Petrides & Pandya, 2002) and to pars opercularis as posterior VLPFC. Dorsolateral PFC (DLPFC) refers to regions within the middle frontal gyrus (areas 8, 9/46, and 46; Petrides & Pandya, 1999). In humans, the ventral bound of this region is defined by the inferior frontal sulcus and the dorsal bound by the superior frontal sulcus. Frontopolar cortex (~BA 10) corresponds to the most rostral portion of PFC, including portions of middle frontal gyrus. The medial wall of PFC includes portions of BAs 8, 9, and 10 and the anterior cingulate cortex (ACC; BAs 24 and 32). Though anatomically distinct, lateral and medial PFC subregions have been shown to be interconnected both with each other and with more posterior regions of cortex, including medial and lateral temporal cortex and posterior parietal cortex (Petrides & Pandya, 1999, 2002, 2007).

Theories of cognitive control

BIASED COMPETITION A prominent theory of cognitive control proposes that top-down signals derived from PFC *bias* processing in posterior brain regions in accordance with current task demands (e.g., Cohen & Servan-Schreiber, 1992; Desimone & Duncan, 1995; Miller & Cohen, 2001).

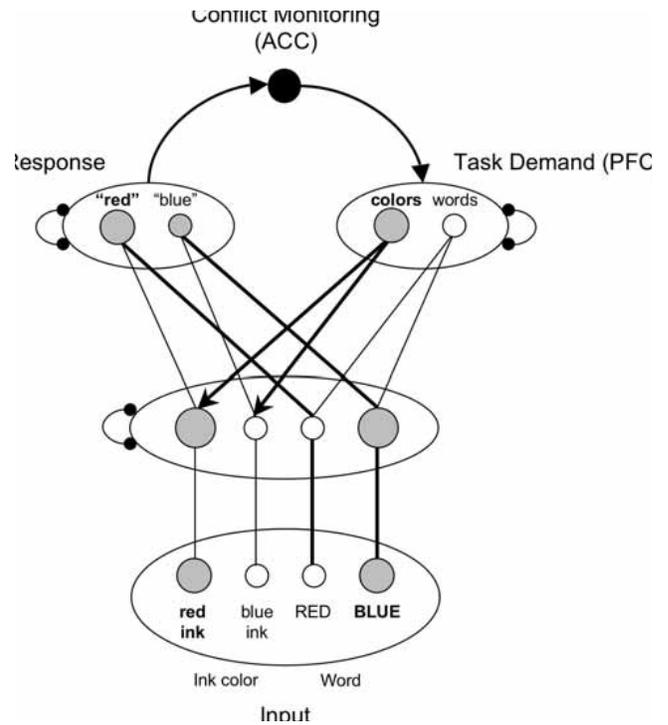

FIGURE 48.2 Model of PFC and anterior cingulate involvement during performance of the Stroop task. Circles represent processing units, which correspond to a population of neurons assumed to code a given piece of information. Lines represent connections between units, with heavier lines indicating stronger connections. Looped connections with black circles indicate mutual inhibition among units within that layer. In the Stroop task, subjects must name the ink color in which a word is presented, rather than read the word. The presentation of a conflict stimulus (the word “blue” displayed in red ink) activates (indicated by gray fill) input layer units representing “red ink” and the word “blue.” The “colors” task demand unit is activated in PFC (gray fill), representing the current goal to name the color of the ink, and passes activation to the intermediate units in the color-naming pathway (indicated by arrows), increasing the activation of those units and biasing processing in favor of activity flowing along the color-naming pathway. This bias favors activation of the response unit (“red”) corresponding to the color input (red ink), even though the connection weights in this pathway are weaker than in the word-reading pathway that would favor a response based on reading the word (“blue”). By computing the level of conflict (or the presence of simultaneously active representations in the response layer), ACC initially detects the need for this top-down bias from PFC. ACC, anterior cingulate cortex. (Adapted with permission from M. M. Botvinick, T. S. Braver, D. M. Barch, C. S. Carter, & J. D. Cohen, 2001. Conflict monitoring and cognitive control. *Psychol. Rev.*, 108, 624–652. Copyright 2001, American Psychological Association.)

Specifically, the maintenance of task-relevant contextual representations in PFC has been proposed to bias establishment of appropriate mappings between sensory inputs, internal states, and motor outputs. In the absence of cognitive control, behavior is driven in an automatic, bottom-up fashion by representations that are most strongly activated by input cues. However, when weakly established (but task-relevant) representations must be selected in the face of competition from stronger (but task-irrelevant) representations, PFC control signals are thought to bias the flow of information processing to enhance the strength of the relevant representations and overcome the task-irrelevant competitors (Cohen, Dunbar, & McLelland, 1990).

Illustrative of this putative bias mechanism, consider the Stroop paradigm, wherein subjects are presented color words in different ink colors and are asked to name the ink color (figure 48.2). Presentation of a word strongly elicits the prepotent response to read the word, because subjects have more experience reading words than naming the color of word print. Thus, if the ink color is incongruent with the color word (e.g., “BLUE” in red ink), a prepotent response (“blue”) must be overcome in favor of a weaker response (“red”). Biased competition theory proposes that lateral PFC represents the current task goal (e.g., name the ink color) and biases processing in color-naming pathways to favor the weaker but goal-relevant response (Cohen, Dunbar, & McClelland, 1990).

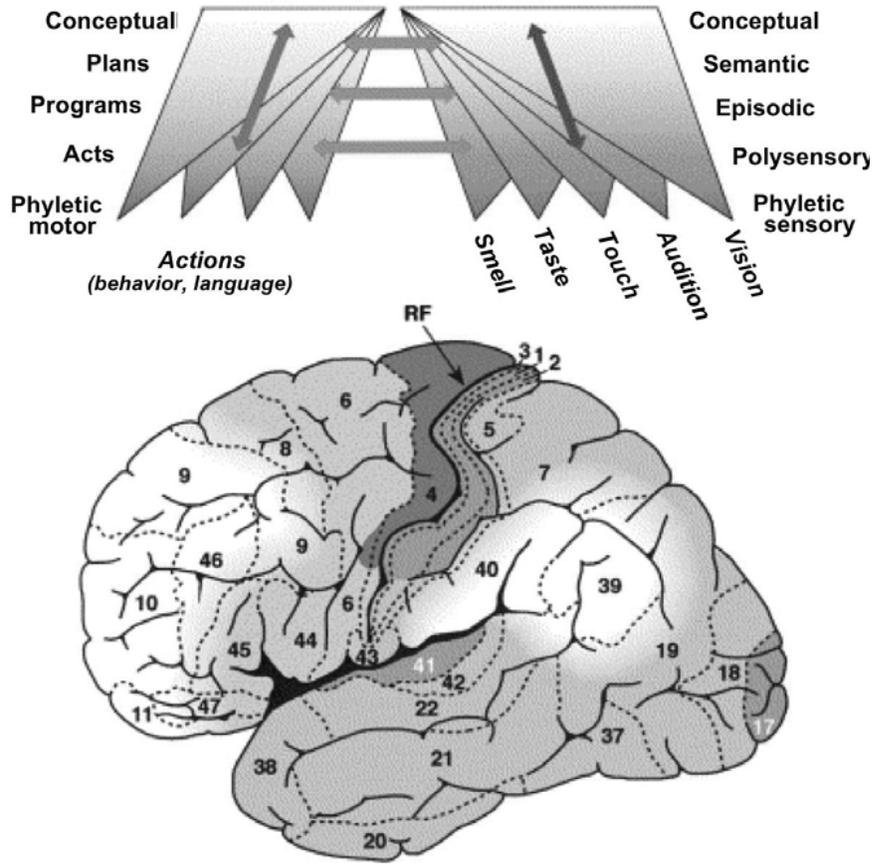

Importantly, top-down bias mechanisms have been argued to support a variety of functions, including working memory, selective attention, controlled retrieval from long-term memory, task switching, response inhibition, and response selection. While the biased competition theory proposes a central mechanism for cognitive control, there may be multiple types of control that differ in their form or domain. In the next sections, we describe several theories that focus on the functional architecture of control and its relationship to the organization of PFC.

THE DORSAL-VENTRAL HYPOTHESIS A complementary perspective on cognitive control suggests that dorsal and ventral regions of lateral PFC mediate dissociable, but interactive, forms of control (Petrides, 1994; Owen, Evans, & Petrides, 1996). In this view, control mechanisms supported by VLPFC and DLPFC operate over different loci or types of representations (Petrides, 1996). VLPFC mechanisms have been proposed to support controlled retrieval and selection of long-term knowledge stored in posterior cortices and the maintenance of these representations within working memory, while DLPFC mechanisms have been proposed to support the monitoring and manipulation of the representations retrieved and maintained by VLPFC (e.g., D’Esposito et al., 1998; Petrides, 2002).

Neuroimaging and lesion data support the proposal that DLPFC and VLPFC functionally differ. For example, lesions of mid-DLPFC (areas 9/46 and 46) produce impairments in the ability to order information in working memory (Petrides, 2000), and functional magnetic resonance imaging (fMRI) studies indicate that DLPFC activity increases during complex working memory tasks, such as when working memory loads are high (Rypma, Prabhakaran, Desmond, Glover, & Gabrieli, 1999), as well as when representations held in working memory must be reordered (D’Esposito, Postle, Ballard, & Lease, 1999; Postle, Berger, & D’Esposito, 1999; Wagner, Maril, Bjork, & Schacter, 2001) or updated (Salmon et al., 1996; Garavan, Ross, Li, & Stein, 2000). Similarly, within episodic retrieval tasks, DLPFC activation has often been associated with monitoring retrieved mnemonic information (e.g., Henson, Rugg, Shallice, & Dolan, 2000; Fletcher & Henson, 2001; Dobbins, Foley, Schacter, & Wagner, 2002; Rugg, Henson, & Robb, 2003; Achim & Lepage, 2005; Dobbins, Simons, & Schacter, 2004). In contrast, neuroimaging studies indicate that activity within VLPFC increases during the controlled retrieval and selection of information from long-term memory, as well as in the presence of mnemonic interference (Thompson-Schill, D’Esposito, Aguirre, & Farah, 1997; Jonides, Smith, Marschuetz, Koeppe, & Reuter-Lorenz, 1998; Bunge, Ochsner, Desmond, Glover, & Gabrieli, 2001; Badre & Wagner, 2002). We will further discuss VLPFC contributions to mnemonic control in the section on the interaction between control and memory.

ROSTROCAUDAL HIERARCHIES In addition to apparent dorsal/ventral dissociations, accumulating evidence suggests that hierarchically organized cognitive control processes map to a functional gradient along the rostrocaudal axis of lateral frontal cortex (Christoff & Gabrieli, 2000; Fuster, 2001; Koehlin, Ody, & Kouneiher, 2003; Wood & Grafman, 2003; Bunge & Zelazo, 2006; Koehlin & Jubault, 2006; Petrides, 2006; Badre & D’Esposito, 2007; Botvinick, 2007; Koehlin & Summerfield, 2007; Badre, 2008). More caudal regions of frontal cortex, inclusive of premotor cortex, are thought to control processing at “lower” levels of representation in the stimulus-action processing hierarchy, such as response selection (figure 48.3). Progressively more anterior regions of frontal cortex are proposed to support control mechanisms that operate upon increasingly “higher” levels of representation (Christoff & Gabrieli, 2000; Badre, 2008), including more abstract higher-order plans or complex schemas. Functional organization along the horizontal axis of lateral PFC has also been characterized as mediating cross-temporal contingencies between past, present, and future events, with caudal PFC mechanisms guiding behavior based upon the immediate context in

A **Executive memory** **Perceptual memory**

B

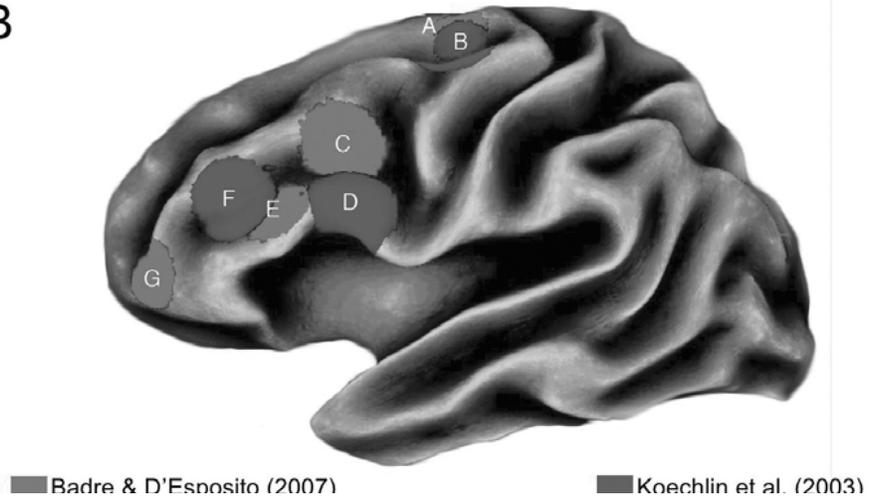

FIGURE 48.3 Hierarchical organization of cognitive representations in lateral cortex. (A) Schema of two hierarchies of cortical memory, executive memory, and perceptual memory, and the distribution of these hierarchies in frontal and posterior cortical regions, respectively. In frontal cortex, representations that are “higher” in the processing hierarchy are mapped to more rostral regions, and “lower”-level representations are mapped to more caudal regions. (Reprinted from J. M. Fuster, 2001, *The prefrontal cortex—An update: Time is of the essence*, *Neuron*, 30, 319–333. Copyright 2001, with permission from Elsevier.) (B) Neuroimaging data providing evidence for representational hierarchies in frontal

cortex. Spheres from Badre and D’Esposito (2007) (red) reflect foci of activation with experimental manipulations at different levels of representation: A, the response level; C, the feature level; E, the dimension level; G, the context level. Spheres from Koechlin, Ody, and Kouneiher (2003) (blue) reflect foci of activation with manipulations of different levels of control: B, sensory control; D, contextual control; F, episodic control. (Adapted with permission from D. Badre & M. D’Esposito, 2007, *Functional magnetic resonance imaging evidence for a hierarchical organization of the prefrontal cortex*, *J. Cogn. Neurosci.*, 19, 2082–2099. Copyright 2007, with permission from the MIT Press.) (See color plate 60.)

which a stimulus occurs and more rostral PFC regions processing information that is successively more remote in time (Fuster, 2001; Braver, Reynolds, & Donaldson, 2003; Koechlin et al., 2003; Koechlin & Summerfield, 2007).

With its location at the most rostral extent of PFC, frontopolar cortex (FPC; ~BA 10; figure 48.1) may be positioned at the apex of the putative control hierarchy (Koechlin & Summerfield, 2007). While the precise functions of FPC remain to be determined, neuroimaging studies have consistently observed FPC activation during higher-level cognitive tasks, complex working memory tasks, and episodic retrieval (Fletcher & Henson, 2001; Ramnani & Owen, 2004). For example, FPC is recruited when previously selected goals or task-relevant information must be maintained in a pending state until ongoing subtasks are executed (Koechlin, Basso, Pietrini, Panzer, & Grafman, 1999; Braver & Bongiolatti, 2002; Badre & Wagner, 2004; Koechlin & Hyafil, 2007). Similarly, FPC has been associated with higher-order functions such as integrating across multiple sources of information (Christoff et al., 2001; Bunge, Wendelken, Badre, & Wagner, 2004; Ramnani & Owen, 2004; Green, Fugelsang, Kraemer, Shamos, & Dunbar, 2006; De Pisapia, Slomski, & Braver, 2007) or evaluating the products of internally generated information (Christoff, Ream, Geddes, & Gabrieli, 2003).

REGULATION OF CONTROL While control mechanisms supported by lateral PFC are thought to drive goal-relevant behavior, equally important are the mechanisms through which control is regulated. Substantial evidence indicates that regions within medial PFC, including the anterior cingulate cortex, serve this modulatory role (but see Fellows & Farah, 2005). Specifically, ACC computations have been alternately proposed to detect the presence of conflict (Botvinick, Cohen, & Carter, 2004; Kerns et al., 2004; MacDonald, Cohen, Stenger, & Carter, 2000), error likelihood (Brown & Braver, 2005), or uncertainty (Walton, Devlin, & Rushworth, 2004), and to signal lateral PFC mechanisms to increase top-down biasing of task-appropriate representations. For example, ACC may detect the presence of simultaneously active, competing representations (such as conflicting responses elicited by incongruent trials in the

Stroop paradigm) and provide feedback signals to lateral PFC that up-regulate control (figure 48.2). Consistent with this proposal, imaging studies have documented functional coactivation of ACC and lateral PFC under situations of response and mnemonic conflict (e.g., Bunge, Burrows, & Wagner, 2004; Badre & Wagner, 2004; Kerns et al., 2004; Kuhl, Dudukovic, Kahn, & Wagner, 2007).

The basal ganglia (BG) have also been implicated in regulating PFC-mediated control processes. For example, in situations of response inhibition it has been argued that the subthalamic nucleus (a component of the BG) interacts with right VLPFC and preSMA such that initiated motor responses can be terminated (Aron & Poldrack, 2006; Aron et al., 2007). It has been argued, through computational models, that PFC-BG interactions also support cognitive operations, such as working memory performance (O’Reilly & Frank, 2006; Hazy, Frank, & O’Reilly, 2007). Specifically, this work has suggested that the BG gate PFC processing depending on task demands, with BG “learning” which PFC mechanisms to gate through dopamine-mediated reinforcement learning. This hypothesis has received support from recent evidence that PFC-BG interactions support working memory performance and that BG activation prior to the onset of working memory trials is predictive of the extent to which task-irrelevant information is successfully gated, or denied processing (McNab & Klingberg, 2008).

Interactions between control and memory

Having surveyed leading theories of how PFC implements cognitive control, we now consider the manner in which prefrontal control interacts with mnemonic operations. However, because there are numerous examples of such interactions across multiple forms and stages of memory and involving multiple PFC subregions (for reviews see Fletcher & Henson, 2001; Wagner, 2002; Buckner, 2003; Simons & Spiers, 2003), we restrict our focus to two examples of PFC involvement in mnemonic processing. Specifically, we consider how VLPFC mechanisms contribute to performance (1) when memory representations interfere with each other and (2) when ineffective retrieval cues yield uncertainty.

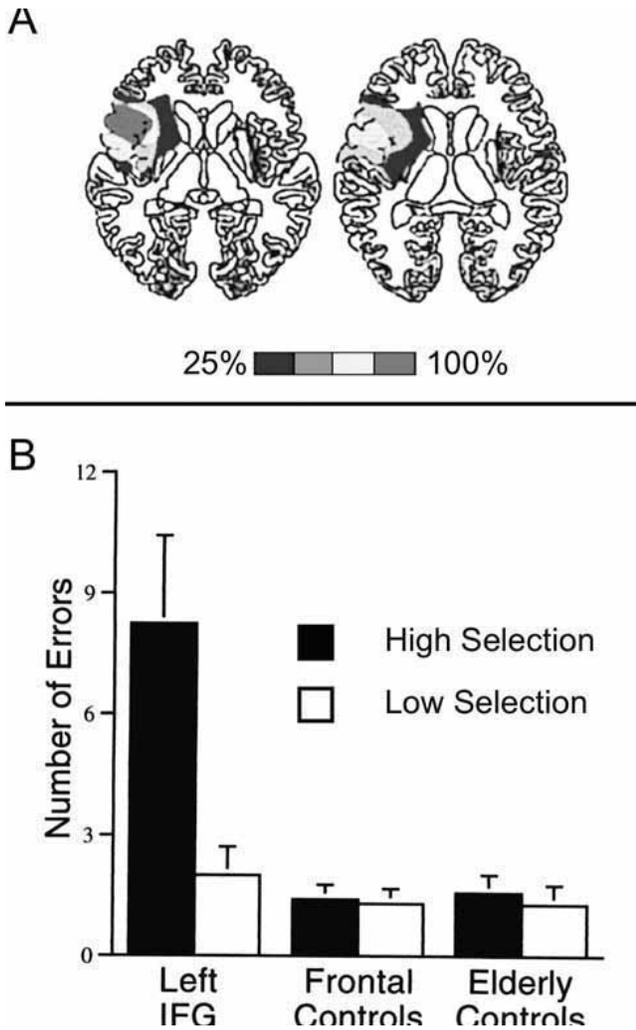

FIGURE 48.4 Damage to mid- and posterior VLPFC in humans impairs the ability to select relevant semantic information under high-selection demands. (A) Location of PFC lesions in patients with selection deficits on a verb-generation task. Scale represents amount of lesion overlap across patient group. (B) Mean number of errors in a task requiring subjects to generate semantically appropriate verbs for concrete nouns under high-selection demands (filled bars) versus low-selection demands (unfilled bars). Nouns in the high-selection group had a lower response-strength ratio (ratio of the relative response frequency of the most common completion to the relative response frequency of the second most common completion) than did nouns in the low-selection condition. Subject groups were composed of patients with lesions restricted to left inferior frontal gyrus (left IFG group), patients with frontal lesions outside of left IFG (frontal controls), and healthy older adults (elderly controls). (Adapted with permission from S. L. Thompson-Schill, D. Swick, M. J. Farah, M. D'Esposito, I. P. Kan, & R. T. Knight, 1998, Verb generation in patients with focal frontal lesions: A neuropsychological test of neuroimaging findings, *Proc. Natl. Acad. Sci. USA*, 95, 15855–15860. Copyright 1999, with permission from National Academy of Sciences, U.S.A.)

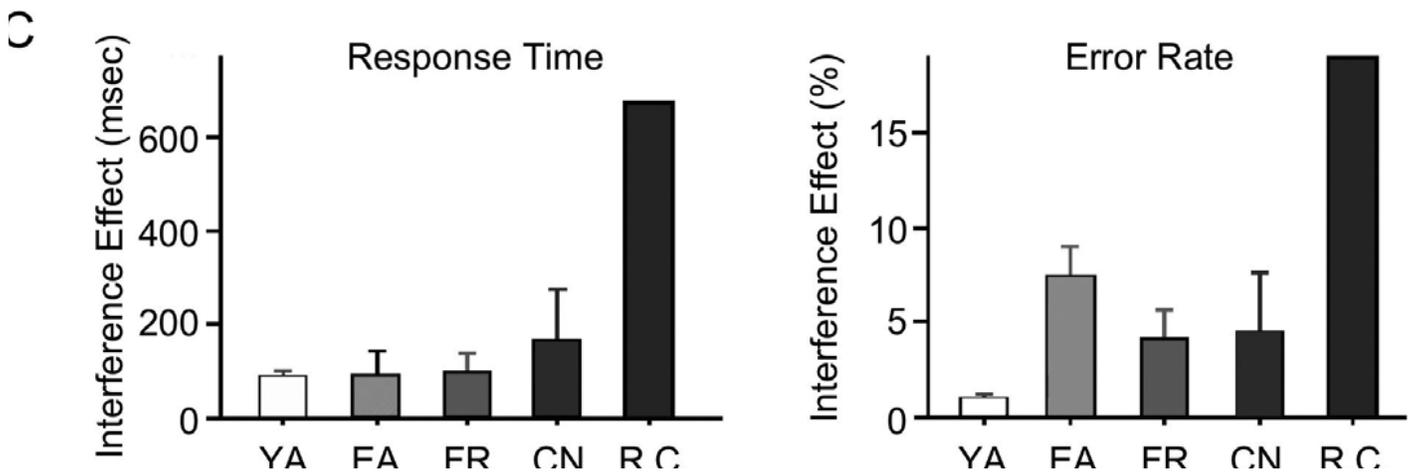

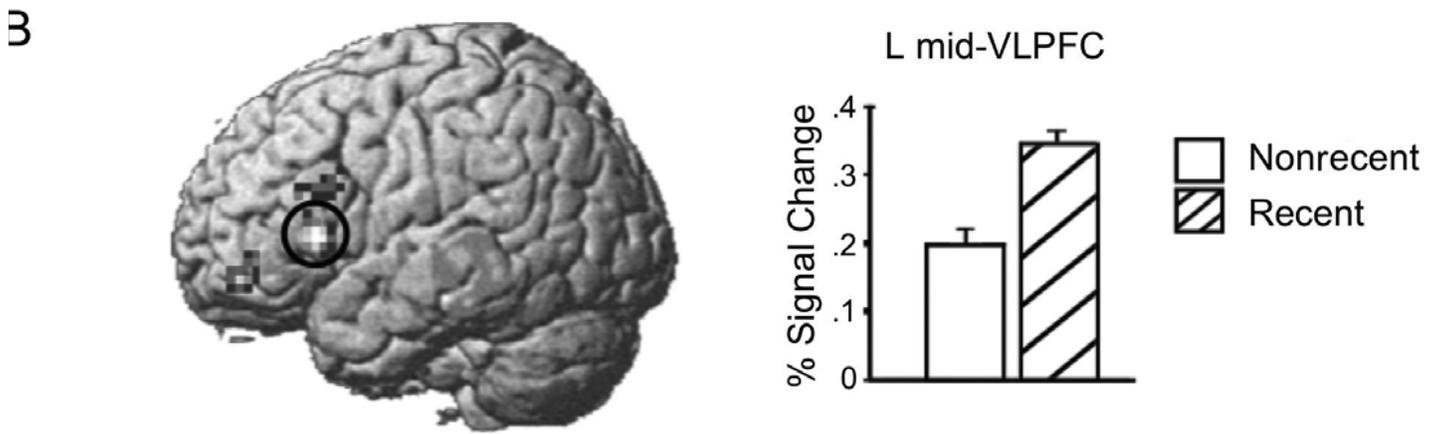

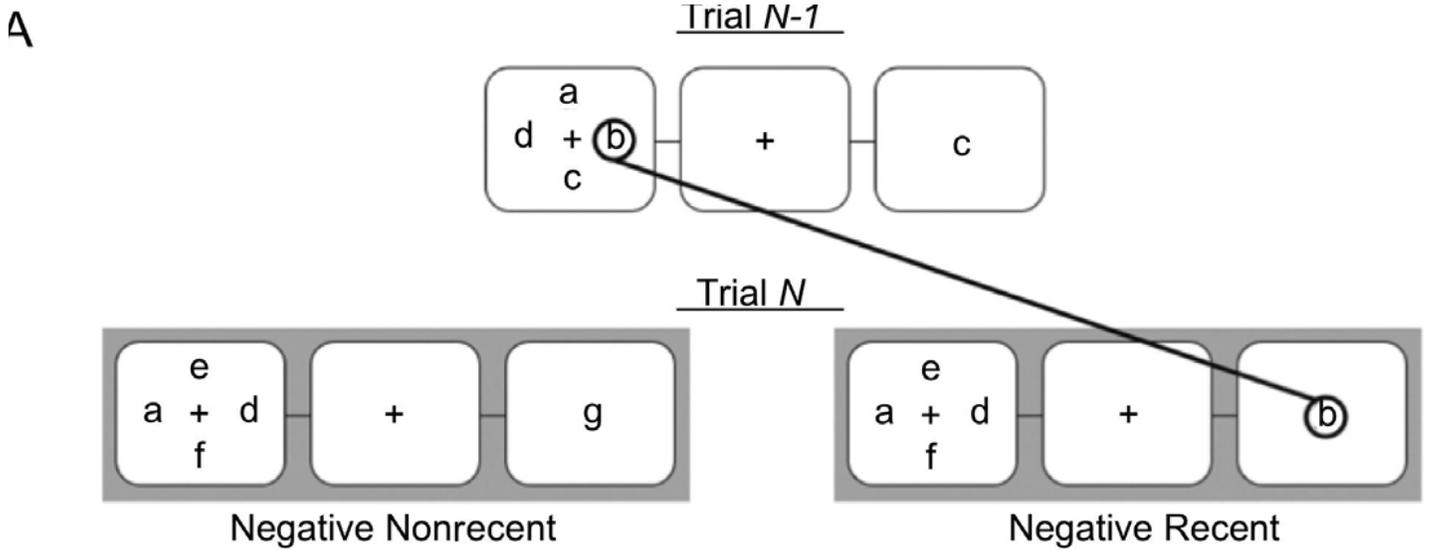

INTERFERENCE Interference refers to the processing costs that arise when irrelevant representations compete with goal-relevant representations. For example, when making a trip to the grocery store to purchase a handful of items, one

may find that remembering the items of interest becomes remarkably difficult while actually walking down the grocery store aisles, owing to the salience of countless products that are *not* the items of interest. Overcoming interference requires a mechanism that selects relevant representations from the set of all active representations. Evidence accumulated across semantic memory, working memory, and episodic memory paradigms has led to the hypothesis that left mid-VLPFC, in particular, supports a *selection* mechanism that plays a fundamental role in resolving mnemonic interference (for review see Badre & Wagner, 2007).

The selection hypothesis of VLPFC function was originally formulated within the context of semantic retrieval. In a seminal paper, Thompson-Schill and colleagues demonstrated that left mid- and posterior VLPFC are engaged to

FIGURE 48.5 Evidence for left mid-VLPFC involvement in resolving interference during the Sternberg working memory task. (A) The interference variant of the Sternberg working memory paradigm in which subjects maintain a set of four letters in working memory until a probe letter appears, at which point they indicate whether the probe is a member of the currently maintained set (positive probe) or is not a member of the currently relevant set (negative probe). Interference occurs when a negative probe is a member of the immediately preceding set (negative recent) relative to a negative probe that is not a member of the immediately preceding set (negative nonrecent). (B) Greater activation in left mid-VLPFC (circled), as measured by fMRI, occurs during negative recent (hatched bar) compared to negative nonrecent trials (unfilled bar), reflecting greater recruitment of left mid-VLPFC in the presence of interference in working memory. (A and B adapted from D. Badre & A. D. Wagner, 2005, Frontal lobe mechanisms that resolve proactive interference, *Cereb. Cortex*,

15, 2003–2012. Copyright 2005, with permission from Oxford University Press.) (C) Damage to left middle and inferior frontal gyri in patient R.C. impairs the ability to successfully reject negative recent probes. Patient R.C., a 51-year-old male with a significant lesion in left middle and inferior frontal gyri, showed a pronounced interference effect in both response times (left panel) and accuracy (right panel) compared to four control groups: control subjects that were matched in age and education to R.C. (Controls: CN); frontal patients with damage outside of left mid-VLPFC (Frontal Patients: FR); older adults matched in age and education to the frontal patient group (Elderly: EA); and a group of young adults (Young: YA). (Adapted with permission from S. L. Thompson-Schill, J. Jonides, C. Marshuetz, E. E. Smith, M. D'Esposito, I. P. Kan, R. T. Knight, & D. Swick, 2002, Effects of frontal lobe damage on interference effects in working memory, *Cogn. Affective Behav. Neurosci.*, 2, 109–120. Copyright 2002, with permission from Psychonomic Society, Inc.)

the extent that semantic decisions require selecting goal-relevant information in the face of competition (Thompson-Schill et al., 1997). For example, in one task subjects were shown nouns and required to generate semantically related verbs; critically, some of the nouns were associated with a dominant verb (e.g., “scissors” strongly elicits “cut”; a low-selection situation), whereas other nouns were associated with multiple verbs (e.g., “wheel” may elicit “turn,” “steer,” and “drive”; a high-selection situation). Functional MRI revealed greater left mid- and posterior VLPFC activation during generation under high- relative to low-selection demands (for related findings, see Thompson-Schill, D’Esposito, & Kan, 1999; Badre, Poldrack, Paré-Blagoev, Insler, & Wagner, 2005). Subsequent work demonstrated that damage to left mid- and posterior VLPFC in humans impairs the ability to select relevant semantic representations—specifically when competition is present—establishing the necessity of this region for resolving semantic interference (figure 48.4; Thompson-Schill et al., 1998).

Additional evidence for the role of left mid-VLPFC in resolving interference comes from studies using the interference variant of the Sternberg working memory paradigm (figure 48.5). In this paradigm, each trial requires the encoding and maintenance of a set of stimuli in working memory and determination of whether a subsequently presented test probe is or is not a member of the currently maintained set (trial N). Interference occurs when the test probe is not a member of the currently maintained set but was a member of the previously maintained set (trial $N - 1$)—“negative recent” probes. The now classic finding is that “negative recent” probes elicit greater activation in left mid-VLPFC than do “negative nonrecent” probes—trials requiring the same decision but without interference (figure 48.5; e.g., Jonides et al., 1998; D’Esposito, Postle, Jonides, & Smith, 1999; Bunge et al., 2001; Badre & Wagner, 2005; Nee, Jonides, & Berman, 2007). Moreover, the ability to successfully reject negative recent probes is compromised by left mid-VLPFC damage (Thompson-Schill et al., 2002; figure 48.5) or disruption by means of transcranial magnetic stimulation (Feredoes, Tononi, & Postle, 2006). Mechanistically, it has been argued that rejecting negative recent probes engages left mid-VLPFC because accurate task performance requires identifying (selecting) the relevant context for the familiar negative probe (i.e., that it appeared in the last trial) so that it can be appropriately rejected (Badre & Wagner, 2005; for alternative interpretations, see Jonides & Nee, 2006).

Within the domain of episodic memory, selection to overcome interference likely plays a role during both encoding and retrieval. In a classic PET study, Dolan and Fletcher (1997) measured neural responses during the encoding of word pairs, manipulating the extent to which prior learning interfered with current encoding (i.e., *proactive interference*).

Specifically, subjects first studied a list of word pairs (e.g., “DOG-BOXER”); next, a second list of word pairs was studied, containing either repeated pairs, completely novel pairs, or pairs that partially overlapped with previously studied pairs (e.g., “SPORTSMAN-BOXER”—the proactive interference condition). Dolan and Fletcher observed that left lateral PFC, inclusive of left mid-VLPFC, was highly sensitive to the presence of interference, as this region was differentially engaged when subjects were encoding word pairs that overlapped with previously studied pairs. Additional findings relating left mid-VLPFC to the resolution of proactive interference have been reported in more recent fMRI studies of episodic encoding (Fletcher, Shallice, & Dolan, 2000; Henson, Shallice, Josephs, & Dolan, 2002), complementing neuropsychological observations that damage to lateral PFC results in an increased susceptibility to proactive interference (e.g., Shimamura, Jurica, Mangels, Gershberg, & Knight, 1995; Smith, Leonard, Crane, & Milner, 1995). It has been argued that, during episodic encoding, left mid-VLPFC-mediated selection may allow for relevant semantic associations between word pairs to be favored in the face of interference from previously learned, irrelevant associations (Henson et al., 2002).

Left mid-VLPFC engagement has also been observed during episodic retrieval situations that are well characterized as requiring selection. For example, with an increase in the number of competing associates that interfere with retrieval of a target associate, left lateral PFC, inclusive of left mid-VLPFC, displays a corresponding increase in retrieval-related activation (Sohn, Goode, Stenger, Carter, & Anderson, 2003; Sohn et al., 2005; Danker, Gunn, & Anderson, 2008). Likewise, when a retrieval task involves recollecting a specific detail of an encoding event over other possible event details (e.g., as in source memory tasks), left mid-VLPFC, among other regions, is engaged (e.g., Nolde, Johnson, & D’Esposito, 1998; Dobbins et al., 2002; Cabeza, Locantore, & Anderson, 2003; Dobbins & Wagner, 2005; Lundstrom, Ingvar, & Petersson, 2005). Importantly, left mid-VLPFC is distinguished from other lateral PFC regions engaged during source retrieval in that it supports source recollection in a domain-general manner (Dobbins & Wagner, 2005). These data complement neuropsychological observations that patients with lateral PFC damage are particularly impaired at attributing retrieved information to its relevant source (Janowsky, Shimamura, & Squire, 1989).

In summary, extant data provide strong support for the hypothesis that left mid-VLPFC mediates the resolution of interference by selecting goal-relevant representations in the face of competition from irrelevant representations. While we have focused on the role of selection in working-memory, semantic-retrieval, and episodic-memory paradigms, it is worth noting that mid-VLPFC selection has also been asso-

ciated with overcoming proactive interference during task switching (Badre & Wagner, 2006). As such, this selection mechanism does not appear to support retrieval, per se (Thompson-Schill et al., 1997); rather, selection likely operates postretrieval such that goal-relevant representations can be favored over goal-irrelevant representations (Badre & Wagner, 2007).

UNCERTAINTY While left mid-VLPFC (~BA 45) is thought to support selection between activated representations, a central question is whether there are additional PFC mechanisms that support the top-down activation of representations under other situations of uncertainty. Here we define uncertainty as the situation in which goal-relevant representations are not automatically activated because of ineffective triggering cues. Under such situations, strategic activation, or *controlled retrieval*, of goal-relevant representations is required to recover relevant knowledge (Wagner, Paré-Blagoev, Clark, & Poldrack, 2001; Badre & Wagner, 2002; Badre et al., 2005; Badre & Wagner, 2007). Extant data indicate that anterior VLPFC (area 47/12) mediates controlled retrieval, with the left homologue differentially supporting such retrieval from semantic memory and the right homologue from visual associative memory.

Evidence for the distinction between selection and controlled retrieval comes from an fMRI study that varied demands on each of these putative control processes (Badre et al., 2005). In that study, controlled retrieval demands were manipulated by varying the strength of the semantic association between a cue and target in a task in which subjects were required to identify semantic associates (targets) of particular cues. For example, identifying the semantic relationship between strongly associated nouns such as “candle” and “flame” places low demands on controlled retrieval, relative to weakly associated nouns such as “candle” and “halo.” The difference in controlled retrieval demands is due to the fact that “candle” is more likely to generate bottom-up activation of the associated concept “flame,” thereby facilitating identification of a semantic relationship; “candle,” however, is less likely to elicit bottom-up activation of weakly associated concepts such as “halo,” meaning that identification of a semantic relationship between these stimuli requires top-down semantic search. Within this same decision task, selection demands were independently manipulated by varying the extent to which irrelevant semantic information was likely to interfere (e.g., by including distracters that were either strongly or weakly interfering). Consistent with the selection literature, Badre and colleagues (2005) reported increases in left mid-VLPFC activity as selection demands increased (figure 48.6). In contrast, increases in controlled retrieval demands were associated with increased engagement of left anterior VLPFC and middle temporal cortex—regions that were not modulated by selection (see also

Wagner, Paré-Blagoev, et al., 2001). The coactivation of left anterior VLPFC and middle temporal cortex suggests a frontal-temporal interaction in which left anterior VLPFC provides a top-down bias that activates semantic representations stored in temporal cortex.

Functional dissociations between left mid-VLPFC and left anterior VLPFC have also been observed in the context of short-term semantic priming (Gold et al., 2006) and episodic retrieval (Danker et al., 2008). For example, Gold and colleagues (2006) used a lexical decision priming task to identify regions in which neural processing demands were (1) decreased with the presentation of semantically related primes and (2) increased with the presentation of semantically unrelated (interfering) primes. These two situations provide a compelling parallel between the controlled retrieval and selection distinction explored by Badre and colleagues (2005). For example, when a “related” semantic prime is presented (e.g., “SPOON” as a prime for the target “FORK”), the prime should elicit bottom-up semantic activation that reduces the demand for *controlled retrieval* once the target appears (i.e., the prime has already activated the relevant semantic information). On the other hand, “unrelated” semantic primes (e.g., “SPOON” as a prime for “COAT”) elicit activation of irrelevant semantic information that may interfere with access to target-related information, thus requiring subsequent *selection* of relevant target-related information in the face of irrelevant information. Strikingly, the presentation of “related” primes resulted in reduced engagement of left anterior VLPFC and middle temporal cortex, presumably because of reduced controlled retrieval demands, relative to a neutral prime control condition. In contrast, the increased selection demands associated with “unrelated” primes resulted in increased engagement of left mid-VLPFC, relative to the neutral prime condition. Paralleling these findings, Danker, Gunn, and Anderson (2008) observed that left mid-VLPFC and anterior VLPFC functionally dissociate during episodic retrieval, with the former being sensitive to mnemonic competition (fan size) and associative memory strength and the latter being selectively sensitive to associative memory strength.

Together, these studies of semantic retrieval (Badre et al., 2005; Gold et al., 2006) and episodic retrieval (Danker, Gunn, & Anderson, 2008; see also Dobbins & Wagner, 2005) provide compelling evidence for a dissociation between a selection mechanism supported by left mid-VLPFC and a controlled retrieval mechanism supported by left anterior VLPFC that interacts with middle temporal cortex. The argument that left anterior VLPFC, in particular, supports controlled semantic retrieval is also supported by evidence that neural disruption (by means of transcranial magnetic stimulation) of left anterior VLPFC, but not left posterior VLPFC, interferes with semantic—but not phonological—processing (Gough, Nobre, & Devlin, 2005).

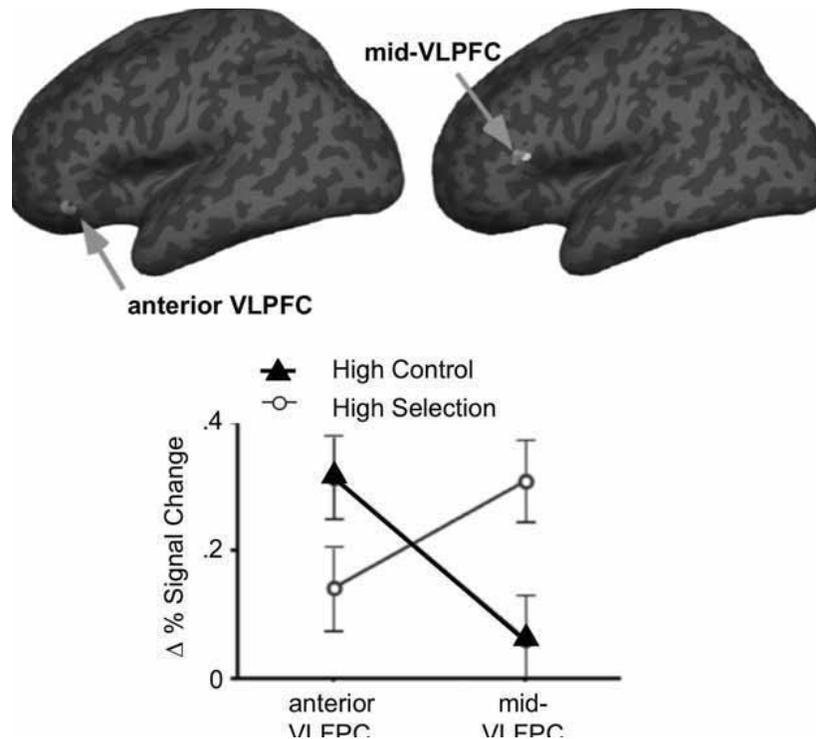

FIGURE 48.6 Left ventrolateral PFC is differentially engaged during controlled retrieval and selection from semantic memory. During a semantic decision task, participants were presented with target words beneath a cue word. On each trial, participants determined which of the target words was semantically related to the cue. Selection demands were manipulated by varying the task requirements for each trial (either a global relatedness judgment or a more specific feature similarity judgment that entailed higher selection demands) and by varying the extent to which irrelevant semantic information was likely to interfere with the decision (i. e., the distracter could be a preexperimental associate of the cue, but not along the relevant dimension). Controlled retrieval demands were manipulated by varying the strength of the association

between a cue and the correct target. Greater controlled retrieval is necessary under conditions of weak cue-target associative strength because of diminished bottom-up activation of relevant knowledge. The top panel shows the location of anterior VLPFC and mid-VLPFC regions of interest. The fMRI data from these regions of interest (bottom panel) reveal a crossover interaction wherein anterior VLPFC displays greater activity with high control demands than with high selection demands, and mid-VLPFC displays greater activity with high selection demands than with high control demands. (Adapted from D. Badre & A. D. Wagner, 2007, *Left ventrolateral prefrontal cortex and the cognitive control of memory, Neuropsychologia, 45*, 2883–2901. Copyright 2007, with permission from Elsevier.)

It should be noted, however, that controlled retrieval does not render selection unnecessary. That is, the combination of automatic and controlled semantic retrieval may result in the activation of multiple representations, from which a subset must be selected. Indeed, Badre and colleagues (2005) describe conditions in which both selection and controlled retrieval demands were high, and these situations engaged both left anterior VLPFC and left mid-VLPFC (see also Danker et al.). Thus, while distinct VLPFC subregions appear to support dissociable forms of cognitive control, these functionally separable regions may act in concert when automatic retrieval is insufficient to arrive at mnemonic goals (Kostopoulos & Petrides, 2003, 2008). Moreover, given the dorsal-ventral hypothesis of prefrontal contributions to cognitive control, it is worth noting that PFC correlates of controlled retrieval and selection have been concentrated in VLPFC, rather than DLPFC, subregions.

Decreased PFC demands through mnemonic suppression and prediction

Thus far, we have described how the recruitment of PFC control processes facilitates achievement of current mnemonic goals. In this final section, we consider how past experience can favor goal-appropriate representations and reduce future demands on cognitive control. We describe evidence for modulation of control by (1) prior acts of selection that strengthen relevant memories and weaken interfering memories, and (2) experience-dependent plasticity that strengthens memory-based predictions to reduce uncertainty at multiple levels of processing between stimulus input and response output.

REDUCED INTERFERENCE Although the presence of competition during retrieval may require PFC mechanisms

that implement interference resolution (e.g., Thompson-Schill et al., 1997; Sohn et al., 2003; Dobbins & Wagner, 2005; Sohn et al., 2005), demands on PFC control mechanisms often change with experience. For example, memories that are repeatedly selected during retrieval accrue a competitive advantage over other memories that are selected against. This advantage stems from both the strengthening of selected memories (e.g., Roediger & Karpicke, 2006) and the weakening of interfering, selected-against memories (M. Anderson, 2003). These adaptive changes in memory strength are thought to “benefit” future processing by favoring memories that are likely to be relevant in the future (J. Anderson, 2007) and reducing interference from memories that are likely to remain irrelevant. Indeed, general support for the processing benefits associated with prior acts of selection comes from fMRI observations of reduced lateral PFC engagement across repeated acts of episodic retrieval relative to initial acts (e.g., Henson et al., 2002; Law et al., 2005). Moreover, electrophysiological evidence indicates that the engagement of PFC during initial selective retrieval is predictive of later forgetting (weakening) of interfering memories, suggesting that reductions in interference occur as a result of prior PFC-mediated mnemonic selection (Johansson, Aslan, Bäuml, Gabel, & Mecklinger, 2007).

Building on these observations, a recent fMRI study examined whether the PFC control mechanisms that support initial mnemonic selection also “benefit”—in terms of reduced subsequent processing demands—from the weakening of interfering memories (Kuhl et al., 2007). At a behavioral level, Kuhl and colleagues (2007) observed that repeated selective retrieval of target memories elicits forgetting of interfering memories, replicating prior observations of retrieval-induced forgetting (M. Anderson, Bjork, & Bjork, 1994; Levy & Anderson, 2002). Critically, when this behavioral effect was related to functional activation during the repeated acts of selective retrieval, the data revealed that the extent to which interfering memories were forgotten was tightly correlated with PFC processing benefits that occurred across the repeated acts of selective retrieval. Specifically, ACC and right anterior VLPFC displayed robust decreases in engagement during future target memory remembering to the extent that interfering memories were forgotten (figure 48.7).

While Kuhl and colleagues’ (2007) data reveal the neural processing benefits of mnemonic filtering (for related findings, see M. Anderson et al., 2004; Depue, Curran, & Banich, 2007), it is important to emphasize that these benefits are obtained only when one’s memory goals remain constant. By contrast, when previously interfering and selected-against memories later become goal-relevant, the weakening that these memories suffered results in *increased* demands on ACC

and right anterior VLPFC processes during their subsequent retrieval (Kuhl, Kahn, Dudukovic, & Wagner, 2008). This dynamic interplay between cognitive control and memory highlights how experience-dependent changes in memory strength and mnemonic competition yield cognitive control benefits and costs, as evidenced by decreasing and increasing demands on PFC control mechanisms during future acts of remembering.

REDUCED UNCERTAINTY Experience-dependent learning also reduces demands on PFC-mediated control by decreasing uncertainty associated with previously encountered stimuli. Illustrative of this point is the phenomenon of *repetition priming*, a form of nondeclarative (or implicit) memory that is expressed behaviorally as faster reaction times, increased response accuracy, or otherwise biased responding when stimuli are repeatedly processed (Tulving & Schacter, 1990; Roediger & McDermott, 1993). For example, stimulus classification decisions—for example, “Is a horse animate?”—are speeded with repetition, reflecting the behavioral benefits of previous stimulus processing. At the neural level, cortical regions that are active during initial stimulus processing frequently show reduced responses during subsequent stimulus processing (e.g., Raichle et al., 1994; Gabrieli et al., 1996; Schacter & Buckner, 1998; Wiggs & Martin, 1998; Henson, 2003)—a phenomenon that has been referred to as *repetition suppression*, *neural priming*, or *fMRI adaptation*. For example, stimulus repetition in the visual domain is associated with reduced activation in visual cortical areas, as expressed in reduced neural firing rates (Desimone, 1996) and reduced PET/fMRI activation (Wiggs & Martin, 1998; Wagner & Koutstaal, 2002). These neural activation reductions are generally thought to reflect computational savings or more efficient processing in neural networks supporting stimulus perception.

While perceptual priming facilitates processing in sensory cortical regions, other forms of priming are associated with repetition suppression in lateral PFC. In particular, *conceptual priming*—implicit memory at the level of semantic or conceptual information—is typically associated with activation reductions in left-lateralized frontotemporal regions (figure 48.8A), including left VLPFC and regions within inferior and lateral temporal cortex (Demb et al., 1995; Wagner, Desmond, Demb, Glover, & Gabrieli, 1997; Buckner et al., 1998; Gabrieli et al., 1996). Conceptual priming is dissociable from perceptual priming in that conceptual priming is invariant to changes in perceptual input across repetitions (e.g., priming will occur across stimulus modality changes such as auditory to visual), whereas perceptual priming occurs to the extent that there is perceptual overlap across repetitions (e.g., words appearing in the same font or same modality) (Roediger & McDermott,

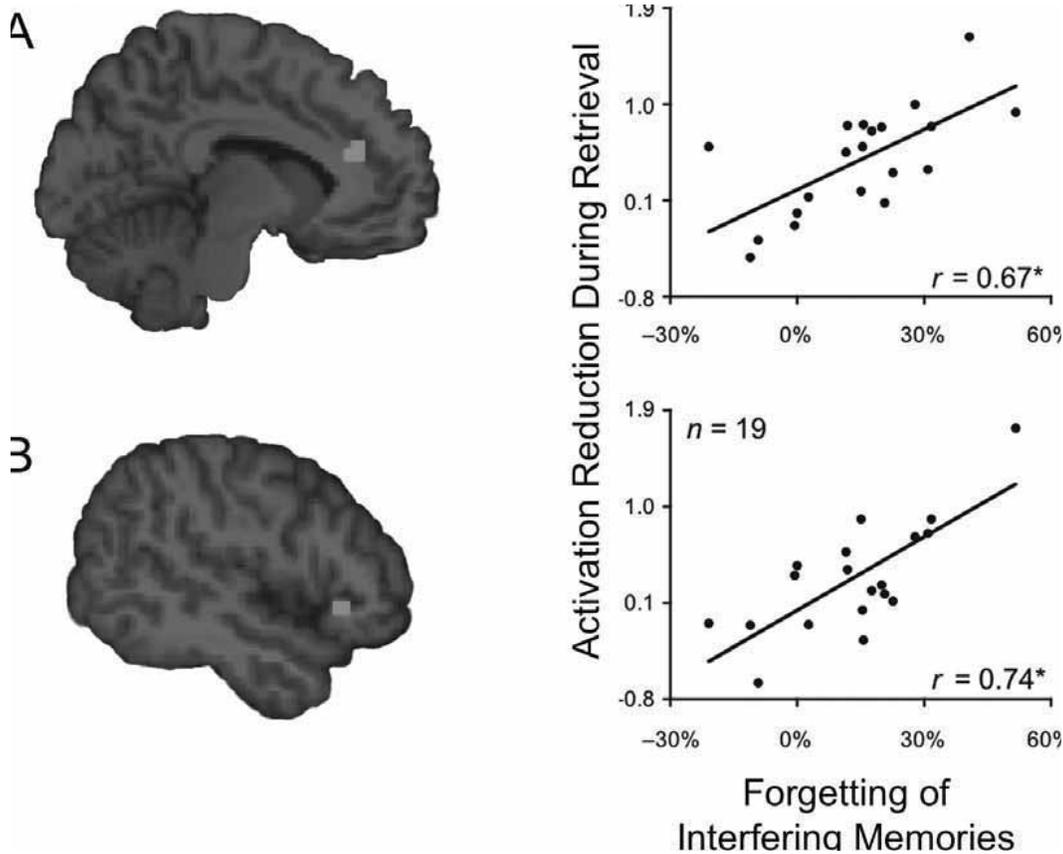

FIGURE 48.7 Demands on PFC control mechanisms that support initial mnemonic selection are reduced with the weakening of interfering memories. During repeated, selective retrieval of goal-relevant memories, fMRI activation reductions in (A) ACC and (B) right anterior VLPFC were correlated with the behavioral evidence that interfering memories were later forgotten, suggesting that pro-

cessing demands on these regions were reduced to the extent that irrelevant memories were forgotten. (Adapted from B. A. Kuhl, N. M. Dudukovic, I. Kahn, & A. D. Wagner, 2007, Decreased demands on cognitive control reveal the neural processing benefits of forgetting. *Nat. Neurosci.*, 10, 908–914. Copyright 2007, reprinted by permission from Macmillan Publishers, Ltd.)

1993; Badgaiyan, Schacter, & Alpert, 2001; Carlesimo et al., 2003).

Although the repetition suppression in left VLPFC and lateral temporal cortex that accompanies conceptual priming is consistent with the hypothesis that these regions interact during controlled retrieval of semantic information (Badre et al., 2005; Gold et al., 2006), at present there is debate regarding the processes underlying repetition suppression in these cortical areas. The dominant, or traditional, view is that representations in cortical regions that store conceptual information are “tuned” with experience, such that previously accessed information is more effectively activated during future processing (Wiggs & Martin, 1998; Grill-Spector, Henson, & Martin, 2006; figure 48.8). Several mechanisms have been proposed to support such cortical “tuning” within a population of neurons, including reductions in overall activation (fatigue model), a reduction in the number of responsive neurons (sharpening model), and faster processing or settling time (facilitation model). Viewed in this light, left VLPFC reduc-

tions in conceptual priming tasks may reflect reduced control demands owing to increased availability of item-related knowledge.

By contrast, an alternative—though not mutually exclusive—account of repetition suppression in VLPFC is that prior processing of a stimulus results in “stimulus-response” learning that facilitates subsequent mappings between the stimulus and a decision or response (Dobbins, Schnyer, Verfaellie, & Schacter, 2004; Schacter, Dobbins, & Schnyer, 2004). For example, when repeatedly asked, “Is a horse animate?” subsequent performance can be facilitated by direct retrieval of a learned association between the “stimulus” with the relevant “response” (“yes”). Thus, while the retrieval of response information previously associated with a stimulus does not reflect facilitated conceptual processing (rather, it may enable the bypassing of controlled semantic retrieval), “stimulus-response” learning may nonetheless reduce demands on PFC control mechanisms that support decision or response selection (Schacter et al., 2004; Schacter, Wig, & Stevens, 2007).

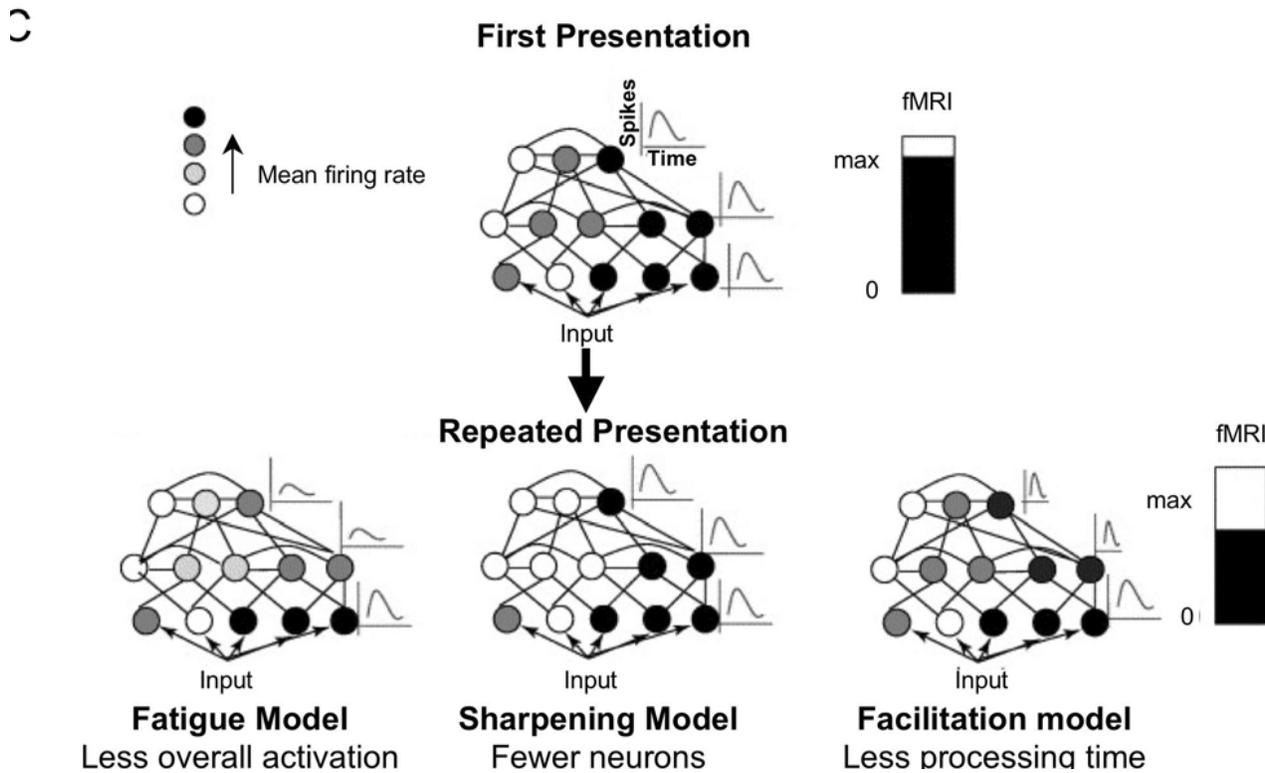

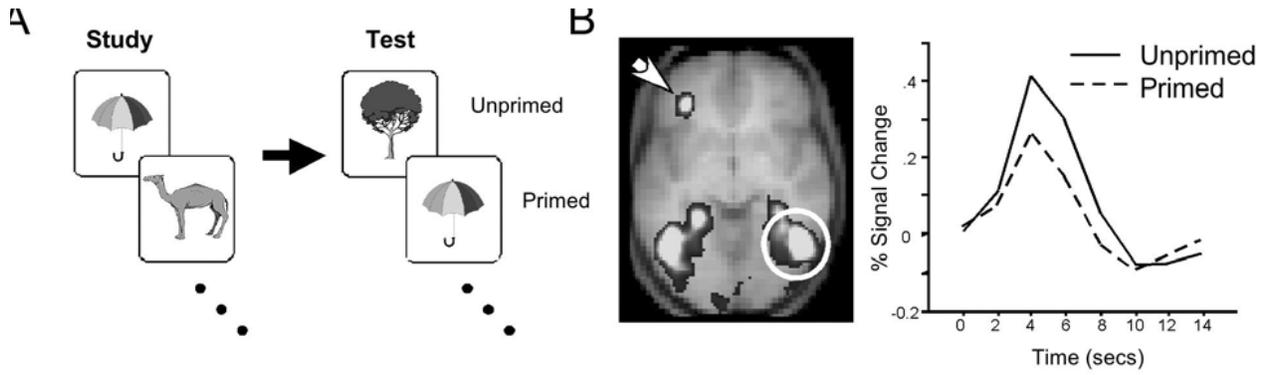

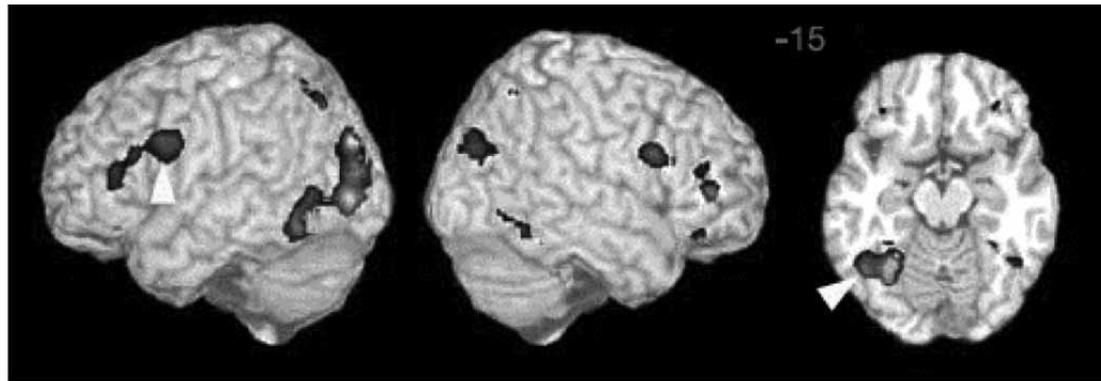

FIGURE 48.8 Repetition priming paradigm, neural priming effects, and hypothesized mechanisms of “cortical tuning.” (A) In semantic priming tasks, subjects initially study a set of stimuli (e.g., pictures or words), making a semantic decision (e.g., size judgment) about those stimuli. Subsequently, during the critical test phase, semantic decisions are made about previously studied (primed) and novel (unprimed) stimuli. Typically, improved behavioral performance measures (e.g., reaction times and accuracy) are observed for primed compared to unprimed stimuli. (B) Functional MRI scanning during the test phase of a semantic classification priming task revealed activation reductions in fusiform (circled) and left ventrolateral PFC (arrow) for primed compared to unprimed stimuli. (Data from W. Koutstaal, A. D. Wagner, M. Rotte, A. Maril, R. L. Buckner, & D. L. Schacter, 2001, Perceptual specificity in visual object priming: Functional magnetic resonance imaging evidence for a laterality difference in fusiform cortex, *Neuropsychologia*, 39, 184–199. Copyright 2001, with permission from Elsevier.)

(C) Proposed experience-dependent changes in a neural network representing visual object features. First presentation of a stimulus activates a network of neurons (circles) coding for relevant and irrelevant features of the stimulus. Repeated presentation “tunes” the stimulus representation, reducing the overall firing rate across this network as well as the associated fMRI signal. Possible mechanisms supporting cortical “tuning” in a population of neurons with repeated stimulus presentation include less overall activation (fatigue model), a reduction in the number of responsive neurons (sharpening model), and faster processing or settling time (facilitation model). (Adapted with permission from K. Grill-Spector, R. Henson, & A. Martin, 2006, Repetition and the brain: Neural models of stimulus-specific effects, *Trends Cogn. Sci.*, 10, 14–23. Copyright 2006, with permission from Elsevier.)

A

B

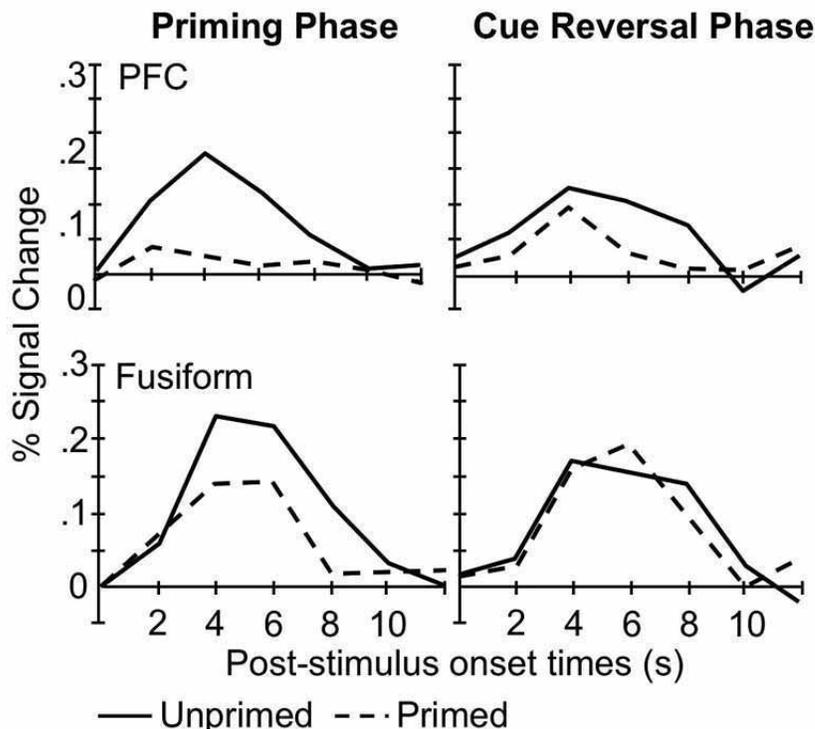

FIGURE 48.9 Contributions of “response learning” to neural priming during a semantic classification task. Subjects semantically classified visually presented objects (“Bigger than a shoe box?”) that were presented once (unprimed) or three times (primed) and responded with a yes/no response. During a subsequent cue reversal phase the task cue was inverted (“Smaller than a shoe box?”), and half of the items from the previous priming phase were re-presented along with a new set of unprimed items. (A) Functional MRI scanning revealed regions displaying reductions in the neural priming signal (difference in activation between primed and unprimed trials) in the cue reversal relative to the priming phase (left panel arrow points to left posterior VLPFC [BA 9/44]; right panel arrow points to left fusiform [BA 37]). (B) Hemodynamic time courses from the two regions of interest indicated in A. Both

posterior VLPFC and fusiform cortex showed significant neural priming during the priming phase when the classification rule was held constant. Inversion of the classification rule in the cue inversion phase reduced neural priming in posterior VLPFC and eliminated priming in fusiform cortex. The disruption of neural priming in the cue reversal phase suggests that subjects could no longer use learned “responses” as a route to action and that neural priming in these regions during the priming phase reflects stimulus-response learning rather than priming of conceptual information. (Adapted with permission from I. G. Dobbins, D. M. Schnyer, M. Verfaellie, & D. L. Schacter, 2004, Cortical activity reductions during repetition priming can result from rapid response learning, *Nature*, 428, 316–319. Copyright 2004, reprinted by permission from Macmillan Publishers, Ltd.)

The role of response learning in conceptual priming tasks has received support from a study by Dobbins, Schnyer, and colleagues (2004). In this study (figure 48.9), stimuli (e.g., “Bulldozer”) were repeatedly semantically classified (e.g., “Larger than a shoebox?”), with the specific classification decision and the corresponding response either being held constant across repetitions or changed across repetitions (e.g., “Smaller than a shoebox?”). While repetition of a stimulus with the identical decision cue was associated with robust repetition suppression in left VLPFC, repetition of a stimulus with the inverted decision cue was associated with diminished repetition suppression in this region. Because the same conceptual information is accessed across the decision cues, the disruption of priming with cue inversion suggests that the left VLPFC repetition suppression effects typically observed in conceptual priming tasks are at least partially attributable to stimulus-response learning rather than priming of conceptual information. While these data provide an important challenge to accounts of left VLPFC priming that focus only on the reduction in cognitive control demands following cortical tuning of semantic representations, one caveat is that the design used by Dobbins and colleagues covaried repetition at the “decision” and “response” levels. That is, switching the decision from “Larger than a shoebox?” to “Smaller than a shoebox?” requires both a decision switch and a response switch (Schacter et al., 2004; Schnyer, Dobbins, Nicholls, Schacter, & Verfaellie, 2006). Indeed, behavioral evidence suggests that priming at the decision level can be dissociated from response repetition (Schnyer et al., 2007).

Together, extant evidence suggests that prior conceptual processing can reduce demands on PFC control mechanisms during future conceptual processing. However, additional work is needed to establish the extent to which these PFC activation reductions reflect priming at different levels of processing (i.e., conceptual, decision, or response). An intriguing hypothesis is that these distinct levels of learning might give rise to dissociable forms of neural priming. For example, priming at the conceptual level may reduce demands on processing in left anterior VLPFC—a region that has repeatedly been implicated in controlled semantic retrieval—whereas learning at the response level may reduce demands on processing in regions more directly related to response selection (e.g., premotor areas) (Race, Shanker, & Wagner, 2008). Of additional interest is whether these distinct forms of priming—from higher-level conceptual priming to lower-level response learning—correspond to a representational hierarchy within PFC (Fuster, 2001; Badre & D’Esposito, 2007; Koechlin & Summerfield, 2007), perhaps organized along an anterior (higher-level) to posterior (lower-level) gradient (Race et al., 2008). Insight into these questions will provide a more complete understanding of the multiple ways in which learning from past experiences

can reduce future uncertainty, and thus demands on PFC-mediated control.

Conclusion

In this chapter we reviewed influential theories of cognitive control and considered the specific manner in which VLPFC control mechanisms serve to resolve interference and reduce uncertainty during mnemonic processing. While our focus on VLPFC operations reflects the considerable progress that has been made in understanding VLPFC function (for reviews, see Petrides, 2005; Badre & Wagner, 2007), it should be emphasized that other PFC mechanisms work in conjunction with VLPFC to achieve mnemonic goals (for reviews, see Fletcher & Henson, 2001; Wagner, 2002; Buckner, 2003; Simons & Spiers, 2003). For example, it has been argued that while VLPFC supports “active retrieval” of mnemonic representations, DLPFC subserves the complementary role of monitoring mnemonic representations once activated (Petrides, 1996, 2005). To the extent that DLPFC supports the monitoring of mnemonic information (Henson et al., 2000; Fletcher & Henson, 2001; Dobbins et al., 2002; Rugg et al., 2003; Achim & Lepage, 2005; Dobbins, Simons, et al., 2004), this argument would suggest a hierarchical, but interactive, relationship between VLPFC and DLPFC retrieval operations. Along similar lines, it has been suggested that VLPFC and DLPFC are hierarchically organized during episodic encoding, with VLPFC serving a general role in encoding (e.g., Wagner et al., 1998; Brewer, Zhao, Desmond, Glover, & Gabrieli, 1998), but DLPFC selectively recruited when encoding involves processing the relationship between multiple stimuli (Blumenfeld & Ranganath, 2006; Murray & Ranganath, 2007). Further delineation of the contributions of DLPFC to mnemonic processing, as well as the nature of DLPFC-VLPFC interactions, remains an important avenue for future research. Finally, frontopolar cortex has frequently been implicated in higher-order forms of mnemonic processing (for reviews, see Rugg & Wilding, 2000; Fletcher & Henson, 2001; Buckner, 2003; Ramnani & Owen, 2004), though ambiguity remains concerning the specific nature of frontopolar interactions with “lower” forms of mnemonic control. Further advances in our understanding of the interplay between PFC control and mnemonic processing will require consideration of both the computations supported by specific PFC subregions and the manner in which coordinated processing across these subregions allows for the achievement of mnemonic goals.

49 Phases of Influence: How Emotion Modulates the Formation and Retrieval of Declarative Memories

ELIZABETH A. KENSINGER

ABSTRACT We tend to remember emotional experiences long after we have forgotten more mundane ones. The beneficial effects of emotion on memory appear to arise through influences between emotion-specific processes and domain-general sensory and mnemonic processes. These interactions arise at every phase of memory, including encoding, consolidation, and retrieval. As this chapter describes, emotion heightens perception and attention during encoding and enhances the likelihood that information is elaborated and organized. Emotion also modulates postencoding consolidation processes, increasing the likelihood that an emotional event is maintained in a durable memory trace. Emotion continues to wield its influence at retrieval, increasing the likelihood that information is retrieved and also augmenting the subjective vividness associated with the retrieved memory. This chapter discusses the neural processes that underlie these effects of emotion on memory. Particular emphasis is placed on understanding the role of the amygdala in emotional memory and how the amygdala exerts its effects by means of interactions with other sensory and mnemonic regions.

Events often elicit short-lived cognitive, physiological, and somatic reactions, otherwise known as emotions (see Barrett, 2006; Izard, 2007; Frijda & Sundararajan, 2007; Panksepp, 2007; Scherer, 2000, for discussion of the best way to think about the term). Emotional reactions accompany many of life's experiences, particularly those we care most about remembering. It is, therefore, critical to understand how emotion influences memory processes, as without this knowledge, it would be nearly impossible to discern how memory operates in everyday life. This realization has sparked interest in the study of "emotional memory," or the examination of how memories for experiences that triggered an emotional response are formed and retrieved.

Extensive research on emotional memory demonstrates that emotional experiences tend to be remembered better than experiences that lack emotional importance, an effect referred to as "emotional memory enhancement" (reviewed

by Buchanan & Adolphs, 2004). This mnemonic benefit conveyed by emotion has long been acknowledged (see Colgrove, 1899, for a study examining memory for the assassination of President Abraham Lincoln), but it is only within recent decades that research has begun to elucidate the processes that give rise to it. Though animal research has clarified many of the mechanisms that support emotion's influence on memory (reviewed by McGaugh, 2004; Phelps & LeDoux, 2005), this chapter focuses exclusively on the effects of emotion on declarative memory in humans, describing how behavioral, neuropsychological, neuropharmacological, and neuroimaging studies have elucidated how emotion influences each phase of memory (see figure 49.1). Because the study of emotional memory in humans is still a relatively young topic of investigation, this chapter concludes with a discussion of directions for future research, including the need to consider individual differences when assessing the effects of emotion on memory.

The influence of emotion during encoding

It is well known that the way in which information is processed initially has downstream consequences on the likelihood that the information is remembered later (Craik & Lockhart, 1972), with information that is detected, attended, and elaborated upon being the most likely to be remembered (Craik, Govoni, Naveh-Benjamin, & Anderson, 1996). Many of emotion's effects on memory appear to arise through broader influences on the way in which emotional information is detected and attended at the outset. Emotional stimuli are noticed more quickly and more often than nonemotional ones (Anderson, 2005; Fox, Russo, Bowles, & Dutton, 2001; Leclerc & Kensinger, 2008; Ohman, Flykt, & Esteves, 2001; Phelps, Ling, & Carrasco, 2006; Williams, Mathews, & MacLeod, 1996), and the processing of emotional information is prioritized so that it can occur even when attentional resources are taxed (reviewed by Dolan & Vuilleumier, 2003; Pessoa, 2005; Vuilleumier & Driver, 2007). Once an emotional item is detected, attention

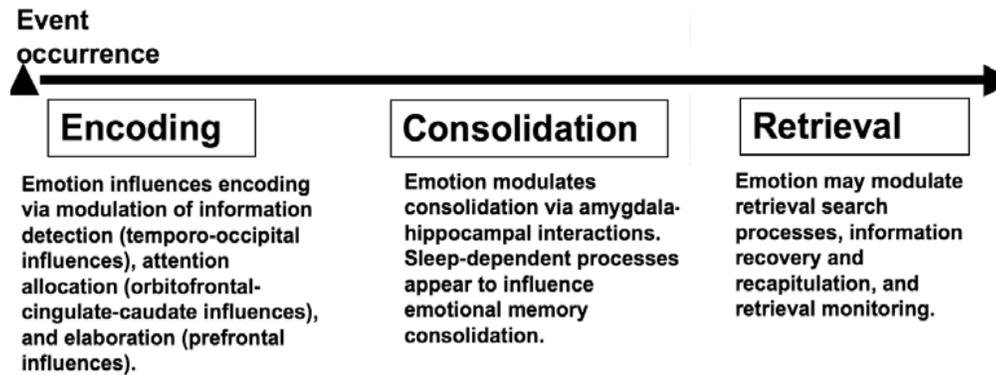

FIGURE 49.1 Overview of the effects of emotion on memory.

also is more likely to be focused and sustained on it (e.g., Armony & Dolan, 2002; Mogg, Bradley, de Bono, & Painter, 1997), and individuals are more likely to elaborate on the emotional information, connecting it with existing semantic or autobiographical information (e.g., Buchanan, Etzel, Adolphs, & Tranel, 2006; Talmi & Moscovitch, 2004; Talmi, Schimmack, Paterson, & Moscovitch, 2007). Each of these factors can increase the likelihood that emotional information is encoded into a stable memory trace. In fact, Talmi, Luk, McGarry, & Moscovitch (2007) have proposed that direct modulation of memory may not be required for short-term enhancements in the retention of emotional information. Rather, emotion's modulation of domain-general processes—enhanced attention, distinctive encoding, and information elaboration and organization—may be sufficient to mediate emotion's benefit on retention of information over relatively short delays. As will be described subsequently, neuroimaging may provide one means to clarify the extent to which emotion's influence on memory is mediated through influences on information processing rather than dependent on direct modulation of memory binding and consolidation processes (see also Talmi, Anderson, Riggs, Caplan, & Moscovitch, 2008).

THE EFFECT OF EMOTION ON INFORMATION DETECTION AND ATTENTION ALLOCATION Many of emotion's influences on detection and attention appear to arise through interactions between the amygdala and other sensory regions. It is proposed that once the amygdala is activated by emotional stimuli, it can modulate the functioning of sensory cortices to assure that emotional information is attended (LeDoux, 1995). This hypothesis is anatomically plausible, because the amygdala has strong reciprocal connections with most sensory regions (Amaral, Price, Pitkanen, & Carmichael, 1992; Amaral, 2003). The hypothesis also is supported by neuroimaging studies that reveal strong correlations between the amount of activity in the amygdala and in visual processing regions including

the fusiform gyrus (e.g., Noesselt, Driver, Heinze, & Dolan, 2005; Vuilleumier, Richardson, Armony, Driver, & Dolan, 2004) and occipital lobe (Tabert et al., 2001; figure 49.24) during the processing of emotional information. Although these correlations cannot establish the directionality of the modulation, they are consistent with the proposal that the amygdala can modulate sensory functioning. Stronger evidence for an amygdala-mediated influence on sensory activity came from a study in which Vuilleumier and colleagues (2004) asked individuals with varying amounts of amygdala damage to view fearful and neutral faces while in an fMRI scanner. Only patients with a functioning amygdala showed fusiform modulation in response to the facial expression, with greater fusiform activity to fearful than to neutral faces. In fact, there was a strong correlation between the amount of intact amygdala and the amount of fusiform modulation in response to the fearful faces, consistent with the proposal that the amygdala has a modulatory effect on visual processing regions, increasing the likelihood that emotional information is detected and processed.

Interactions between the amygdala and sensory regions also seem to enhance memory for the visual details of emotional stimuli (Mickley & Kensinger, 2008; Kensinger, Garoff-Eaton, & Schacter, 2007b). Participants are more likely to remember the precise visual attributes of a negative item as compared to a neutral one; for example, they recognize exactly which grenade they have seen more often than they recognize which blender they have seen (Kensinger, Garoff-Eaton, & Schacter, 2006). This effect appears to arise from interactions between the amygdala and the fusiform gyrus during encoding. As compared to the processing of neutral items, during the processing of negative items that will later be remembered with precise visual detail, there is increased activity in the amygdala and the right fusiform gyrus. There also is a strong correlation between the amount of activity in these two regions during the processing of negative items, whereas no such correlation exists during the

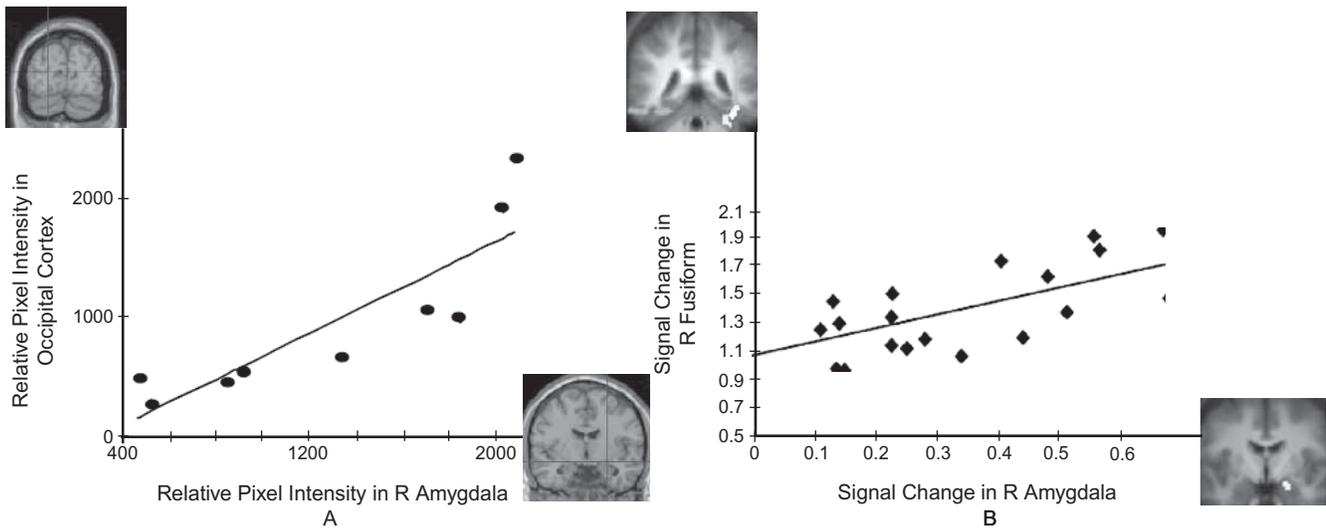

FIGURE 49.2 During the processing of negatively emotional information, there often are robust correlations between amygdala activity and activity in sensory processing regions (panel *A*, adapted from Tabert et al., 2001; images depict coordinates reported in that

paper). These correlations are particularly strong during the encoding of negative items that will later be remembered with specific visual details (panel *B*, data from Kensinger, Garoff-Eaton, & Schacter, 2007b).

processing of neutral items (Kensinger et al., 2007b; figure 49.2*B*). The right fusiform gyrus is a region that is associated with the processing of visually specific details (e.g., Koutstaal et al., 2001) and with subsequent memory for the visual details of neutral items (Garoff, Slotnick, & Schacter, 2005). Therefore, it makes sense that enhanced activity within this region could increase the likelihood that the visual details of a negatively emotional item are remembered.

items may be remembered in a detailed fashion because attention is focused on the intrinsic details of those items; however, by focusing on those emotional elements, other event details may be missed or easily forgotten.

Modulation of sensory processes does not appear to be the only avenue by which emotion enhances memory for visual detail. The ability to remember the visual details of emotional items also may be tied to the way in which attention is allocated during encoding. Emotion does not seem to uniformly enhance memory for all aspects of an experience. Rather, some event details are remembered well and others are readily forgotten (reviewed by Buchanan & Adolphs, 2002; Kensinger, 2007; Mather, 2007; Reisberg & Heuer, 2004). For example, when presented with complex visual scenes, it often is that case that the visual details of the emotional aspects are remembered well but the visual details of the nonemotional aspects are remembered poorly (e.g., Kensinger, Garoff-Eaton, & Schacter, 2007a; Payne, Stickgold, Swanberg, & Kensinger, 2008; figure 49.3). An fMRI study revealed that activity in an affective-attentional network, including the right orbitofrontal cortex, the anterior cingulate gyrus, and the caudate nucleus, corresponds with the ability to remember the visual details of an emotional item but also with the inability to remember other aspects associated with the item's presentation, such as what decision a person made about an item (Kensinger et al., 2007b; figure 49.4). This finding suggests that emotional

It is interesting to note that this attentional focusing on emotional items does not arise through engagement of the same frontoparietal attention circuits that guide attention toward nonemotional, task-relevant information (reviewed by Corbetta & Shulman, 2002). Rather, when attention is focused on emotional information, it appears to be through engagement of emotion-specific processes that are brought online when a task requires engagement of motivational processes and of attention to affective stimuli (e.g., Robbins & Everitt, 1996; Schultz, 2000). This dissociation suggests that emotional information may be attended as a result of the engagement of emotion-specific processes rather than the domain-general ones that guide attention toward any task-relevant piece of information (and see Vuilleumier & Driver, 2007, for further discussion). Thus, when an individual is affectively focused on an item, attention appears to be drawn to the intrinsic attributes of that emotional item. This selective attention seems to have downstream mnemonic consequences, leading those intrinsic item details to be remembered better than elements only extrinsically linked to the emotional item (see Kensinger, 2007; Mather, 2007, for further discussion). These findings highlight that even when emotion's effects on memory seem to be mediated by influences on domain-general processes (such as attention allocation), this mediation may actually reflect emotion-specific modulation of sensory and attentional processes.

FIGURE 49.3 After experiencing an emotional event—such as a car accident (*A*)—participants may retain good memory for the details of the accident itself, but poor memory for the contextual

details, such as what the street looked like (*B*). Modulation of attentional focusing at encoding, as well as of consolidation processes, appears to contribute to this effect.

EFFECTS ON ELABORATION AND ORGANIZATION OF INPUT

In addition to these effects of emotion on information detection and attention allocation, emotion also appears to influence the likelihood that information is elaborated and organized. It is well known that events that elicit negative emotions are elaborated and rehearsed more often than events that elicit no emotion (reviewed by Ochsner & Schacter, 2003). Emotional items also benefit from organizational clustering to a greater degree than do nonemotional items (Buchanan, Etzel, et al., 2006; Talmi & Moscovitch, 2004; Talmi, Schimmack, et al., 2007). Because information that is elaborated and well organized is more likely to be remembered (Craik & Lockhart, 1972), it makes sense that if emotion provides an organizing structure or a basis for elaboration, these features would convey benefits to memory. Indeed, a number of behavioral studies have demonstrated an important role for elaborative and organizational processes in enhancing emotional memory (Phelps et al., 1998; Talmi & Moscovitch, 2004), and neuroimaging studies have confirmed that regions implicated in elaborative processing—including the lateral prefrontal cortex—often are disproportionately recruited during the successful encoding of emotional information (e.g., Dolcos, LaBar, & Cabeza, 2004; Kensinger & Corkin, 2004; Maratos, Allan, & Rugg, 2000). These elaborative processes appear to be particularly essential for boosting the encoding of emotional information that is not highly arousing (e.g., Buchanan, Etzel, et al., 2006; Bush & Geer, 2001; Kensinger & Corkin, 2003; Talmi, Schimmack, et al., 2007), perhaps because these items do not benefit from the same amygdala-mediated enhancements in detection and attention (reviewed by Kensinger, 2004). Thus, when elaborative processes cannot be engaged easily (for example, when

attention is divided), the mnemonic enhancement for nonarousing emotional items disappears (Bush & Geer, 2001; Kensinger & Corkin, 2004; Kern, Libkuman, Otoni, & Holmes, 2005).

CONCLUSIONS ABOUT ENCODING

Nearly all studies examining memory for emotional information have revealed a strong correlation between how active the amygdala is during the encoding of emotional information and how well that emotional information is remembered (reviewed by Hamann, 2001; LaBar & Cabeza, 2006). These correlations exist both across participants (e.g., Cahill et al., 1996) and within a single participant (e.g., Canli, Zhao, Brewer, Gabrieli, & Cahill, 2000). They arise in tasks using verbal stimuli (e.g., Erk et al., 2003; Kensinger & Corkin, 2004), slide shows (e.g., Cahill et al., 1996), facial expressions (e.g., Sergerie, Lepage, & Armony, 2006), and colored photographs (e.g., Dolcos et al., 2004; Sharot, Delgado, & Phelps, 2004), and they hold across a range of encoding tasks. Though many of these studies have focused on the amygdala's modulation of hippocampal binding and consolidation processes (an issue we will return to in the next section), the studies reviewed have revealed that emotion can exert many of its influences on memory by means of alterations in earlier stages of information processing. In particular, engagement of emotion-specific processes, implemented by the amygdala and orbitofrontal cortex, can influence memory by modulating sensory and conceptual processes. These interactions can ensure that emotional information is detected, attended, and elaborated (see also Duncan & Barrett, 2007; Talmi et al., 2008). Thus, regardless of the particular stimuli, encoding instructions, or task design, the engagement of emotion-specific processes during

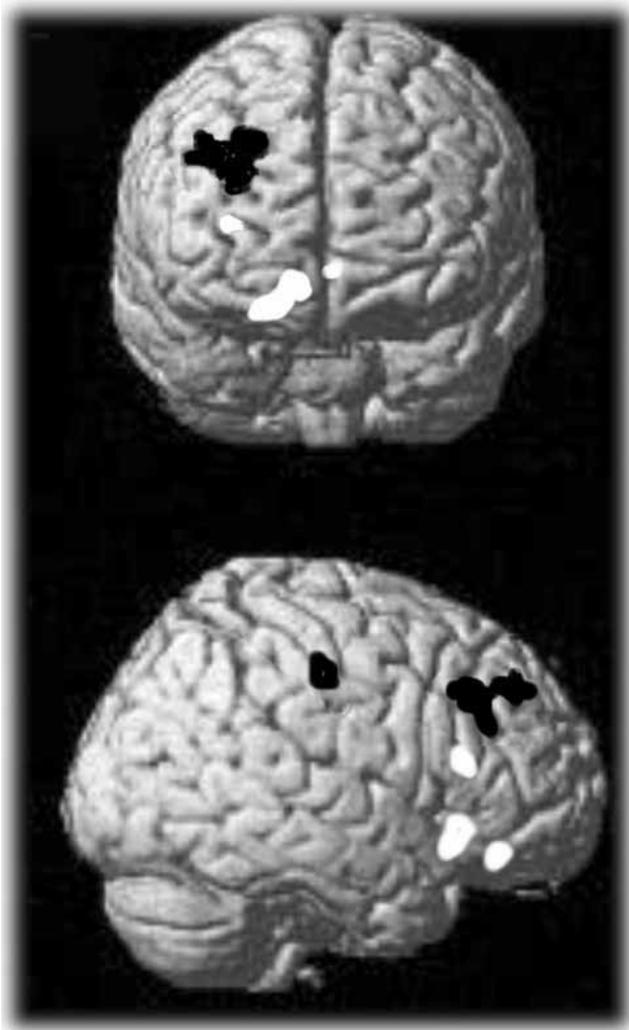

FIGURE 49.4 When participants view items and are asked to make a decision about them (e.g., to decide either whether it is alive or whether it is commonly encountered), participants often have good memory for the visual details of the item but poor memory for which decision they made about the item. Encoding-related activity can predict which items will later be remembered with visual detail but without memory for the decision. The activity that predicts this pattern of memory performance differs based on whether the items are negative (white regions) or neutral (black regions). This dissociation suggests that the narrowing of attention on intrinsic item attributes (such as an item's visual details) is mediated by different processes when the items are emotional versus nonemotional. (Adapted from Kensinger, Garoff-Eaton, & Schacter, 2007b.)

encoding is critically tied to the emotional memory enhancement effect.

Emotion influences consolidation processes

The effects of emotion on encoding processes can explain why emotional information is better remembered than neutral information across a range of delays. If emotional

information is more likely to be detected, attended, and elaborated, then it would make sense that the information would be remembered well after both short and long delays. Interestingly, however, the effects of emotion often become exaggerated after a long delay (e.g., Kleinsmith & Kaplan, 1963; Walker & Tarte, 1963; Sharot, Verfaellie, & Yonelinas, 2007; Sharot & Yonelinas, 2008), and damage to the amygdala tends to disproportionately influence the retention of emotional information over long delays while having a lesser influence on the ability to retain emotional information for only a short duration of time (Phelps, LaBar, & Spencer, 1997; Phelps et al., 1998; LaBar & Phelps, 1998). These findings cannot easily be explained by effects of emotion on encoding processes. Rather, these results point to the ability of emotion to influence the likelihood that memories are solidified into stable long-term traces. If emotion—through the actions of the amygdala—serves to increase the probability that a memory is consolidated, then it should follow that the benefit for emotional compared to nonemotional memories increases as the retention interval lengthens and that amygdala damage disrupts this effect. Indeed, as will be described later, there is abundant evidence to suggest that the amygdala modulates consolidation processes, enhancing the likelihood that an emotional memory can be remembered after a long delay.

AMYGDALA MODULATION OF HIPPOCAMPAL CONSOLIDATION

Extensive evidence for emotion's effects on hippocampal consolidation comes from animal studies of emotional learning. These studies reveal that stress hormones released as part of an affective response can trigger a cascade of neurotransmission and hormone release, ultimately leading to amygdalar modulation of hippocampal consolidation (reviewed by McGaugh, 2004; Phelps, 2004; Phelps & LeDoux, 2005). Paralleling these animal findings, research in humans suggests that emotion conveys benefits on the hippocampal consolidation of declarative memories. In particular, neuroimaging studies provide strong evidence for interactions between the amygdala and the hippocampus. The amygdala and hippocampus often are coactivated during the successful encoding of emotional information (e.g., Dolcos et al., 2004; Kensinger & Corkin, 2004), and there is a strong correlation between the activity in these regions (Kensinger & Corkin, 2004; Kensinger & Schacter, 2005a; Richardson, Strange, & Dolan, 2004), as well as an increase in functional connectivity between the regions (Kilpatrick & Cahill, 2003), as individuals learn emotional information. Although these studies cannot determine whether such interactions signify influences on memory consolidation per se, or on other mnemonic processes implemented by the hippocampal formation, the results are consistent with a modulatory role on consolidation processes.

The importance of consolidation processes in emotional memory also is suggested by the fact that many of the interactions between the amygdala and the hippocampus seem to be mediated by the influence of stress hormones. Administration of cortisol enhances the long-term recall of emotional information (Buchanan & Lovullo, 2001), whereas administration of beta blockers eliminates the enhancement (Cahill, Babinsky, Markowitsch, & McGaugh, 1995). Moreover, amygdala activation without an accompanying arousal response does not appear sufficient for a hippocampal-mediated boost in memory (e.g., Anderson, Yamaguchi, Grabski, & Lacka, 2006; Kensinger & Corkin, 2004), suggesting that both amygdala activation and a concurrent stress response are required. Although these studies cannot conclusively demonstrate an influence upon consolidation processes, because the amygdala's influence on hippocampal consolidation processes is thought to be modulated by release of stress hormones (McGaugh, 2004), these neuropharmacological and neuroimaging findings are consistent with a role for arousal-dependent amygdalar modulation of consolidation.

EMOTION, SLEEP, AND MEMORY CONSOLIDATION Some of the mnemonic effects of emotion seem to be exerted through sleep-dependent consolidation processes. Although the details of how sleep influences memory consolidation are still debated (see Born, Rasch, & Gais, 2006; Ellenbogen, Hulbert, Stickgold, Dinges, & Thompson-Schill, 2006; Frank & Benington, 2006), extensive evidence suggests that sleep can benefit performance on both implicit and explicit memory tasks (reviewed by Payne, Ellenbogen, Walker, & Stickgold, in press; Stickgold, 2005; Walker & Stickgold, 2006). Sleep after learning can increase the rate of information acquisition (Born et al.; Gais, Lucas, & Born, 2006) and can make information less prone to interference and decay over time (Ellenbogen, Payne, & Stickgold, 2006). By contrast, sleep deprivation can impair declarative learning, suggesting that sleep is necessary for optimal hippocampal-dependent memory consolidation (C. Smith & Rose, 1996). Slow-wave sleep may be particularly essential to the consolidation of episodic memories, with the reactivation and redistribution of hippocampal neural ensembles occurring during this sleep phase (reviewed by Marshall & Born, 2007; Rasch & Born, 2008).

Although only a few studies have compared the effects of sleep on memory for emotional versus nonemotional information, all of these studies supply evidence that sleep provides particular benefits for emotional memory. In one such study, Wagner, Hallschmid, Rasch, and Born (2006) asked participants to study narratives that were either emotional or neutral in content. Some participants slept for three hours after reading the narratives while other participants remained

awake. Four years later, the benefits of sleep on emotional memory were apparent: sleep had no influence on the likelihood of remembering the topics of the neutral narratives, but the participants who slept after reading the narratives were more likely to remember the topics of the emotional narratives than were those who remained awake. Thus sleep conferred a particular mnemonic benefit for the emotional information.

We need not wait multiple years to see the benefits that sleep conveys to emotional memory. A few studies have revealed that emotional memory is better either after a brief (3-hour) period of REM-intensive sleep or after a full night of sleep rather than after a similar period of wakefulness (e.g., Hu, Stylos-Allan, & Walker, 2006; Wagner, Gais, & Born, 2001; Wagner et al., 2006; Wagner, Kashyap, Diekelmann, & Born, 2007). For example, Hu and colleagues presented participants with colored photographs from the International Affective Picture System (Lang, Bradley, & Cuthbert, 1999). Some photographs were emotionally arousing, and others were neutral. Participants' memory for the photos was tested 12 hours later, and the critical finding was that while sleep had no impact on memory for the neutral pictures, memory for the arousing pictures was better after a night of sleep than after an equivalent period of time spent awake.

Although sleep conveys benefits to memory for emotional items, it does not appear to enhance memory for all aspects of those items equally well. Rather, sleep's memory-enhancing effects appear to be specific to the most emotional aspects of a stimulus. When Payne, Stickgold, and colleagues (2008) presented participants with scenes including an emotional object placed on a neutral background (e.g., a snake in a forest), they found that sleep selectively preserved memory for the emotional object while conveying no memory benefit for the accompanying background (figure 49.5). This finding is intriguing, suggesting that not all aspects of an emotional event are consolidated as a single, bound entity. Rather, sleep appears to preferentially preserve memory for those elements of an experience that are strongly tied to the emotional nature of the event. This result suggests that there is an important interaction between emotion and sleep-mediated consolidation processes, with sleep having the greatest preservative benefit on memory for emotional information.

CONCLUDING REMARKS REGARDING CONSOLIDATION

There is no question that emotion modulates the consolidation of memories, with emotional experiences being more likely to be retained over time than nonemotional ones. What is less clear, however, is what attributes of an emotional experience benefit from enhanced consolidation. Within the emotional memory literature, there is an increasing

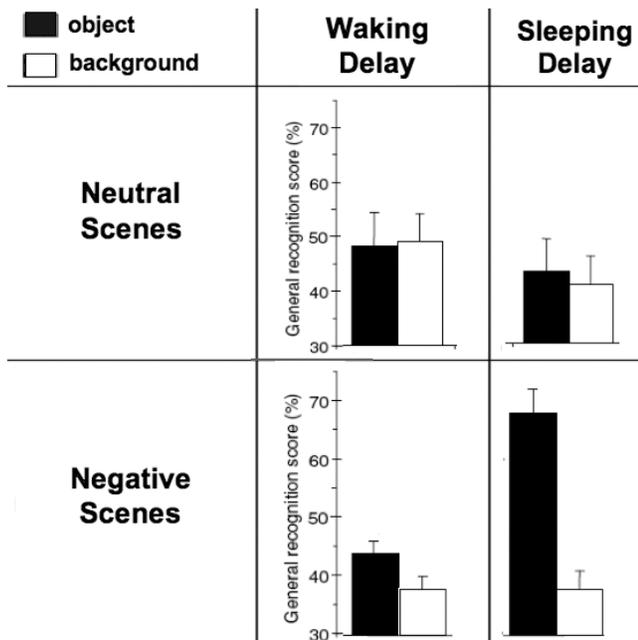

FIGURE 49.5 When participants study visual scenes and are tested on their memory for those scenes after either a 12-hour delay including a night of sleep or a 12-hour period of time spent awake, memory for the negative objects within scenes is selectively enhanced across a sleeping as compared to a waking delay. Memory for the backgrounds of those same scenes is unaffected by whether the delay included time spent awake or time spent asleep. (Data from Payne, Stickgold, Swanberg, & Kensinger, 2008.)

appreciation for the fact that not all aspects of an emotional experience are equally likely to be remembered (e.g., Reisberg & Heuer, 2004; Kensinger, 2007; Mather, 2007). Although many of these selective effects likely arise from attentional focusing at encoding (as discussed in the previous section), some of the effects may also arise through focal influences on consolidation. As noted earlier, sleep does not appear to benefit consolidation of all event attributes to an equal degree; rather, the benefits seem to be particularly pronounced for those details that are intrinsic to the emotional items. Further research is needed to reveal the extent to which encoding processes versus postencoding consolidation mechanisms lead to the focal enhancements in emotional memory, leading only some attributes of an emotional event to be remembered well.

The influence of emotion during retrieval

In comparison to the extensive number of studies that have examined the effects of emotion on encoding and consolidation processes, relatively few studies have investigated the influence of emotion during memory retrieval. However, the extant data indicate that emotion can modulate retrieval processes. The role of emotion in memory retrieval recently

has been reviewed thoroughly (by Buchanan, 2007), and so here I will focus on the specific question of the amygdala's role during retrieval.

It is well established that the amygdala is active during the retrieval of emotional memories. Neuroimaging studies have revealed that amygdala engagement occurs both when the retrieval cue itself is emotional (e.g., Dolan, Lane, Chua, & Fletcher, 2000; Kensinger & Schacter, 2005b) and when the cue is neutral but the associated study context is emotional (e.g., Maratos, Dolan, Morris, Henson, & Rugg, 2001; Smith, Henson, Dolan, & Rugg, 2004; A. Smith, Henson, Rugg, & Dolan, 2005; Somerville, Wig, Whalen, & Kelley, 2006; Sterpenich et al., 2006). In one study, participants were asked to view objects that were presented against either neutral or emotional backgrounds. During recognition, they were shown the objects in isolation, and they had to indicate whether each object had been studied previously. The critical finding was that amygdala activity was greater during retrieval of items that had been studied with an emotional context than during retrieval of items that had been studied with a nonemotional context (A. Smith et al., 2004). The fact that amygdala activity was influenced by the study context, even when the retrieval cue itself was neutral, suggests that amygdala engagement during retrieval may not merely represent an emotional response to a retrieval cue. Rather, amygdala activity may be directly tied to the recovery of emotionally relevant information present during the encoding episode.

Though neuroimaging studies indicate that the amygdala is involved in the retrieval of emotional memories, they cannot speak to the necessity of the region. Indeed, there have been extensive discussions about whether the amygdala is essential for the retrieval of emotional memories (see Nader, 2003; LeDoux, 2000, for discussion). At least with regard to the retrieval of emotional autobiographical memories, recent patient studies have provided evidence that this region does play an essential role. Patients with damage to the amygdala have difficulty retrieving emotional memories, even of events that were experienced prior to the onset of their amygdala damage (Buchanan, Tranel, & Adolphs, 2005, 2006). Even when they do recall emotional experiences, patients with amygdala lesions rate them as being less emotional, as well as less vivid, than do control participants, suggesting that without the amygdala, emotional memories cannot be remembered as often or with the same qualitative richness as with an intact amygdala.

These studies cannot clarify the specific role played by the amygdala during the retrieval of emotional memories. In particular, it is unclear whether the amygdala's retrieval-related activity leads to or is caused by successful retrieval. It is widely accepted that memory retrieval consists of at

least a few distinct processes. After we receive a cue—passing someone familiar in the hallway, for example—we implement search processes to help us efficiently narrow down and sift through the information we have stored in mind in order to generate the sought-after information—such as where we last saw the person. If the search process is successful, the desired information will be recovered. After information is recovered, we assess whether it is what we were searching for, by engaging in retrieval monitoring processes. We may evaluate the plausibility of the retrieved information (“Could we really have seen this colleague on our flight back from Australia?”) or consider our confidence in our memory (“Are we certain enough to mention the turbulent flight?”). Superimposed on all these processes, our brains seem to configure themselves into a “retrieval mode,” allowing us to optimally query and evaluate the contents of our memory in order to reexperience past events (discussed by Rugg & Wilding, 2000; Sakai, 2003). Emotion could influence any of these stages of retrieval, and a great deal of ongoing research is investigating at which of these many phases emotion intervenes.

The amygdala may guide the search processes that lead to successful recovery of information. As noted earlier, patients with amygdala damage seem to select emotional memories less often than control participants (Buchanan, Tranel, & Adolphs, 2005, 2006). This finding is consistent with the hypothesis that amygdala damage results in altered mnemonic search process. In particular, if the amygdala typically boosts the efficiency or efficacy of the search process, making it more likely that relevant emotional information is recovered, then without this amygdala-facilitated search process, it would make sense that these patients would not receive any benefit when searching for information tied to an emotional experience. Neuroimaging evidence also indicates that amygdala activity can occur early in the retrieval process, before a memory has been fully elaborated, suggesting a role in the search process (Daselaar et al., 2008). Thus these findings lend credence to the proposal that amygdala activity modulates the search processes that lead to the successful recovery of emotional memories.

In addition to a role in the retrieval search process, amygdala engagement during retrieval also may be a reflection of the successful recovery of information. Retrieval-related activity can be tied to recapitulation, or the reinstatement of processes engaged during encoding. For example, when retrieving a word that was paired with a sound at encoding, activity in auditory cortex often is high, whereas when retrieving information associated with pictorial information at encoding, visual activity can be enhanced (Kahn, Davachi, & Wagner, 2004; Wheeler, Petersen, & Buckner, 2000; Nyberg, Habib, McIntosh, & Tulving, 2000; Vaidya, Zhao, Desmond, & Gabrieli, 2002). In the same way as this activity is presumed to reflect the recapitulation of sensory processes

engaged during encoding, so might amygdala engagement during retrieval reflect the reinstatement of emotional processes engaged during encoding. Support for this hypothesis comes from studies demonstrating that amygdala activity during retrieval can be higher when participants are asked to determine whether an item was encoded in an emotional context than when they are asked to focus on nonemotional aspects of the item’s presentation (A. Smith et al., 2004, 2005; A. Smith, Stephan, Rugg, & Dolan, 2006). This finding may suggest that the amygdala activity reflects the reinstatement of the emotional context in which an event was learned. The fact that similar limbic regions often are associated both with successful encoding and with accurate retrieval of information (e.g., Fenker, Schott, Richardson-Klavehn, Heinze, & Duzel, 2005; Kensinger & Schacter, 2005a, 2005b) also may suggest that these regions’ retrieval-related activity reflects the bringing online of the emotional information present during encoding or results from the reexperiencing of the emotion elicited during encoding.

Though these studies suggest a role for the amygdala in search and recovery processes, it also is possible that amygdala engagement is tied to memory monitoring processes and to metamemory assessments. In ERP studies, emotion can modulate late-onset positive potentials, believed to correspond with postretrieval monitoring processes (A. Smith et al., 2004). Though these studies do not implicate the amygdala specifically, they certainly suggest that emotion is likely to influence monitoring processes. However, the specific influence of emotion on mnemonic monitoring has been debated. Some hypothesize that amygdala engagement may bias monitoring processes in such a way as to lead people to believe that they have retrieved a particularly vivid and detailed memory. By this account, amygdala activity at retrieval may inflate a person’s confidence in a memory, leading to a disconnect between the subjective vividness of a memory and the objective amount of detail included in that memory (see Sharot et al., 2004). Although there is evidence that amygdala engagement at retrieval is associated with the subjective vividness of a memory (Dolcos, LaBar, & Cabeza, 2005; Sharot et al.), its activity also can be elicited specifically during accurate retrieval (Kensinger & Schacter, 2005b, 2007). For this reason, it does not appear that amygdala engagement at retrieval serves only to inflate a person’s confidence in a memory. Nevertheless, it is possible that amygdala engagement modulates processes tied to retrieval monitoring as well as those tied to retrieval success. More generally, it seems likely that amygdala activity is both a cause and consequence of emotional memory retrieval; however, further research is needed to examine whether there are situations in which amygdala activity is more strongly tied to one aspect of retrieval than to another.

CONCLUSIONS ABOUT RETRIEVAL Though it is clear that amygdala engagement enhances encoding processes and facilitates consolidation, it is more widely debated whether the amygdala confers a benefit upon emotional memory retrieval. There is some evidence to suggest that limbic engagement primarily inflates a person's confidence in a memory (e.g., Sharot et al., 2004); but there is other evidence that limbic engagement at retrieval may be tied to remembering event details (e.g., Kensinger & Schacter, 2005b, 2008; A. Smith et al., 2006). It seems likely that, just as with its modulation of encoding and consolidation processes, the amygdala's influence during retrieval may critically depend on the types of details that a person is trying to recover. Perhaps amygdala engagement during retrieval facilitates the recovery of details intrinsically linked to an experience (e.g., the details of the emotional aspect of the event) but does not help with the recovery of details more peripheral to the elicited emotion (e.g., the nonemotional context in which the event occurred). Indeed, a study by Sharot, Martorella, Delgado, and Phelps (2007) revealed that enhanced amygdala activity during retrieval was associated with a reduction of activity in regions associated with retrieval of broader spatiotemporal context. It may be that when the amygdala is engaged, details intrinsic to the emotional aspects of the event are remembered, whereas retrieval of more peripheral, contextual details is impeded. Future research will do well to examine the validity of this hypothesis.

Concluding remarks and future directions

Emotion appears to influence the processes engaged during every phase of memory, but there are still many unanswered questions regarding how emotion exerts its influence. First, as alluded to in the preceding sections, we do not yet have a firm understanding of when emotion enhances, hinders, or exerts no influence on the likelihood of remembering information. It is well known that emotion does not lead to a picture-perfect memory (reviewed by Mather, 2007; Reisberg & Heuer, 2004). Nevertheless, emotional information—and particularly negative information—can be remembered with greater accuracy than nonemotional information (reviewed by Kensinger, 2007). Additional research is needed to understand which types of details are remembered well for emotional experiences and at which memory phases emotion conveys its mnemonic advantage. Future research will do well to investigate these issues not only through presentation of controlled stimuli within a laboratory setting, but also through assessment of participants' memories for emotional, autobiographical experiences.

Second, though researchers often assume that memory processes are consistent from one individual to the next,

when it comes to emotion-memory interactions, there appear to be important individual differences. The sex of an individual can influence the neural processes that correspond with emotional memory enhancement, with men often showing more right-lateralized amygdala activity and women showing more left-lateralized amygdala activity (reviewed by Cahill, 2003; Hamann, 2005). Sex also can influence the magnitude of memory enhancement or memory trade-off elicited by emotion (discussed in Hamann, 2005). Personality characteristics, such as how neurotic someone is, also seem to influence the amount of amygdala activity elicited by stimuli (Hamann & Canli, 2004) and the likelihood that emotional information is detected (discussed by Duncan & Barrett, 2007), perhaps having downstream effects on the magnitude of emotional memory enhancement demonstrated. A person's level of anxiety or cognitive abilities also can influence emotional memory enhancement and the extent of mnemonic trade-off elicited when an emotional item is embedded in a nonemotional context (Waring, Payne, Schacter, & Kensinger, in press). A person's age also has fundamental influences on how emotional information is processed and remembered (reviewed by Kensinger & Leclerc, in press; Mather, 2006). These studies emphasize that research must examine not only how emotion impacts memory across all individuals, but also how individual differences influence the nature of emotion-memory interactions.

Third, as the resolution of MRI scans increases, it will be important for future research to move beyond thinking about the amygdala and the hippocampal memory system as single entities and to more thoroughly investigate how reciprocal influences are likely to depend on the particular subdivisions of each of these regions. Animal research has suggested that not all regions of the amygdala play the same modulatory role and that amygdalar interactions may not be equivalently strong with all medial temporal lobe structures (Davachi, 2006; McDonald, 2003). A finer appreciation of these anatomical distinctions within the human brain may go a long way toward revealing how emotion exerts its complex influences on memory formation, consolidation, and retrieval.

ACKNOWLEDGMENTS I thank Keely Muscatell, Jessica Payne, and Daniel Schacter for helpful discussion and for assistance in the preparation of this chapter. I gratefully acknowledge funding from the National Science Foundation (grant BCS-0542694) and the National Institute of Mental Health (grant MH080833).

50 Individual Differences in the Engagement of the Cortex during an Episodic Memory Task

MICHAEL B. MILLER

ABSTRACT There is a wealth of information at the individual level regarding the neural basis of episodic memory that may be lost by relying on group averages. The topography of brain activity underlying an episodic memory task is enormously variable from individual to individual. Despite this variability, individual patterns of brain activity are relatively stable over time. This stability suggests that there are systematic factors, either cognitive or physiological, between individuals that can account for the variability. We have found that individual differences in memory strategy, as well as other factors, can account for a significant portion of the variance between individuals in their patterns of brain activity. These findings demonstrate that, while performance of a typical episodic memory task engages widespread specialized brain regions throughout most of the cortex, different strategies may differentially engage these various brain regions.

It can be just as important to study the things that make us different from each other as it is to study the things that we have in common. This fact has been appreciated since at least 1911, when the eminent learning theorist E. L. Thorndike wrote, “If we could thus adequately describe each of a million human beings, . . . the million men would be found to differ widely. . . . We may study the features of intellect and character which are common to all men; or we may study the differences in intellect and character which distinguish individual men.” One of the important things that make us different is the unique ways in which we remember past events. Further, these uniquely individual approaches to memory likely result in extensive variability in the engagement of specialized, universal brain regions. This is particularly evident in the variable pattern of brain activity observed in fMRI studies across individuals performing an episodic memory task. Patterns of individual brain activity are as unique and persistent as fingerprints. Yet, unlike fingerprints, these unique and persistent patterns of brain activity may also be quite informative about individuals and how they go about remembering past events. And,

MICHAEL B. MILLER Department of Psychology, University of California, Santa Barbara, California

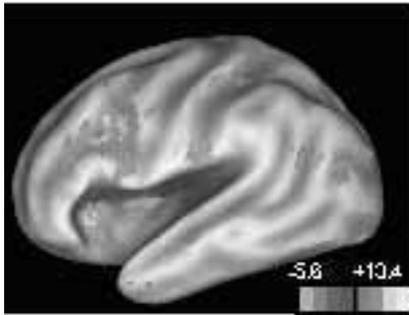

while variability is often treated as a nuisance, controlled by averaging across individuals, relying on a group map can also be a lost opportunity to realize the full extent of the brain’s involvement in particular tasks, particularly a task as dynamic, complex, and strategic as episodic memory.

Group maps of whole-brain activity during an episodic retrieval task, no matter how sophisticated and rigorous the statistical analyses, have been shown to be poor representations of the pattern of activations and deactivations that occur at the individual level (Miller et al., 2002; Miller et al., in press). The individual differences in the patterns of activity were observed to be so extensive that one subject, for example, had significant activity in the dorsolateral regions of the prefrontal and parietal cortex while another subject had significant activity in the ventrolateral regions only. Yet, when we brought the subjects back for another session months later, the individual patterns of activity were relatively stable, indicating that a significant portion of the variance between individuals was not due to random fluctuations of noise. We replicated this finding in a recent fMRI study that compared individual patterns of brain activity across repeated sessions (Miller et al., in press). As shown in figure 50.1, the patterns of activations and deactivations were quite unique from individual to individual. Yet the individual patterns of activity persisted over an extended period of time (in this case, between 2 and 4 months). This stability indicated that the variations observed between individuals were not due to random fluctuations, but represented some systematic differences between individuals that were greatly affecting the pattern of brain activity across the whole brain. It has been our observation across several studies of episodic memory that the group maps are not representative of the patterns of activations occurring at the individual level.

The dangers of averaging across subjects

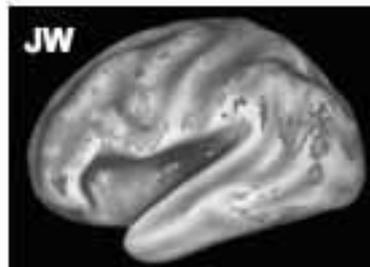

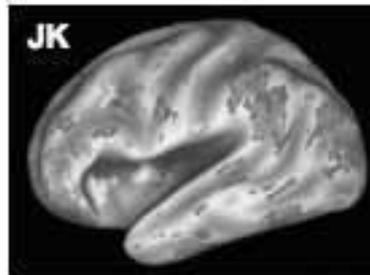

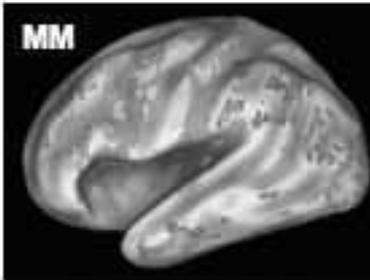

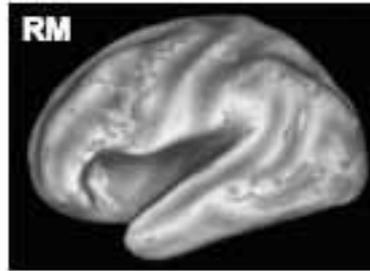

Within the field of psychology, there have been numerous examples over the years of erroneous conclusions based

Random effects group map

Contrast between recognition trials and baseline ($p < .001$ u.c.)

Session 1

Session 2

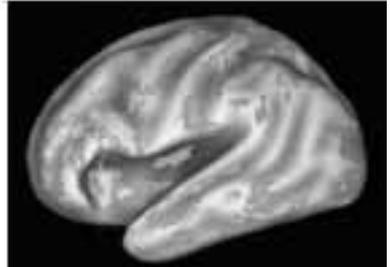

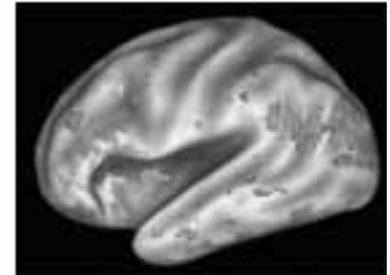

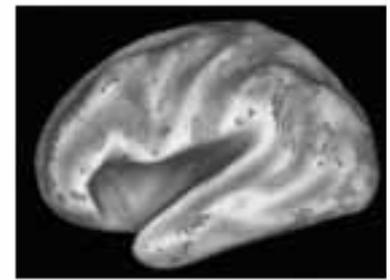

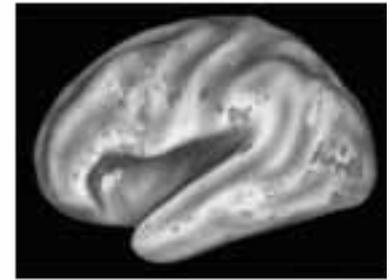

FIGURE 50.1 The left hemisphere patterns of activations and deactivations during an episodic retrieval task for the group and for 4 of the 14 individuals that made up the group. The random-effects group map and the individual t -maps are a contrast between the retrieval condition and baseline, statistically thresholded at $p < .001$ uncorrected for multiple comparisons. The thresholding

was done for visualization purposes only. Displayed for each individual is the t -map for the first and second sessions. The images are representative of the high degree of variability between individuals, yet the relative stability in the individual patterns of activity over time. (From Miller et al., in press.) (See color plate 61.)

on averaged data. In one compelling example, Gallistel, Fairhurst, and Balsam (2004) demonstrated in a basic animal learning paradigm that the negatively accelerated, gradually increasing learning curve (a basic assumption of most learning theorists) is an artifact of averaging across individuals. Using conditioned responses in pigeons (pecking a key), Gallistel and colleagues effectively showed that learning

within individual birds was actually abrupt and steplike. An abrupt and steplike learning process is a fundamentally different psychological process from a gradual learning process over time. William Estes recently noted that, whereas a model built on group data can illustrate real trends, it can be a poor fit to individual data, and it can be a major source of distortion. In discussing the efforts of a number of inves-

tigators in the 1950s to raise awareness about the dangers of group data, Estes wrote, "It is not easy, however, to change the habits of people who are comfortable with traditional ways of doing things, and developers of cognitive models have continued to rely for support mainly on the fitting of functions such as curves of learning, retention, and generalization to averaged data" (Estes, 2002, p. 6).

The issue of relying on commonalities across individuals has also been debated repeatedly in the fields of neurology and neuropsychology for over a century (Caramazza, 1986; Sokol, McCloskey, Cohen, & Alimonsa, 1991; Robertson, Knight, Rafal, & Shimamura, 1993). In the mid-1800s, Paul Broca argued that speech production could be localized to the third convolution of the left inferior frontal gyrus by examining the common area of damage across a group of patients exhibiting similar speech production deficits. At the same time, however, another neurologist, John Hughlings Jackson, argued against a centralized region for speech based on his observations of wide variations in the extent and location of damage in patients exhibiting similar aphasic symptoms and wide variations in symptoms in patients with similar damage. Contrary to Broca, Jackson proposed that speech was a widely distributed function within the brain (Critchley & Critchley, 1998). Of course, Broca's view held sway for the next century and eventually led to models of language, such as the Wernicke-Geschwind model, that relied on these distinct and localized modules of language function. However, more recent studies have suggested that, although this classic brain-language model is useful as a heuristic, it is empirically wrong because it cannot account for the range of aphasic symptoms, it is underspecified linguistically and anatomically, and it does not take into account the extensive individual variability in symptoms of brain-damaged patients and in the location and extent of their damage (Benson, 1985; Poeppel & Hickok, 2004). For example, Nina Dronkers (1996) reported on 22 patients with lesions in Broca's area with only 10 having Broca's aphasia. Ojemann, Ojemann, Lettich, and Berger (2008) reported on cortical stimulation during neurosurgery of 117 patients and found that language disruption occurred in individualized mosaics of cortex with substantial variability in the location of these mosaics, some of which correlated with sex and intelligence. It is clear that, on one hand, localizing brain functions by isolating common areas of brain damage across patients with similar deficits has been useful and, to a certain extent, necessary given that brain damage is rarely confined to one specific functional region, and that reliance on case studies can "sacrifice generalizability, predictability, and the possibility of refutation" due to subject variability (Robertson et al., 1993, p. 716). On the other hand, case-study-by-case-study approaches can accomplish a similar winnowing and modeling of function/brain relationships while preserving much of the information that is at the indi-

vidual level but lost in a group average (Caramazza, 1986; Sokol et al., 1991).

Individual differences and neuroimaging

Neuroimaging faced a similar issue in its early years. Marc Raichle has commented that many of the early researchers worried that the creation of group maps by averaging neuroimaging data across subjects would greatly diminish the signal due to inherently high individual variability (Raichle, 1997). Yet those early studies reliably demonstrated retinotopic mapping of the primary visual cortex (Fox et al., 1986), as well as mapping of higher-order association areas (Petersen, Fox, Posner, Mintun, & Raichle, 1988), using group maps. Since that time, group maps have become much more sophisticated and population-based, and more emphasis has been placed on them given the struggle to overcome the inherently low overall signal-to-noise ratio of neuroimaging data. It is interesting to note, however, that many vision researchers have reverted back to relying on individual data by retinotopically mapping individuals and testing hypotheses on an individual basis with many trials (Warnking et al., 2002). In addition, many researchers are relying on functional localizers in several tasks because of individual differences in the specific location of specialized regions within the brain (Saxe, Brett, & Kanwisher, 2006). We argue that a general reliance on group maps to represent the pattern of activity across the whole brain for a particular task needs to be reevaluated.

Few studies have attempted to systematically examine the individual variability of brain activity associated with a cognitive task. In general, most neuroimaging studies involving individual differences can be divided into four categories: (1) studies that correlate a particular behavioral performance with modulated activity in a specific brain region; (2) studies that divide subjects into smaller groups based on a behavioral measure and then look for differences in activations between the groups; (3) studies that look at the overlap of individual brain activations and variations of activity around a circumscribed region; and (4) studies that look at the degree to which group activations are reproducible. Each of these techniques has been reviewed previously (Miller & Van Horn, 2007), and each can be a useful analytical tool. For example, a convincing way to demonstrate the function of a given brain region is to show that the activity in that region is modulated by individual differences in behavior, as has been demonstrated in numerous neuroimaging studies from correlations of individual differences in procedural learning and the modulation of activity in the motor cortex (Grafton, Woods, & Tyszka, 1994) to individual differences in memory performance and modulation of the medial temporal lobe (Nyberg, McIntosh, Houle, Nilsson, & Tulving, 1996; Tulving, Habib, Nyberg, Lepage, & McIntosh, 1999). Some

of these studies have even considered the correlation between individual differences in memory-encoding strategies and particular brain regions or differences in the patterns of activity by grouping individuals by particular encoding strategies (Savage et al., 2001; Casasanto et al., 2002; Kirchoff & Buckner, 2006). Yet most of these studies still rely on a common area of activation across a group of subjects, and only a few studies to our knowledge consider the individual variability and reliability of activity across the whole brain volume (Heun et al., 2000; Machielsen, Rombouts, Barkhof, Scheltens, & Witter, 2000; Miller et al., 2002).

One notable exception was a study conducted by McGonigle and colleagues (2000). Although the study consisted of only a single subject, that subject participated in 33 scanning sessions and performed a simple motor, visual, and cognitive task in each session. The authors found that many voxels displaying significant session-by-condition interactions were not activated on average across all the sessions, and many of those that were activated using a fixed-effects analysis did not survive a random-effects analysis across sessions. The authors cautioned that single-session data from individuals may lead to erroneous conclusions. But a subsequent follow-up study by the same authors revealed that the intersession variability was no greater than the intrasession variability (Smith et al., 2005).

The effectiveness or ineffectiveness of group maps may depend on the intended use. For instance, group maps can be very effective when used as a tool to increase the signal-to-noise ratio in a study that is systematically examining some a priori brain region. Wagner and colleagues (1998), for example, utilized a group map to examine the BOLD response in the medial temporal lobe. They demonstrated that activity in the medial temporal lobe during an encoding task varied according to whether an item was subsequently recognized. This was a critically important study given that activation in the medial temporal lobe was conspicuously absent in most previous neuroimaging studies of episodic memory. Group maps used in this way can only aid our understanding of mind/brain relationships.

However, group maps can be a problem if they are meant to characterize or profile the pattern of activity across the whole brain for a given task. For example, we conducted a study with the purpose of characterizing the pattern of activity associated with shifts of criterion on a recognition test (Miller, Handy, Cutler, Inati, & Wolford, 2001). We published several group maps, including one meant to characterize activity during blocks of recognition trials compared to blocks of fixation trials. The results of a group analysis revealed activations associated with recognition in discrete regions of the dorsolateral prefrontal and parietal cortex. However, a subsequent analysis revealed that the group map was not representative of a pattern of activations in many of the individual subjects (Miller et al., 2002). In the end, using

group maps to profile patterns of activity may be more appropriate for some cognitive tasks and not others. For example, some cognitive tasks may engage a more restricted set of brain regions that vary little from subject to subject than does an episodic retrieval task. In general, though, we think caution should be used when employing a group map to characterize patterns of activity across the whole brain for a given task. Does a group map represent the patterns of activations for the individuals that make up the group? For episodic retrieval tasks, the answer is no.

Quantifying the degree of similarity between two patterns of brain activity

It is clear from viewing the thresholded activation maps shown in figure 50.1 that there is enormous variability from individual to individual, but we needed a method to quantify those differences. Furthermore, we needed a method that did not rely on the arbitrary setting of a statistical threshold. So we devised a method to simply cross-correlate the unthresholded image volumes across subjects and sessions (Miller et al., 2002). If one takes a three-dimensional volume of continuous values in each voxel and correlates that volume with another three-dimensional volume of continuous values in the same voxel matrix and atlas space, then the result will be a single correlation value that represents how similar the two volumes are. A similar correlational approach has been used with smaller patches of cortex in pattern classification studies of object recognition (Haxby, 2004; Norman, Polyn, Detre, & Haxby, 2006). In our original study (Miller et al., 2002) we correlated volumes of raw signal intensity values, but those correlations may have been sensitive to individual differences in basic physiology, such as individual differences in vasculature and individual differences in the timing of the BOLD response. In order to attenuate those particular differences in physiology in recent studies, we correlated volumes containing unthresholded t -values (t -maps) derived from the contrast between task trials and baseline within each individual (Miller et al., in press) and masked (with masks derived from the group analysis) to exclude extra-brain voxels. This method provides a convenient measure of the degree of similarity between any two volumes of brain activity.

Using this method, we are able to quantify the observation that individual brain activity during the episodic retrieval task is quite variable from individual to individual, yet it is also relatively stable over time. In one of our recent studies, we found that the average correlation between two volumes from the same subject performing the same episodic retrieval task but in different sessions separated by 2 to 4 months was $r = .435$. This was significantly higher than the average correlation between two volumes from different subjects performing the same task, which was $r = .218$ (Miller et al.,

in press). The relative stability of the individual patterns of activity over long periods of time suggested that unique individual activations were not necessarily noise but instead were likely to reflect cognitive processing that was unique to the individual and was related to how the individual performed the task and/or other unique physiological properties related to that individual. The persistence of these uniquely individual patterns of activity should be viewed as an opportunity and not as a nuisance. The opportunity it affords us is the ability to explore the fundamentally different ways we remember past events and the unique brain regions we recruit to accomplish that task.

The inherently variable nature of episodic memory and the brain regions underlying it

Episodic memory “stores and makes possible subsequent recovery of information about personal experiences from the past. It enables people to travel back in time, as it were, into their personal past, and to become consciously aware of having witnessed or participated in events and happenings at earlier times.” (Tulving, 1989, p. 362). However, the methods used to probe episodic memory experimentally, such as a standard recognition test, utilize not only bits of information from episodic memory but bits of information from other systems as well, such as semantic memory. As Endel Tulving once wrote, “It is probably as difficult to find ‘pure’ episodic-memory tasks and ‘pure’ semantic tasks as it is to find sodium and chlorine as free elements in nature, although their compound, NaCl, is found in abundance” (Tulving, 1983, p. 55). A “remembered” response on a recognition test can be influenced by a variety of nonepisodic processes like semantic associations (Underwood, 1965), schematic reconstructions (Brewer & Treyns, 1981; Miller & Gazzaniga, 1998), perceptual fluency (Jacoby & Dallas, 1981), shifting criterion (Miller & Wolford, 1999), and so on (for reviews see Roediger, 1996; Schacter, 1999).

Further, episodic memory is widely distributed throughout the cortex, with different regions storing different aspects of the complete memory trace (Squire, 1987). It relies on an extensive hippocampal-cortical network for the consolidation, storage, and utilization of information, and the hippocampus is not involved in the permanent storage of information per se, but rather serves to facilitate consolidation of a distributed cortical memory trace (Squire et al., 1992; Wittenberg & Tsien, 2002; but see also Nadel & Moscovitch, 1997). A principal characteristic of this distributed network is that it affords the rapid and flexible formation of multimodal memories. In addition to widely distributed information, there is also a broad network of specialized brain regions that are influential in, but not necessary for, the completion of the task. After all, only damage to the medial temporal lobe causes severe amnesia

(Squire, Stark, & Clark, 2004; Eichenbaum, Yonelinas, & Ranganath, 2007). Many memory researchers have suggested that prefrontal and parietal areas support episodic memory with cognitive processes peripheral to the actual retrieval process, with evidence derived from brain-damaged patient studies (Incisa della Rocchetta & Milner, 1993; Janowsky, Shimamura, Kritchevsky, & Squire, 1989; Petrides, 1996; Ranganath, Johnson, & D’Esposito, 2003; Knight, 1991) and neuroimaging studies (Nyberg et al., 1995; Buckner, Koustaal, Schacter, Wagner, & Rosen, 1998; Rugg et al., 1998; Fletcher, Shallice, Frith, Frackowiak, & Dolan, 1998; Cabeza et al., 2003; Nolde, Johnson, & D’Esposito, 1998; Henson, Shallice, & Dolan, 1999; Dobbins, Rice, Wagner, & Schacter, 2003). One potential implication of this architecture is that one and the same behavioral outcome—such as an “old” response on a recognition test—could be based on a distinct set of information and a distinct combination of neural circuits in two different individuals.

Therefore the emerging picture of the neural basis of episodic retrieval is that it comprises several distinct brain regions and that these distinct brain regions may be engaged differentially depending on unique individual strategies and demands. There is substantial evidence that people will employ a multitude of strategies during the encoding and retrieval phases of a standard memory task (Stoff & Eagle, 1971; Battig, 1975; Weinstein, Underwood, Wicker, & Cubberly, 1979; Paivio, 1983; Reder, 1987; Graf & Birt, 1996). There is also substantial evidence from neuroimaging studies that individual differences in memory strategy can alter which brain regions become activated (Savage et al., 2001; Casasanto et al., 2002; Speer, Jacoby, & Braver, 2003; Kondo et al., 2005; Tsukiura, Mochizuki-Kawai, & Fujii, 2005). One notable study (Kirchoff & Buckner, 2006) identified the various strategies people adopt during an unconstrained encoding of unrelated pairs of pictures. They found that two strategies in particular, verbal elaboration and visual inspection, correlated with memory performance and with brain activity in distinct regions: verbal elaboration correlated with activity in prefrontal regions associated with controlled verbal processing, whereas visual inspection correlated with activity in the extrastriate cortex.

The variable, unconstrained, and widely distributed nature of brain activity during an episodic retrieval task is particularly evident in the reported sites of activations across studies when compared to the reported sites of activations from other tasks, such as semantic retrieval. Cabeza and Nyberg (2000) categorized hundreds of neuroimaging studies by cognitive domain and then plotted the reported sites of activations for each study within each cognitive domain as a point on a glass brain. A cursory review of their findings reveals a general consistency in the localization of activity across studies for most of the cognitive domains, but not for episodic retrieval. Even in more constrained versions of

the task, the reported sites of activation were widely distributed throughout the cortex. However, the reported sites of activations for other tasks appear to be more concentrated in discrete regions of the cortex. This pattern may result from cognitive processing that is more constrained in general during a controlled semantic retrieval task, for example, than during an episodic retrieval task. Controlled semantic retrieval is known to unambiguously engage the left ventrolateral prefrontal cortex (Wagner, Pare-Blagoev, Clark, & Poldrack, 2001). For this task, the divergence of brain regions that any particular individual is likely to engage in order to accomplish the task may be relatively small.

We recently found that the topographical pattern of brain activity during an episodic retrieval task (subjects responded “old” or “new” to previously studied words) was significantly more variable between individuals than a semantic retrieval task (subjects responded “abstract” or “concrete” to words similar to the episodic task) or a working memory task (subjects responded “match to three trials back” or “no match” to a sequence of letters) (Miller et al., 2002). Further, by examining the variance across individuals on a voxel-by-voxel basis, we found that the variance in activity during an episodic memory task occurred throughout the whole cortex, whereas the variance in activity during a semantic memory task and a working memory task occurred in much more discrete regions of the cortex (see figure 50.2). However, some of the differences between tasks could be attributed to different demand characteristics. Also, there is no reason to assume that a task like working memory could not have some of the same properties (the variable and strategic engagement of widely distributed brain regions) as an episodic memory task. Future research will need to determine the extent to which brain activity during an episodic memory task may be more variable than other cognitive tasks.

What makes us unique?

The opportunity afforded by an inherently strategic task like episodic retrieval and the brain activity underlying it is that it provides a lot of useful information at the individual level that may enhance our understanding of episodic memory in general. Our previous results indicate that a large portion of the variance in brain activity from individual to individual is not necessarily random and that some factor or factors must be accounting for the variance systematically (Miller et al., 2002, in press). In order to understand the sources of this variability, we have recently focused on three general categories of factors: (1) situational differences; (2) anatomical/physiological differences, and (3) cognitive/psychological differences.

In a recent study (Miller et al., in press), we investigated some of these possible sources of individual variability during an episodic retrieval task. During the episodic retrieval task,

subjects simply made an “old/new” recognition judgment to words, some of which were previously studied. Fourteen subjects were scanned in two sessions separated by 2 to 4 months. After cross-correlating the *t*-maps from a recognition versus baseline contrast across subjects and sessions, the correlation values were then submitted to a hierarchical regression analysis in order to determine whether certain factors could account for the degree of similarity between subjects. In this study, we had a limited number of factors, but they included anatomical similarity, memory performance (*d'*), reaction time, and retrieval strategy (as measured by a decision criterion). The placement of a decision criterion during a recognition test is often the result of a general strategy or bias (Murdock, 1974; Ratcliff, Sheu, & Gronlund, 1992; Miller & Wolford, 1999). For example, some subjects may have responded “old” to a test item only if they were absolutely certain they encountered the item during the study session (maybe based on some clear visual recollection). The criterion measures from those subjects would have tended to be conservative. For example, in a debriefing after the scanning session, one subject stated, “I only said ‘recognize’ when I was pretty certain,” and her criterion measure reflected a conservative strategy ($C = +.46$). Other subjects may have simply responded “old” to any item that seemed familiar to them regardless of whether or not they had a clear recollection of the item in the study session. For example, another subject stated, “The recognition test was kind of hard, but I would just press ‘yes’ if the words seemed familiar.” Her criterion measure ($C = -.23$) reflected a much more liberal strategy, one based more on familiarity. One of the key findings of this study was that only the difference in criterion values between two subjects was predictive of the similarity in their patterns of brain activity. No other factor was predictive. Therefore, the more similar two individuals’ retrieval strategy was, the more similar was their pattern of brain activity during an episodic memory task.

A number of encoding and retrieval strategies have been identified, decision criterion placement being just one example. The most extensively studied strategy, however, has been elaboration, including both imaginal elaboration (mental imagery) and verbal elaboration (Paivio, 1971). For example, some people (who could be called verbalizers) are better at processing words and may rely on semantic associations and verbal content when remembering a past event, while other people (who could be called visualizers) are better at processing pictures and may rely on visual imagery and visual recollections when remembering a past event. To test whether the tendency or preference of a person to think visually or verbally is related to the observed variability in an episodic memory task, we conducted a study in which 20 subjects studied lists of highly imageable words, which allow for both verbal and visual elaboration (Donovan & Miller, 2008). Participants were simply

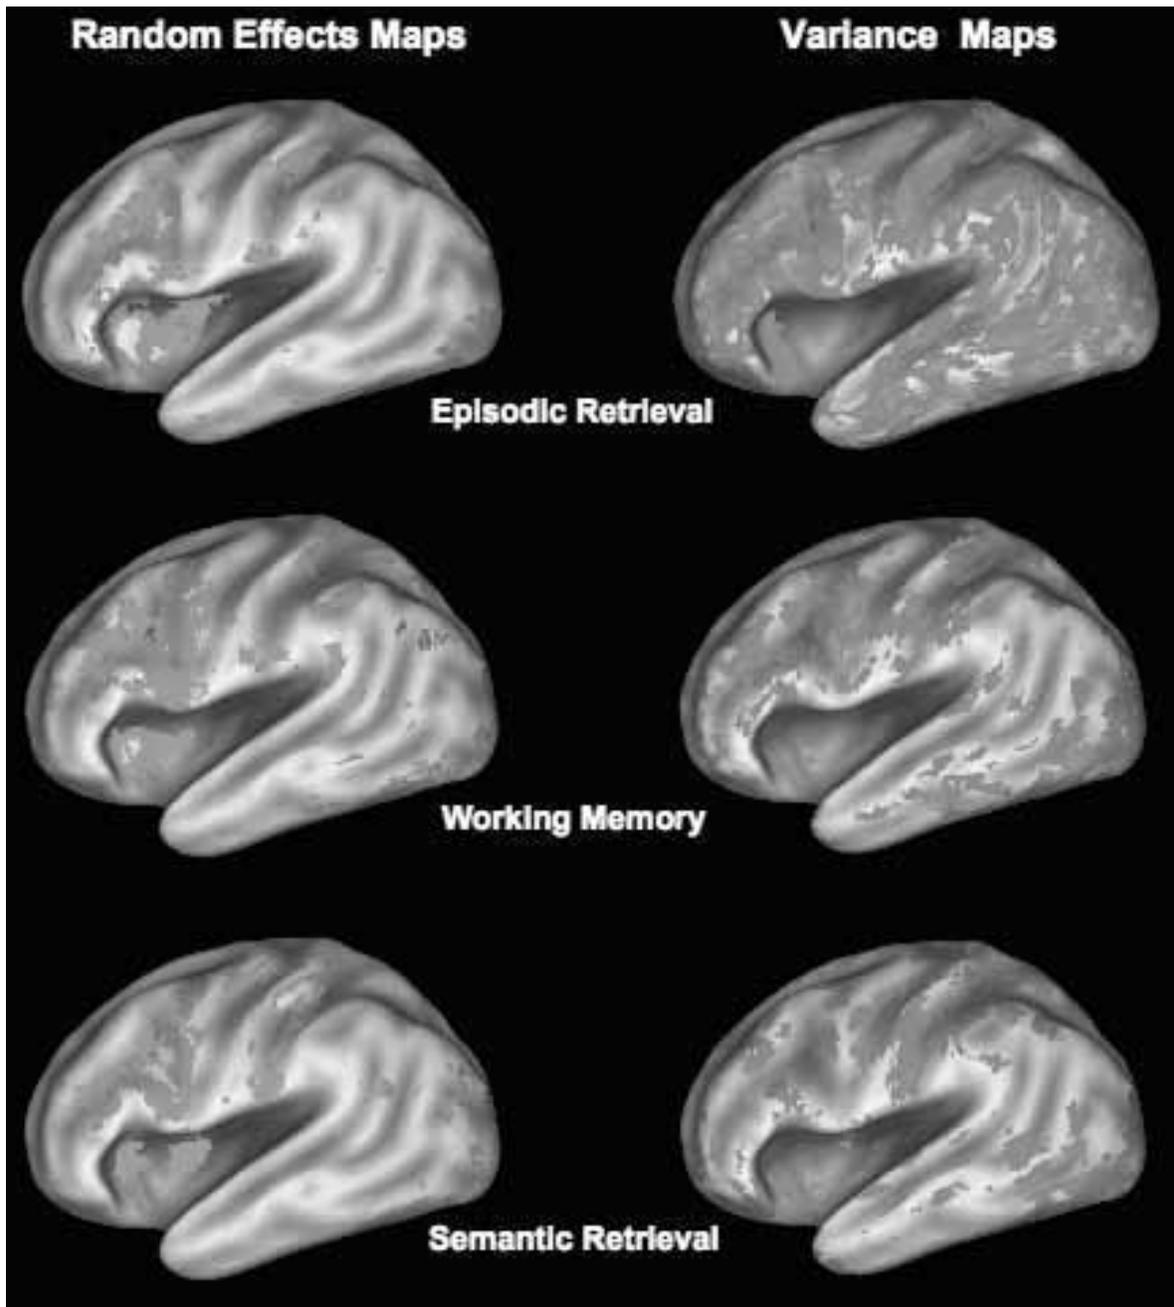

FIGURE 50.2 A comparison of random-effects group maps and variance maps across three memory tasks. The random-effects maps are a statistically thresholded ($p < .001$ uncorrected for multiple comparisons) representation of the common areas of brain activity across 14 individuals. The variance maps to the right

display the standard deviations across the 14 individuals at each voxel above a threshold of 2 standard deviations. As the variance maps indicate, individuals variably engaged much wider regions of the cortex during episodic retrieval than during semantic retrieval or working memory. (See color plate 62.)

instructed to learn the words for a later recognition memory test and hence were free to choose whatever strategy came most naturally. During the episodic retrieval task, subjects simply made an “old/new” recognition judgment of the words, half of which were previously studied. In a hierarchical regression analysis, we included several factors to assess their relative contribution to the observed variabil-

ity: anatomical similarity, connectivity similarity (measured by computing fractional anisotropy maps from DTI images), default mode network similarity, encoding strategy, visualizer/verbalizer trait factor scores, and performance measures. As predicted, we found that the more similar two individuals’ tendency to visualize, the more similar their patterns of brain activity.

In this same study, we also assessed whether differences in the default mode network between individuals might also be related to the similarity of their activity patterns during an episodic memory task. We computed functional connectivity for three seed regions from functional data collected while the subjects were at rest. Coherence maps were constructed by computing the coherence of the time series of each voxel with that of seed regions in the posterior cingulate/precuneus (PCC), the ventral anterior cingulate cortex (vACC) (Greicius, Krasnow, Reiss, & Menon, 2003), and the hippocampal formation (Vincent et al., 2006). Interestingly, we found that similarity in coherence maps predicted similarity in functional activity during retrieval but not during encoding. Schacter, Addis, and Buckner (2008) have made the suggestion that the default mode network may serve as a simulator of past and future events, which would explain why the relationship between coherence maps and functional activity occurs during the retrieval task but not during the encoding task.

Table 50.1 lists some of the factors that have been found across several studies to be related to the degree of similarity between any two individuals' brain activity patterns. In

terms of situational factors, circumstances of the experimental setup can play a major role in the degree of similarity in brain activity between individuals. Two of the strongest factors are the experimental design and the stimulus type. We have found that the difference between a blocked design and event-related design can account for 40% of the variance in correlation values, with brain activity from a blocked design being much less variable between individuals than an event-related design. We have also found that stimulus type can account for 28% of the variance, with brain activity associated with remembering faces being much less variable between individuals than brain activity associated with remembering words. These are remarkably strong factors given that the difference between memory tasks discussed earlier accounted for only 8% of the variance. Another key situational factor is constraining the task. We recently found that making the recollection of a studied item easy to recall resulted in much less variability between individuals than when the recollection of a studied item is more difficult. All of these situational factors must be carefully controlled or accounted for when considering the influence of individual difference factors.

TABLE 50.1
Factors that are related to the degree of similarity between any two brain volumes of activity during an episodic memory task

Factors Related to Variability in Brain Activity	ΔR^2
Situational Factors	
Experimental design: blocked or event-related	40%
Stimulus type (faces or words)	28%
Different sessions	n.s.
Different tasks	8%
Task difficulty	5%
Individual Differences in Physiology and Anatomy	
Structural anatomy	n.s.
Default mode network (coherence maps)	4%
White matter connectivity (fractional anisotropy)	7%
Individual Differences in Cognition and Information Processing	
Retrieval strategy (criteria)	8%
Memory performance (d prime)	n.s.
Reaction time	n.s.
Tendency to visualize	5%
Tendency to verbalize	n.s.
Individual Deviations Unaccounted For	16–44%

Data from Miller et al., in press; Donovan & Miller, 2008; Guerin & Miller, 2009. ΔR^2 values are from hierarchical regression analyses conducted in each study with the variables entered in the order noted on the table. Not all variables were represented in each study. The values varied considerably from study to study, with representative values listed here. Factors with "n.s." were not significant in any of the studies.

In terms of individual differences in physiology and anatomy, we have found that similarity in white matter connectivity and in the default mode network are both factors, but not individual differences in structural anatomy. Although all brain volumes are spatially normalized before being analyzed, there still exists a considerable difference between individuals in the orientation and precise location of cortical landmarks. Yet those anatomical differences are not predictive of functional activation differences. As for individual differences in cognition and information processing, it is becoming clear in our studies using episodic memory tasks that individual differences in strategy have a significant effect, but not individual differences in memory performance and accuracy. Much work still needs to be done to determine the full range of factors that contribute to the individual variability. This need is evident in the last factor that is listed in table 50.1. In all our hierarchical regression analyses we include dummy variables for each individual. These dummy variables are always entered last after accounting for all the other individual difference factors. Yet these individual variables still account for around 40% of the variance, suggesting that some individuals are more deviant from the group than others and that we have yet to find the factors that account for that fact.

It should also be noted that many of the factors that distinguish individuals on an episodic memory task may also distinguish those individuals on other tasks as well. We found in the study comparing activity across three different memory tasks (an episodic retrieval task, a working memory task, and a semantic retrieval task) that the brain activity of an individual performing an episodic retrieval task is more similar on average to that same individual performing an entirely different task than it is to a different individual performing the same episodic retrieval task (Miller et al., in press).

Conclusion

Individuals vary enormously in their patterns of brain activity. This variability is particularly widespread during an episodic memory task, and it extends across most of the cortex. These fluctuations in activity between individuals are not random because they are relatively stable over time. Furthermore, we have been able to account for significant portions of this variability, including differences in white matter connectivity and differences in strategy. A clear and full understanding of all the sources of variability between individuals will be necessary in order for us to determine whether a pattern of brain activity observed during a memory task is truly reflective of that individual's thoughts and traits. It will be critical for future neuroimaging studies of episodic memory to explore what makes us unique as well as to explore what we have in common.

51 Constructive Memory and the Simulation of Future Events

DANIEL L. SCHACTER, DONNA ROSE ADDIS, AND RANDY L. BUCKNER

ABSTRACT Memory is widely conceived as a fundamentally constructive rather than purely reproductive process. One well-known source of evidence for constructive remembering is provided by various kinds of memory errors and illusions. A second line of evidence, which has recently emerged into the forefront of cognitive neuroscience, concerns the processes involved in imagining or simulating future events and novel scenes. In this chapter we discuss recent studies using various patient populations and neuroimaging techniques to examine future-event simulation and its relation to episodic memory, and we also link this research with earlier studies of constructive memory. Converging evidence supports the idea that imagining possible future events depends on much of the same neural machinery as does remembering past events, which we refer to as the core network. We consider conceptual and theoretical issues raised by this work, and also discuss adaptive functions of future-event simulation and related processes in the context of a constructive approach to memory.

The first notion to get rid of is that memory is primarily or literally reduplicative, or reproductive. In a world of constantly changing environment, literal recall is extraordinarily unimportant . . . memory appears to be an affair of construction rather than reproduction.

—Bartlett, 1932, pp. 204–205

When Sir Frederic Bartlett drew on experimental observations of errors and distortions in recall of complex stories to argue that memory is a fundamentally constructive process, his claims had little influence on his contemporaries. Psychological research on memory at the time was dominated by studies of rote learning in simple paired-associate paradigms; Bartlett's methods and theories made little sense in the context of the prevailing behaviorist zeitgeist. Several decades passed before Bartlett's ideas about constructive memory, revived by

the publication of Neisser's (1967) seminal analysis of constructive processes in perception and memory, began to receive support from cognitive studies during the 1970s (for historical reviews, see Roediger, 1996; Schacter, 1995). Since that time, overwhelming cognitive evidence has accumulated in favor of Bartlett's claim that memory is "an affair of construction rather than reproduction" (for overviews, see Brainerd & Reyna, 2005; Loftus, 2003; Schacter, 1996, 2001).

When we turn to the cognitive neuroscience of memory, the situation looks a bit different. While cognitive neuroscientists have not opposed the idea that memory involves constructive processes, sustained interest in constructive aspects of memory has developed only recently. Of course, neurologists and neuropsychologists have long been interested in the phenomenon of confabulation, where patients with damage to various regions within prefrontal cortex and related regions produce vivid but highly inaccurate "recollections" of events that never happened. Clinicians have produced striking clinical reports of confabulation (e.g., Talland, 1961), and more recently a number of investigators have approached the phenomenon experimentally (for review, see Schnider, 2008). During the past decade, investigations of memory distortions in other patient populations, as well as neuroimaging studies of accurate versus inaccurate remembering in healthy individuals, have greatly increased our understanding of the cognitive neuroscience of constructive memory (Schacter, Norman, & Koutstaal, 1998; Schacter & Slotnick, 2004).

Even more recently—during just the past few years—there has been a dramatic increase in research on a related topic that also illuminates the constructive nature of memory: the role of memory in imagining or simulating possible future events (cf., Buckner & Carroll, 2007; Buckner, Andrews, & Schacter, 2008; Schacter, Addis, & Buckner, 2007, 2008; Suddendorf & Corballis, 2007). Evidence has rapidly accumulated to support the idea that memory—especially episodic memory, the system that allows individuals to recollect past events—is also critically involved in our ability to imagine future happenings and carry out related kinds of mental simulations. Furthermore, brain regions traditionally identified with memory, including the hippocampus, are similarly engaged when people carry out various

RANDY L. BUCKNER Department of Psychology, Center for Brain Sciences, Harvard University, Cambridge, Massachusetts; Athinoula A. Martinos Center for Biomedical Imaging, Massachusetts General Hospital, Charlestown, Massachusetts; Howard Hughes Medical Institute, Cambridge, Massachusetts

mental simulations. These investigations have provided new evidence concerning constructive processes in memory and may even provide clues concerning the functions of such constructive processes (Hassabis, Kumaran, & Maguire, 2007; Schacter & Addis, 2007a, 2007b).

One important impetus for this new wave of research emerged from claims made by Tulving (1983, 2002) that episodic memory supports “mental time travel” in both the past and the future. Tulving, influenced by prior related ideas from the Swedish neuroscientist David Ingvar (1979, 1985; for further discussion, see Buckner & Carroll, 2007; Schacter et al., 2008), suggested that mental time travel supports “autonoetic,” or self-knowing, consciousness, which allows individuals to view themselves as temporally extended entities whose present awareness is influenced by the recollected past and imagined future.

During the 1990s, these ideas about mental time travel became associated with discussions concerning whether this capacity is unique to human beings or whether nonhuman animals also possess some form of autonoetic consciousness that allows them to revisit the past and anticipate the future. Suddendorf and Corballis (1997, 2007) and Tulving (2002, 2005) have both argued forcefully that mental time travel is restricted to human beings. While both Tulving (2002, 2005) and Suddendorf and Corballis (1997, 2007) allow that nonhuman animals can use semantic or procedural memory systems to gain access to stored information, they assert that such processes need not involve either recollecting a past event or using mental simulation to “preexperience” a future event—the essence of mental time travel.

This strong claim has spurred considerable debate (see Clayton, Bussey, & Dickinson, 2003, and commentaries on Suddendorf & Corballis, 2007) and will likely be difficult to resolve definitively owing to limitations on our ability to assess inner experience in nonhumans, which is central to the concept of mental time travel. Some compelling experimental demonstrations, at the very least, cast doubt on the strong claim for human uniqueness. For example, Clayton and Dickinson (1998) showed that food-caching scrub jays are able to retrieve detailed information about what food they cached as well as when and where they cached it, and Raby, Alexis, Dickinson, and Clayton (2007) have shown that conditions exist in which jays cache food in a way that appears to indicate some type of planning for the future. In a related line of research with rodents, several investigators have provided evidence indicating some of type of prospective coding, including evidence that hippocampal neurons encode not only a rat’s current location and recent memory, but also encode prospective information concerning where the rat needs to go in the immediate future (Diba & Buzsáki, 2007; Ferbinteanu & Shapiro, 2003; Foster & Wilson, 2006; A. Johnson & Redish, 2007; Pastalkova, Itskov, Anavasingham, & Buzsáki, 2008). Whether or not

such observations indicate the occurrence of mental time travel in rats, they do suggest that the hippocampus may provide prospective signals that could be used as a basis for making decisions.

Perhaps overlooked in the intensive discussion over whether animals can engage in mental time travel is that relatively little is known about how humans use memory to imagine or simulate future events. Although cognitive neuroscience has made much progress in delineating the nature of remembering, it has barely scratched the surface in studying how memory is used to imagine future events and to engage in related forms of mental simulation. The upsurge in relevant research during the past few years has begun to rectify the situation. In this chapter, we will focus on recent cognitive neuroscience research that has examined relations among memory, imagination, and future-event simulation.

Imagining future events: Findings and ideas

Insights into the nature of future-event simulation have been gained by cognitive studies of healthy young adults and memory-impaired populations, and more recently by neuroimaging studies. In the present chapter, we focus on memory-impaired populations and neuroimaging studies (for more general reviews, see Buckner et al., 2008; Schacter et al., 2008).

STUDIES OF FUTURE-EVENT SIMULATION IN MEMORY-IMPAIRED POPULATIONS We consider here three memory-impaired populations in which future-event simulation has been examined: amnesic patients, older adults, and psychopathological populations.

Amnesic patients It is well-established that the amnesic syndrome resulting from damage to the medial temporal lobes and related structures is associated with a severe impairment in the ability to remember past experiences (see chapter 46 by Shrager and Squire, this volume). Early clinical observations (Talland, 1965) suggested that amnesic patients might also have problems envisioning their personal futures and planning for upcoming events. Tulving (1985) reported that the densely amnesic patient KC, who cannot remember any specific episodes from his past (for a review of KC, see Rosenbaum et al., 2005), exhibits similar problems envisioning any specific episodes in his future (Rosenbaum, Gilboa, Levine, Winocur, & Moscovitch, in press; Tulving, 1985; Tulving, Schacter, McLachlan, & Moscovitch, 1988). Note, however, that KC is characterized by fairly extensive brain damage, including damage to medial temporal, prefrontal, and other regions (see Rosenbaum et al.), thereby limiting the specificity with which his problems remembering the past or imagining the future can be associated with particular brain regions. A similar issue applies to a later and more

systematic study by Klein, Loftus, and Kihlstrom (2002) concerning patient DB, who became amnesic as a result of cardiac arrest and consequent anoxia. DB showed marked deficits on a 10-item questionnaire probing past and future events that were matched for temporal distance from the present (e.g., “What did you do yesterday? What are you going to do tomorrow?”). The patient’s deficit in simulating future events appeared to involve only his personal future, since DB showed little difficulty imagining possible future happenings in the public domain, such as political events.

More recently, Hassabis, Kumaran, Vann, and Maguire (2007) examined the ability of five patients with documented bilateral hippocampal amnesia to imagine novel experiences, such as “Imagine you’re lying on a white sandy beach in a beautiful tropical bay.” The experimenters scored the constructions of patients and controls based on the content, spatial coherence, and subjective qualities of the imagined scenarios. Four of the five hippocampal patients produced constructions that were significantly reduced in richness and content compared with those of controls, especially for the measure of spatial coherence. The single patient who performed normally on the imaginary scene task was characterized by some residual hippocampal tissue. Because the lesions in the other cases appear to specifically include the hippocampal formation, this study strengthens the link between event simulation and hippocampal function. Note, however, that Hassabis and colleagues did not specifically require participants to imagine *future* events, indicating that the amnesic patients suffer from an impairment in event simulation that is not restricted to a particular time interval.

Older adults It is well known that healthy older adults exhibit a variety of episodic memory deficits (e.g., Craik & Salthouse, 2000), but little is known about future-event simulation in aging. Addis, Wong, and Schacter (2008) recently investigated the issue. They noted earlier work showing that aging is associated with reduced specificity during the recall of past autobiographical episodes. Levine, Svoboda, Hay, Winocur, and Moscovitch (2002) reported such age-related changes in the episodic quality of past events using the Autobiographical Interview (AI), a measure that distinguishes episodic information from other “external” details (e.g., semantic information, other external events, repetitions) that comprise a participant’s description of a past event. Levine and colleagues observed that older adults recalled significantly fewer internal/episodic details and tended to produce more external/semantic information.

Addis, Wong, and Schacter (2008) used an adapted version of the Autobiographical Interview that required young and older participants to generate memories of past events and simulations of future events in response to individual word cues. They allowed participants three minutes to describe each episode, and transcriptions of the events

were segmented into distinct details that were classified as either internal (episodic) or external (semantic). The key finding was that older adults generated fewer internal details than younger adults; importantly, this effect was observed to the same extent for future events as for past events. By contrast, older adults showed small but significant increases relative to young adults in the production of external details for both past and future events. Furthermore, there were strong positive correlations across past and future events for both internal and external detail scores, whereas internal and external detail scores were not correlated with one another. Finally, the internal (but not external) detail score correlated significantly with a measure of relational memory (paired-associate learning), known to be dependent on the hippocampus, a point to which we will return later when discussing theoretical accounts of future-event simulation. Overall, the results reveal a strong link between remembering the past and imagining the future in older adults. These findings dovetail nicely with observations from Spreng and Levine (2006), who reported similar temporal distributions for past and future events in aging: when remembering past events or imagining future events that are likely to happen, both older and younger adults generated the highest number of events near the present, with the frequency declining as a function of time in a manner well described by a power function.

Psychopathological populations A growing number of studies have examined future-event simulation in patients with various forms of psychopathology. We have reviewed this literature in detail elsewhere (Schacter et al., 2008) and summarize several key findings here. Williams and colleagues (1996) reported a seminal study in which they found that suicidally depressed patients have difficulty recalling specific memories of past events and also in generating specific simulations of future events. Compared to nondepressed controls, the past and future events generated by depressed patients in response to cue words lacked specific detail and thus were characterized as “overgeneral”; these reductions in specificity of past and future events were significantly correlated. Similar findings have been reported in milder forms of depression (e.g., Dickson & Bates, 2005; MacLeod, Rose, & Williams, 1993) and also in anxious individuals (Stöber & Borkovec, 2002).

Williams and colleagues (1996) found that past and future events generated by suicidally depressed patients were overgeneral for both positive and negative events. However, others have reported effects of valence. For instance, MacLeod and colleagues (1993) found that suicidally depressed patients were less able to envision *positive* future episodes (see also Dickson & Bates, 2006). Indeed, reduced access to positive future events correlates with the severity of hopelessness (MacLeod & Cropley, 1995), suggesting that

simulation deficits may help to maintain the sense of hopelessness that typically characterizes depression (for related neuroimaging research concerning neural correlates of optimism, see Sharot, Riccardi, Raio, & Phelps, 2007, and commentary by Schacter & Addis, 2007c). Similarly, increased access to simulations of negative future events is characteristic of anxiety disorders (e.g., MacLeod, Tata, Kentish, Carroll, & Hunter, 1997; Ruane, MacLeod, & Holmes, 2005).

Such observations in patients with depression and anxiety disorders have led to the proposal that the reduced specificity of autobiographical memories and future-event simulations reflects problems with affect regulation: patients produce overgeneral events because they truncate search or construction to protect themselves from experiencing potentially destabilizing memories or simulations (Williams, 1996, 2006). Recently, D'Argembeau, Raffard, and Van der Linden (2008) reported that schizophrenics generated significantly fewer specific past and future events than did healthy controls. Such findings are less likely to be attributable to the kinds of affect-regulation problems that occur in depression and anxiety. Moreover, the findings from depression, anxiety, and schizophrenia are quite similar to those considered earlier from amnesic patients and older adults.

Taken together, these observations encourage further consideration of the possible role of neuropsychological deficits that may contribute to the reduced specificity of events evident in both psychiatric and nonpsychiatric populations. For example, we have suggested (Schacter et al., 2008) that the aforementioned data from amnesic patients (and data to be considered shortly from neuroimaging studies) implicating the hippocampus in event simulation raise the possibility that hippocampal dysfunction might contribute to overgeneral simulations of past and future events. Hippocampal atrophy is evident in a number of psychiatric conditions in which simulation deficits have been documented, including depression (Bremner et al., 2000; Campbell & Macqueen, 2004) and schizophrenia (Velakoulis et al., 2006), and it also has been documented in older adults (e.g., Driscoll et al., 2003; Golomb et al., 1993). It is therefore possible that hippocampal dysfunction contributes to simulation deficits observed across these varied populations.

NEUROIMAGING OF FUTURE-EVENT SIMULATION During the past couple of years, several studies have used neuroimaging techniques to compare the neural correlates of imagining future events with those that characterize remembering past events. We first review key experimental findings and related observations before turning to some emerging conceptual issues.

Basic findings: The core network A consistent finding across studies has been that remembering the past and imagining

the future recruit a similar network of brain regions. Such findings were reported initially in an early positron emission tomography (PET) study from Okuda and colleagues (2003; see also Partiot, Grafman, Sadato, Wachs, & Hallett, 1995, for related early findings). During scanning, participants talked freely about either the near past or future (i.e., the last or next few days) or the distant past or future (i.e., the last or next few years). Similar levels of activation were observed during past and future conditions in several prefrontal regions, as well as in the medial temporal lobe (right hippocampus and bilateral parahippocampal gyrus). Note, however, that because Okuda and colleagues used a relatively unconstrained paradigm that did not probe participants about particular events, it is unclear whether these reports consisted of episodic memories and simulations (unique events specific in time and place) or general semantic information about an individual's past or future. More recent fMRI studies have used event-related designs to yield information regarding the neural bases of specific past and future events.

Szpunar, Watson, and McDermott (2007) instructed participants to remember specific events that occurred in their personal past, imagine specific future events that might occur in their personal future, or imagine specific events involving a familiar individual (Bill Clinton) in response to event cues (e.g., past birthday, retirement party). Consistent with previous observations, there was considerable overlap in activity associated with past and future events in the bilateral frontopolar and medial temporal lobe regions, as well as in posterior cingulate cortex. Note also that these regions were not activated to the same degree when participants imagined events involving Bill Clinton, seeming to demonstrate a neural signature that is unique to the construction of events in one's *personal* past or future.

One general issue that applies to the foregoing studies, and potentially to any neuroimaging study that compares the neural correlates of remembering past events and imagining future events, is that remembering is usually associated with greater levels of episodic detail than is imagining (e.g., M. Johnson, Foley, Suengas, & Raye, 1988). To the extent that this outcome occurs, comparisons between past and future events will be partly or entirely confounded by differences in level of detail. Using event-related fMRI, Addis, Wong, and Schacter (2007) attempted to equate experimentally the level of detail and related phenomenological features of past and future events. Also, taking advantage of the temporal resolution of fMRI, the past and future tasks were divided into two phases: (1) an initial construction phase during which participants generated a past or future event in response to an event cue (e.g., "dress") and pressed a button when they had an event in mind, and (2) an elaboration phase during which participants generated as much detail as they could about the event.

PAST AND FUTURE EVENT ELABORATION

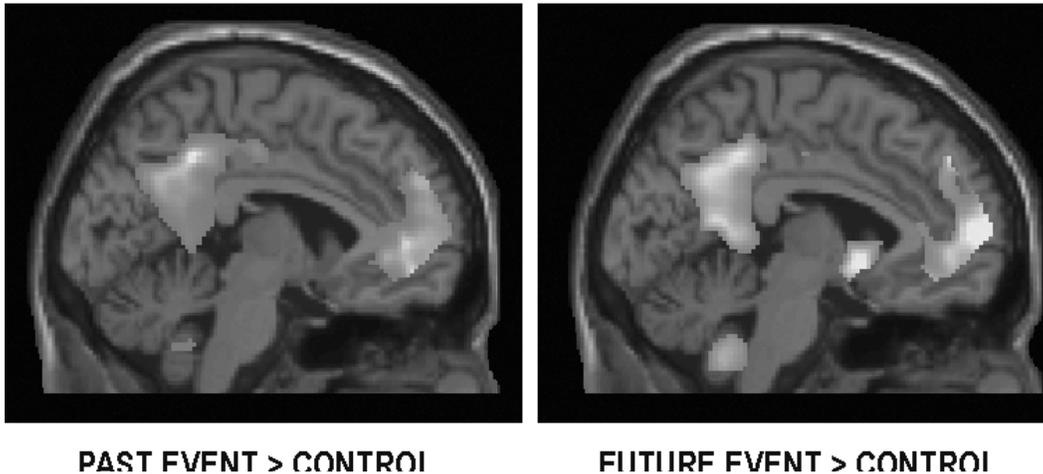

FIGURE 51.1 Sagittal slice ($x = -4$) illustrating the striking commonalities in the medial left prefrontal and parietal regions engaged when remembering the past (*left panel*) and imagining the future (*right panel*). These marked similarities of activation were also evident in areas of the medial temporal lobe (left hippocampus, bilateral parahippocampal gyrus) and lateral cortex (left temporal pole and left bilateral inferior parietal cortex). This extensive

pattern of common activity was not present during the construction of past and future events; it only emerged during the elaboration of these events (shown here, relative to the elaboration phase of a semantic and an imagery control task; significant at $p < .001$, uncorrected; shown at $p < .005$, uncorrected.) (Originally published in Addis, Wong, & Schacter, 2007.) (See color plate 63.)

The construction phase was associated with some common past-future activity in posterior visual regions and left hippocampus. During the elaboration phase, when participants focused on generating details about the remembered or imagined event, there was even more extensive overlap between the past and future tasks (see figure 51.1). Both event types were associated with activity in a network of regions including medial temporal (hippocampus and parahippocampal gyrus) and prefrontal cortex, as well as medial parietal and retrosplenial cortex.

Botzung, Denkova, and Manning (2008) have recently reported data from an fMRI study that are mainly consistent with those from the preceding studies. The day before scanning, subjects initially reported on 20 past events from the last week and 20 future events planned for the next week. The experimenters constructed cue words for these events that were presented to subjects the next day during scanning, when they were instructed to think of past or future events to each cue. Past and future events produced activation in a network similar to that reported by Addis and colleagues (2007).

Collectively, the results from the preceding imaging studies consistently implicate a core network of structures in both remembering the past and imagining the future (Buckner & Carroll, 2007; Buckner et al., 2008; Schacter et al., 2007, 2008). This network consists of prefrontal and medial temporal lobe regions, as well as posterior regions including lateral parietal, posterior cingulate, and retrosplenial cortices that have previously been observed as components of brain

networks important to memory retrieval (Cabeza & St Jacques, 2007; Gilboa, 2004; Maguire, 2001; Spreng, Mar, & Kim, in press; Svoboda, McKinnon, & Levine, 2006; Wagner, Shannon, Kahn, & Buckner, 2005). Analyses of the interactions among the brain regions within this core network demonstrate that all of the component regions are selectively correlated with one another within a large-scale brain system that includes the hippocampal formation (Greicius, Srivastava, Reiss, & Menon, 2004; Kahn, Andrews-Hanna, Vincent, Snyder, & Buckner, 2008; Vincent et al., 2006), and that the network likely consists of distinct interacting subsystems (Buckner et al., 2008).

Although it seems clear that remembering the past and imagining the future are both associated to some extent with a common core network, neuroimaging studies have also yielded a number of findings that point to possible differences between the two. First, direct comparisons have consistently shown greater activity in several brain regions when individuals imagine the future than when they remember the past. For example, Okuda and colleagues (2003) reported greater activity in frontopolar and medial temporal regions when people talked about the future than the past; Szpunar and colleagues (2007) reported that bilateral premotor cortex and left precuneus were more active for future relative to past events, but not vice versa; and Addis and colleagues (2007) found that during the early construction phase of future simulation, several regions showed greater activity for future versus past events (but not the reverse), including right hippocampus and frontopolar cortex.

In a more recent study, Addis, Cheng, and Schacter (2008) contrasted activity when individuals were cued to remember or imagine specific events, as in previous studies, versus when they were cued to remember general, routine events (e.g., having brunch after attending church) or to imagine generic events that might occur sometime in their personal futures (e.g., reading the newspaper each morning). Addis and colleagues replicated the foregoing findings of greater activity for future than past events during the early phase of event construction. Furthermore, they found that the left frontal pole showed this future > past effect for both specific and generic events, suggesting a general role in prospection irrespective of the specificity of the event. However, the right hippocampus showed the future > past effect only for specific events; in fact, there was no evidence for right hippocampal activity during construction of generic future events.

These observations are open to multiple interpretations (note also that Botzung et al., 2008, reported evidence for increased activity for past versus future events; but see Schacter et al., 2008, for discussion of methodological issues that complicate interpretation of this finding). For example, Szpunar and colleagues (2007) suggested that a more active type of imagery processing might be required by future than past events. Addis and colleagues (2007) hypothesized that more intensive constructive processes are required by imagining future events than by retrieving past events. While both past- and future-event tasks require the retrieval of information from memory, thus engaging common memory networks, only the future task requires that event details gleaned from various past events be flexibly recombined into an imaginary event, perhaps resulting in increased activity during future-event tasks. A related possibility is that imagined future events are more novel than remembered past events; increased activity during future-event tasks might reflect some form of novelty encoding. This latter idea is potentially applicable to findings of increased hippocampal activation during future-event tasks, since it is well known that encoding novel events can be associated with increased hippocampal activity (e.g., Ranganath & Rainer, 2003). Note, however, that Addis, Cheng, and Schacter's (2008) finding that increased right hippocampal activity for future events was observed for specific but not generic events would appear to be inconsistent with a simple novelty-encoding account, because both the specific and generic future events were novel.

Addis and Schacter (2008) report additional findings concerning differential neural responses to past and future events. They conducted parametric modulation analyses, with temporal distance and detail as covariates, focusing on the hippocampal and the frontopolar regions. They hypothesized that *reintegrating* increasing amounts of detail for either a past or future event would be associated with increasing

levels of hippocampal activity. By contrast, because future events are thought to require more intensive *recombining* of disparate details into a coherent event, the hippocampal response to increasing amounts of future-event detail should be larger than that for past-event detail. In addition, since the frontal pole is thought to play a role in prospective thinking (e.g., Okuda et al., 2003), this region should also exhibit a future > past detail response if it is specifically involved in the generation of future details.

Consistent with predictions, the analysis showed that the left posterior hippocampus was responsive to the amount of detail comprising both past and future events. In contrast, a separate region in the left anterior hippocampus responded differentially to the amount of detail comprising future events, possibly reflecting the recombination of details into a novel future event. Moreover, the right frontal pole responded significantly more to the generation of future-relative to past-event details, again suggesting that this region might be involved specifically in prospective thinking.

The parametric modulation analysis of temporal distance revealed that the increasing recency of past events was associated with activity in the right parahippocampus gyrus (BA 35/36), while activity in the bilateral hippocampus was associated with the increasing remoteness of future events. Addis and Schacter (2008) proposed that the hippocampal response to the distance of future events reflects the increasing disparate-ness of details likely included in remote future events and the intensive relational processing required for integrating such details into a coherent episodic simulation of the future. More generally, these results suggest that the core network supporting past- and future-event simulation can be recruited in different ways depending on whether the generated event is in the past or future.

Conceptual issues: Past versus future or remembering versus imagining? The preceding observations raise a general point concerning the growing number of studies that have compared remembering the past with imagining the future. When differences between these two conditions are observed, they are typically attributed to differences in the way that the brain handles past and future events. However, in the reviewed studies past events are remembered whereas future events are imagined; accordingly, the differences could equally well be attributed to differences between remembering and imagining, rather than differences between past and future per se. Of course, the future cannot be remembered because it has not yet happened. However, both the past and the future can be imagined. Furthermore, events can be imagined without any specific reference to a particular time point. Therefore, it would be of interest to determine whether any of the foregoing findings are indeed specifically related to imagining future events, or whether such findings are observed when people imagine events (1) that lack a specific

temporal reference or (2) that might have occurred in their personal pasts. Recent studies provide evidence concerning both points.

Hassabis, Kumaran, and Maguire (2007) adapted the experimental paradigm that they had used previously with amnesic patients for an fMRI study with healthy volunteers in which participants were asked to imagine novel, fictitious scenes, without explicit reference to whether those scenes should be placed in the past, present, or future. Subjects were then scanned in a subsequent session in which they were cued to remember the previously constructed fictitious scenes, construct additional novel fictitious scenes, or recall real episodic memories from their personal pasts. Hassabis and colleagues found that all three conditions were associated with activations in some of the regions within the core network that were associated with future-event simulation in previously reviewed studies, including hippocampus, parahippocampal gyrus, and retrosplenial cortex. The results thus indicate that activity in these regions is not restricted to conditions that explicitly require imagining future events. However, Hassabis and colleagues also reported that remembering “real” episodic memories yielded increased activity in several core network regions—notably anterior medial prefrontal cortex and posterior cingulate cortex—in comparison with constructing fictitious events. We will return shortly to the theoretical implications of these latter findings.

In a related study, Addis, Pan, Vu, Laiser, and Schacter (in press) attempted to disambiguate whether future-event-related activity is specifically associated with prospective thinking or with the more general demands of imagining an episodic event in either temporal direction by instructing subjects to imagine events that might occur in their personal future or events that might have occurred in their personal pasts. Prior to scanning, participants provided episodic memories of actual experiences that included details about a *person, object, and place* involved in that event. During scanning, the subjects were cued to recall some of the events that had actually occurred, and for the conditions in which they imagined events, the experimenters randomly recombined details concerning person, object, and place from separate episodes. Participants were thus presented with cues for a person, object, and place taken from multiple episodes, and were instructed to imagine them together in a single, novel episode that included the specified details.

Addis and colleagues (in press) reported that all regions within the core network (including medial prefrontal and frontopolar cortex, hippocampus, parahippocampal gyrus, lateral temporal and temporopolar cortex, medial parietal cortex including posterior cingulate and retrosplenial cortex, and lateral parietal cortex) were similarly engaged when participants imagined future and past events, suggesting that

the network can be used for event simulation regardless of the temporal location of the event.

Theoretical implications: Future event simulation and constructive memory

Neuroimaging and neuropsychological observations have led to a number of new theoretical proposals, involving both attempts to describe the critical cognitive processes associated with core network activation and attempts to consider functional aspects of future-event simulation. We have reviewed these proposals in detail elsewhere (Buckner & Carroll, 2007; Buckner et al., 2008; Schacter et al., 2007, 2008). Here, we briefly summarize the main ideas. We first consider two related attempts to delineate key processes associated with the core network, and then describe a related idea that attempts to link the core network and future-event simulation with memory errors and related constructive aspects of remembering.

CORE NETWORK ACTIVATION: CRITICAL COGNITIVE PROCESSES The experimental work that we have reviewed has sparked a number of attempts to characterize the key processes subserved by the core network that is consistently activated in recent studies of imagining and remembering (Buckner & Carroll, 2007; Hassabis, Kumaran, & Maguire, 2007; Hassabis, Kumaran, Vann, et al., 2007; Hassabis & Maguire, 2007; Schacter & Addis, 2007a, 2007b; Spreng et al., in press). As we have noted in our previous reviews, these perspectives share much in common and differ mainly in points of emphasis and focus.

Buckner and Carroll (2007) and Buckner and colleagues (2008) argued that the core network serves a common set of processes by which past experiences are used adaptively to imagine perspectives and events beyond those that emerge from the immediate environment. By this view, the functions of the core network are not restricted to tasks requiring mental time travel. In addition to the network’s role in remembering the past and envisioning the future, the core network is hypothesized to contribute to more general functions, extending to diverse tasks that require mental simulation of alternative perspectives. They observed that some, but not all, regions within the core network are engaged during theory-of-mind tasks that require thinking about the perspectives of others (e.g., Saxe & Kanwisher, 2003), and they also noted that such regions may be engaged during certain kinds of spatial navigation tasks (e.g., Byrne, Becker, & Burgess, 2007). Buckner and Carroll suggested that the core brain network is commonly engaged when individuals are simulating alternative perspectives, including alternatives in the present and possibilities in the future—a process they provisionally termed *self-projection*. This view predicts that activation of the core network should correspond to the

extent that a task encourages simulation of an alternative perspective not beyond the immediate environment. Spreng and colleagues (in press) performed a meta-analysis of studies that generally supported this broad hypothesis.

In a detailed analysis of the anatomy and functional connections among the regions within the network, Buckner and colleagues (2008) recently expanded on this perspective and showed that the core network comprises *at least two* interacting subsystems: the medial temporal lobe subsystem functions to provide information from memory; the dorsal medial prefrontal cortex subsystem participates to derive self-relevant mental simulations. The two subsystems interact through hubs, including the posterior cingulate, but can be dissociated using the observation that dorsal medial prefrontal cortex and the medial temporal lobe are not intrinsically correlated with one another. One possibility is that mental simulations such as remembering and envisioning the future draw heavily on contributions from both subsystems, whereas other forms of task rely preferentially on one subsystem. For example, theory-of-mind tasks that do not draw on memory rely primarily on the medial prefrontal subsystem, as evidenced by strong activation of that system and not the medial temporal lobe. Consistent with this idea, patients with medial temporal lesions exhibit intact performance on theory-of-mind tasks that do not draw on past memories (Rosenbaum, Stuss, Levine, & Tulving, 2007). However, the neuropsychological data also indicate that patients with damage to medial prefrontal regions (Bird, Castelli, Malik, Frith, & Husain, 2004) show intact performance on several theory-of-mind tasks, which is perplexing in light of the common activation of this region in imaging studies.

Hassabis and Maguire (2007) have argued that a process they refer to as *scene construction* links together various tasks that depend on many regions within the core network, in particular those associated with the medial temporal subsystem. Scene construction focuses on visuospatial aspects of mental simulations and was motivated initially by the previously discussed finding that amnesic patients with medial temporal damage show deficits when asked to imagine novel scenes, with a disproportionate impairment in the spatial coherence of the imagined scenes (Hassabis, Kumaran, Vann, et al., 2007). Neuroimaging findings from the same task likewise show core network activity (Hassabis, Kumaran, & Maguire, 2007). Because the novel-scenes task does not explicitly require mental time travel, Hassabis and Maguire contended that projecting oneself into the past or the future is not the critical process for activating the medial temporal subsystem.

Taken in the context of the anatomic analysis of Buckner and colleagues (2008), the collective results begin to converge on the idea that the core network comprises at least two subsystems that interact to accomplish autobiographical

remembering and envisioning the future but that are also used to varying degrees across a diverse set of tasks that extend well beyond forms of “mental time travel” (for further discussion of the neural correlates of mental time travel, see Arzy, Molnar-Szarkacs, & Blanke, 2008).

EPISODIC SIMULATION, THE CORE NETWORK, AND CONSTRUCTIVE MEMORY Schacter and Addis (2007a, 2007b; for related ideas, see Dudai & Carruthers, 2005; Suddendorf & Corballis, 1997; Suddendorf & Busby, 2005) have linked findings concerning event simulation and core network activity to the observation that memory involves a constructive process of piecing together bits and pieces of information. According to the *constructive episodic simulation hypothesis*, imagining future events requires a system that can flexibly recombine details from past events. From this perspective, past and future events draw on similar information stored in episodic memory and rely on similar underlying processes; episodic memory supports the construction of future events by extracting and recombining stored information into a simulation of a novel event. The adaptive value of such a system is that it enables past information to be used flexibly in simulating alternative future scenarios without engaging in actual behavior. A potential downside of such a system, however, is that it is vulnerable to memory errors, such as misattribution and false recognition (for examples, see Schacter & Addis, 2007a, 2007b). This observation suggests, intriguingly, that certain kinds of memory errors may be the by-product of a system whose adaptive function is to make available information from the past in a flexible form that supports simulations of future events.

The constructive episodic simulation hypothesis receives general support from the previously reviewed findings of neural and cognitive overlap between past and future events; and, because it emphasizes the importance of flexibly relating and recombining information from past episodes, the hypothesis is more specifically supported by the mounting evidence from amnesia (Hassabis, Kumaran, Vann, et al., 2007), neuroimaging (Addis et al., 2007; Addis & Schacter, 2008; Botzung et al., 2008; Hassabis, Kumaran, & Maguire, 2007; Okuda et al., 2003), and aging (Addis, Wong, & Schacter, 2008), linking hippocampal function and relational processing with episodic simulation. The hippocampal region is thought to support relational memory processes (e.g., Eichenbaum & Cohen, 2001); and, according to the constructive episodic simulation hypothesis, these processes are critical for recombining stored information into future-event simulations.

Because the constructive episodic simulation hypothesis places great emphasis on the process of recombining event details, it is critical to determine whether such recombination

processes are critical for future-event simulation, or whether such simulations are based on retrieval of entire past episodes, or fragments of such episodes, which are simply recast as possible future events. Relevant data are provided by the aforementioned study by Addis and colleagues (in press) using experimental recombination of details from distinct episodes: core network activation, including the hippocampus, was observed under conditions that effectively ruled out recasting of a single past episode as a future event.

Although further research is required to delineate the exact role of the hippocampus in mental simulation, it may be worth noting that research on other aspects of constructive memory has also highlighted the involvement of the hippocampus and related medial temporal lobe regions. For instance, some neuroimaging studies of false recognition, where individuals claim to have previously encountered a novel item that is conceptually or perceptually related to a previously studied item, have documented hippocampal/medial temporal lobe activation during false recognition of semantically associated words (e.g., Cabeza, Rao, Wagner, Mayer, & Schacter, 2001) or abstract shapes (Slotnick & Schacter, 2004). Similarly, several studies have shown that amnesic patients with medial temporal lobe damage show reduced levels of false recognition for various kinds of materials, suggesting that the hippocampal region is involved with encoding and/or retrieving the information that drives false recognition effects (e.g., Schacter, Verfaellie, & Pradere, 1996; Verfaellie, Page, Orlando, & Schacter, 2005). Taken together with the evidence for hippocampal involvement during simulation of future or novel events, it seems increasingly clear that the hippocampus is related importantly to constructive aspects of memory.

Studies of future-event simulation also bring into sharp focus fundamental issues concerning processes of *reality monitoring*, which allow us to distinguish between remembered and imagined events (Johnson & Raye, 1981). If remembering past events and imagining future or novel events recruit largely overlapping brain networks, how can individuals distinguish fantasy from reality?

Hassabis, Kumaran, and Maguire (2007) addressed this issue in the context of their neuroimaging study, where they found, as noted earlier, that anterior medial prefrontal cortex and posterior cingulate cortex showed greater activity when individuals recollected real episodic memories as compared to when they imagined novel scenes. Because their novel-scenes task does not require mental time travel or projection of the self, Hassabis, Kumaran, and Maguire suggested that anterior medial prefrontal cortex and posterior cingulate cortex “support episodic memory over and above scene construction” (2007, p. 14372), perhaps contributing to effective reality monitoring. While this conclusion may be accurate in the context of the scene-construction task, these regions

typically activate as part of the core network when individuals imagine themselves in personal future events (Addis et al., 2007; Szpunar et al., 2007). Interestingly, in a recent study (Abraham, von Cramon, & Schubotz, 2008) where participants were asked to imagine scenarios that involved meeting real people (e.g., George Bush) versus fictional characters (e.g., Cinderella), anterior prefrontal and posterior cingulate were more active during the former than the latter condition, possibly indicating greater ease of self-projection when imagining oneself meeting an actual person (medial temporal regions were similarly active in the two conditions). Taken together, the foregoing studies suggest that additional areas and processes (beyond anterior medial prefrontal and posterior cingulate) must be recruited to allow one to distinguish an episodic memory from a realistic future simulation that engages the self.

Here, it seems likely that there is a role for the long-standing idea from research on reality monitoring that remembering events that one has actually experienced is associated with greater numbers of sensory and perceptual details than remembering previously imagined events (e.g., Johnson & Raye, 1981). This idea has received support from behavioral studies (e.g., Johnson et al., 1988) as well as neuromaging research (Kensinger & Schacter, 2006; see also Slotnick & Schacter, 2004). Most directly related to the present concerns, Addis and colleagues (in press) report preliminary evidence that remembering actual autobiographical events is more strongly associated with activity in posterior visual cortex (and some medial temporal regions) than is imagining future or past events using the previously described procedure of cuing imagined events by recombining details from different actual events. In this study, remembered events were rated as significantly more detailed than imagined events, so it would make sense from the perspective of the reality-monitoring framework that regions associated with processing of sensory and contextual details would show greater activity for real events than for imagined ones.

Although still in its infancy, it seems clear that research on future-event simulation and related forms of internally directed cognition has much to offer memory research. At the very least, the striking similarities observed during remembering the past and imagining the future are consistent with Bartlett’s (1932) claim that “memory appears to be an affair of construction rather than reproduction.” We are optimistic that further study of such processes as future-event simulation, scene construction, and self-projection will teach us much about the constructive nature of memory.

ACKNOWLEDGMENTS Preparation of this chapter was supported by grants from the NIA, NIMH, and HHMI. We thank Adrian Gilmore for help with preparation of the manuscript.

Introduction

ALFONSO CARAMAZZA

UNTIL FAIRLY RECENTLY almost everything we knew about the cognitive neuroscience of language came to us from investigation of the correlations between patterns of language impairment and their associated loci of brain damage. This approach has contributed importantly to a first-pass characterization of the distribution of language functions in the brain. But its contribution has been even greater to the development of functional theories of language processing. The patterns of dissociations and associations of deficits have informed theories of various language processes from the perception and production of speech, to the organization of the lexicon, to the syntactic and semantic processes involved in sentence comprehension and production. Especially important inroads have been made in characterizing the processing machinery that makes reading and writing possible. Another fertile area of research has been the relation between cognitive and linguistic processes, such as the role of working memory in sentence processing.

Sometimes the observed dissociations and associations of deficits have been rather unexpected, forcing reconsideration of the received view in a given area of language processing. For example, it is now well established that there are patients who make semantic errors in naming pictures orally but can write the name without difficulty, and there are patients with the reverse pattern of dissociation, who make semantic errors in writing the name of an object but who can name orally without problem. These results imply, perhaps unsurprisingly, that the phonological and the orthographic forms of words are represented by distinct neural mechanisms. However, they are not so easily accommodated in theoretical frameworks that hypothesize an abstract lexical representation between the semantic and lexical form levels. Furthermore, since these modality-specific naming deficits have also been found to be restricted to words of one

grammatical class or another, they place even stronger constraints on a biologically defensible theory of the lexicon. Thus, for example, it has been shown that patients may have difficulty in writing verbs but not nouns or speaking verbs but not nouns, while showing no difficulty in the other modality of output for both verbs and nouns (Caramazza & Hillis, 1991). The reverse dissociation, modality-specific selective difficulty with nouns, has also been documented. One implication of these results is that grammatical operations are carried out over modality-specific and not abstract lexical representations. This conclusion is in line with several of the chapters in this section that emphasize the “task-dependent” nature of the representations computed in the course of language processing.

Highly selective dissociations such as those mentioned here place strong constraints on theories of the functional organization of language processes. However, they have been less useful in informing theories of the brain structures that are associated with hypothesized cognitive and linguistic processes. The reason for this discrepancy may be found in the fact that these highly selective deficits are rare and that they are associated with fairly large lesions, making it extremely difficult, if not impossible, to identify the brain regions causally related to the observed dissociations.

Fortunately, the neuropsychological approach is now complemented by various neuroimaging methods that can be used to systematically assess cognitively motivated hypotheses in the intact human brain. This approach is extremely promising but is still in its early stages of development. It has proven difficult to ascribe a causal role to the many brain areas that are activated when performing a complex task. For this reason, it is important to combine the methods of neuropsychology (or transcranial magnetic stimulation), which allow stronger inferences about the causal role of a brain area in the performance of a task, with the increasingly sophisticated use of MRI, EEG, and MEG methods. The chapters in this section fully exemplify the close link between the study of language disorders and neuroimaging research that are being used to converge on a cognitive neuroscience theory of language.

The chapters in this section cover only a limited set of questions about language, reflecting the areas of greatest current interest. The topics include phonological (Hickok) and morphological processing (Shapiro and Caramazza), reading (Cohen and Dehaene), syntactic (Caplan) and semantic processing (Hagoort, Baggio, and Willems), language acquisition (Kuhl), and the genetics (Ramus and Fisher) and evolution of language (Fitch). And, as already noted, in all the chapters that focused on human research,

the interplay between the results obtained from the study of language disorders and those obtained from neuroimaging research plays a central role. The result is a comprehensive view of our current understanding of the neurobiology of language.

Consider as an example chapter 54, on reading, which focuses on the word-recognition component of the reading process. Cohen and Dehaene review the various forms of reading impairments that affect some or other aspect of word recognition and conclude that the impairments can be subdivided into two sets: those that principally involve letter recognition and those that involve operations over letters, such as attention mechanisms and serial decoding. They note that the lesions associated with these two broad types of processes concern, respectively, ventral and dorsal visual pathways. They also review imaging results that converge with this interpretation of the neuropsychological evidence. The result is a fairly comprehensive if preliminary view of the neural machinery involved in visual word recognition.

Or consider the case of phonological processing. In chapter 52, Hickok also argues for a two-stream circuit for phonological processing, one dedicated to speech recognition and the other to speech production. Recognition involves primarily a circuit that includes the superior temporal sulcus bilaterally, while production involves a left-dominant frontoparietal/temporal circuit. The evidence for this distinction comes primarily from the patterns of phonological processing deficits in aphasic patients, but Hickok also reviews imaging results that converge with the neuropsychological evidence.

Despite the important developments charted in the chapters included in this section, it is clear that we are still very far from an articulated theory of the biology of language. In some respects we are really only now beginning to develop the methodological and theoretical foundations for such a theory. This fact is illustrated in the beautiful work on the genetics of language described in chapter 58 by Ramus and Fisher, where it is clear that we have only begun to scratch the surface of the many complicated factors that enter in a genetic theory. The same is true for cognitive neuroscience accounts of language, especially for the more complex functions such as syntactic processing and semantic integration. At this stage of the game we have many titillating insights but not yet articulated theories.

52 The Cortical Organization of Phonological Processing

GREGORY HICKOK

ABSTRACT Phonological processing refers to mechanisms involved in representing, accessing, or manipulating information related to the sound structure of language. The goal of this chapter is to review what is known about the neural basis of phonological processes in three broad domains: speech recognition, speech production, and verbal short-term memory. In particular, we will outline evidence showing that phonological processing is task dependent, that phonological-level aspects of speech recognition are bilaterally organized (but computationally asymmetric), and that posterior phonological information interacts with frontal motor systems by means of a sensory-motor integration network that supports aspects of speech production and verbal working memory. These findings are organized theoretically into a dual-stream model, which is closely related to dual-stream models proposed in the visual domain.

Phonological processing refers to mechanisms involved in representing, accessing, or manipulating information related to the sound structure of language.¹ As such, phonological processes are involved in a range of language abilities. The goal of this chapter is to review what is known about the neural basis of phonological processes in three broad domains: speech recognition, speech production, and verbal short-term memory. We will also examine the relation between these various domains and explore possible parallels and connections between phonological processing networks and cortical systems outside the domain of speech and language.

Phonological processing is task dependent

Given that phonological information is involved in a broad range of linguistic abilities, it is perhaps not surprising that we should find evidence for task dependence in the neural systems recruited to perform this range of tasks. For example, the set of neural circuits involved in, say, verbatim repetition of a heard phonological word form must be at least partially different from the set of neural circuits involved in comprehending the meaning of a heard phonological word form, as the former involves mapping phonological information onto

motor-articulatory mechanisms, whereas the later involves mapping phonological information onto lexical-semantic representations. It is an open question whether the phonological *representations* involved in input-related processes, output-related processes, or other processes are shared or distinct—for example, whether there are distinct phonological lexicons (Hickok, 2001; Shelton & Caramazza, 1999)—but it is clear that there are, minimally, distinct and task-dependent *interfaces* that phonological representations enter into (figure 52.1).

A relevant observation regarding task differences in phonological processing comes from a set of studies that were conducted in the late 1970s and early 1980s that showed a double dissociation in two tasks involving phonological processing (Basso, Casati, & Vignolo, 1977; Blumstein, Cooper, Zurif, & Caramazza, 1977; Miceli, Gainotti, Caltagirone, & Masullo, 1980). These studies examined the ability of aphasic patients to perform a syllable discrimination task (e.g., decide whether pairs of syllables such as /da/–/ta/ are the same or different). A prominent theory at the time was that auditory comprehension deficits in aphasia resulted from a deficit in the ability to perceive phonological information in speech (Luria, 1970). Such an account predicted that deficits in syllable discrimination would be strongly associated with auditory comprehension deficits in aphasia. This prediction turned out to be incorrect: a consistent finding was that syllable discrimination and word-level comprehension doubly dissociate, even when the comprehension task involved phonological foils (Baker, Blumstein, & Goodglass, 1981; Miceli et al.). Further, the patient group that tended to perform the worst on syllable discrimination consisted of nonfluent patients with *good* auditory comprehension (Basso et al.). Thus data from aphasia show that it is quite possible to use phonological information to access lexical-semantic information in a comprehension task, yet fail to discriminate syllables, *and* that it is also possible to be able to use phonological information to discriminate syllables, yet fail to comprehend words. See Hickok and Poeppel (2004) for further discussion of these data.

This double dissociation does not imply that there are distinct networks (or lexicons) of phonological *representations*, one involved in syllable discrimination and the other involved

GREGORY HICKOK Center for Cognitive Neuroscience, University of California, Irvine, California

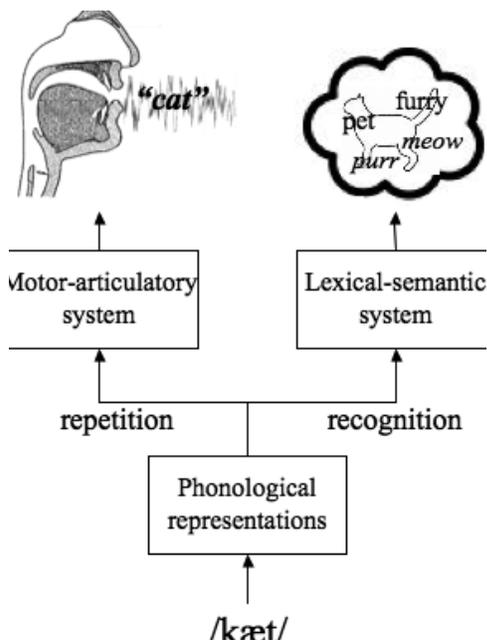

FIGURE 52.1 Distinct mappings from phonological representations to the motor system versus the conceptual-semantic system.

in comprehension. Instead, a more likely explanation is that when these abilities dissociate, the breakdown on the two tasks results from disruption of the task-specific *interface* mechanisms required to perform the respective tasks. For example, auditory comprehension deficits in aphasia appear to arise primarily from postphonemic deficits such as disruption of lexical-semantic access (Baker et al., 1981; Hickok & Poeppel, 2000, 2004, 2007). Similarly, deficits in syllable discrimination (particularly when they occur in nonfluent frontal-lobe-damaged patients with good comprehension) may result from disruption of some component of working memory for phonological information.

The general point is that a deficit on a given phonological task could result from any number of factors that may or may not be task specific. The specific point is that data from syllable discrimination tasks and the like—which are by far the most common means to examine phonological processing—are *not* necessarily measuring the same set of phonological processes involved in auditory comprehension. This is an important point because if we relied on tasks such as syllable discrimination to build our neuroanatomical model, we would conclude that phonological processes are strongly left-hemisphere dominant and are primarily located in the frontal lobe. But if we look instead at phonological processing in the context of auditory comprehension tasks, we arrive at a very different picture, where the system is more bilaterally organized and involves primarily temporal lobe regions (see the next section). Which conclusion is right? The answer is both, and neither. Both are correct in mapping *some* aspect of phonological processing—but clearly different aspects. At

the same time, neither is entirely correct because each one alone only paints part of the picture. What is required is the development of a model that can accommodate all sources of data and explain how the involvement of various components of the overall network varies as a function of task.

Spoken word recognition is bilaterally organized

One of the most common, everyday tasks that involve phonological processing is the comprehension of spoken words. According to the dominant theoretical accounts, such as the TRACE (McClelland & Elman, 1986), cohort (Marslen-Wilson, 1987), and neighborhood activation (Luce & Pisoni, 1998) models, spoken word recognition involves several stages of processing, with access to phonological information a critical step in the mapping from sound to meaning. What brain networks support this ability?

Evidence from a variety of sources indicates that spoken word recognition is supported by neural systems in the superior temporal lobe—superior temporal gyrus (STG) and superior temporal sulcus (STS), bilaterally. In neuroimaging studies, a consistent and uncontroversial finding is that, when contrasted with a resting baseline, listening to speech activates the superior temporal lobe bilaterally (Binder et al., 2000, 1994; Mazoyer et al., 1993; Price et al., 1996; Schlosser, Aoyagi, Fulbright, Gore, & McCarthy, 1998; Zatorre, Meyer, Gjedde, & Evans, 1996). It is possible that while activation in spoken word recognition is bilateral, phonological stages of processing are nonetheless restricted to the left hemisphere. This hypothesis predicts that damage to the left posterior superior temporal lobe should produce profound phonological deficits in spoken word recognition. However, this is not the case. Damage to the posterior superior temporal lobe, such as in Wernicke's aphasia (A. Damasio, 1991, 1992) *does* produce deficits in spoken word recognition (Goodglass, 1993; Goodglass, Kaplan, & Barresi, 2001); however, these deficits involve only mild phonological processing impairment and, in fact, appear to result predominantly from a disruption to lexical-semantic-level processes (Bachman & Albert, 1988; Baker et al., 1981; Gainotti, Micelli, Silveri, & Villa, 1982; Miceli et al., 1980). This conclusion is based on experiments in which patients are presented with a spoken word and asked to point to a matching picture within an array that includes phonological, semantic, and unrelated foils; phonological error rates are low overall (5–12%) with semantic errors dominating. This tendency also holds in acute aphasia (Breese & Hillis, 2004; Rogalsky, Pitz, Hillis, & Hickok, 2008) showing that the relative preservation of phonological abilities in unilateral aphasia is not a result of long-term plastic reorganization. Data from split-brain (Zaidel, 1985) and Wada procedures (McGlone, 1984; Hickok et al., 2008) also indicate that the right hemisphere alone is capable of good auditory comprehension at the word level.

In sum, disruption of the left superior temporal lobe does not lead to severe impairments in phonological processing during spoken word recognition. This observation has led to the claim that phonological processes are bilaterally organized in the superior temporal lobe (Hickok & Poeppel, 2000, 2004, 2007). This claim predicts that damage to the STG bilaterally should produce profound impairment in spoken word recognition, which in fact it does in the form of word deafness (Buchman, Garron, Trost-Cardamone, Wichter, & Schwartz, 1986).

The superior temporal sulcus is a critical site for phonological processing

Beyond the earliest stages of speech recognition there is accumulating evidence that portions of the STS are important for representing and/or processing phonological information (Binder et al., 2000; Hickok & Poeppel, 2004, 2007; Indefrey & Levelt, 2004; Liebenthal, Binder, Spitzer, Possing, & Medler, 2005; Price et al., 1996). The STS is activated by a range of tasks that require access to phonological information, including speech perception and production (Indefrey & Levelt, 2004), and the active short-term maintenance of phonemic information (Buchsbaum, Hickok, & Humphries, 2001; Hickok, Buchsbaum, Humphries, & Muftuler, 2003). Functional imaging studies that attempt to isolate phonological processes in perception by contrasting speech stimuli with complex nonspeech signals have found activation along the STS (Liebenthal et al., 2005; Narain et al., 2003; Obleser, Zimmermann, Van Meter, & Rauschecker, 2006; Scott, Blank, Rosen, & Wise, 2000; Spitsyna, Warren, Scott, Turkheimer, & Wise, 2006; Vouloumanos, Kiehl, Werker, & Liddle, 2001), as have studies that manipulate psycholinguistic variables that tap phonological networks (Okada & Hickok, 2006), such as phonological neighborhood density (the number of words that sound similar to a target word). Although many authors consider this system to be strongly left dominant, both lesion evidence and imaging evidence suggest a bilateral organization (Hickok & Poeppel, 2007).

One currently unresolved question is the relative contribution of anterior versus posterior STS regions in phonological processing. Lesion evidence indicates that damage to posterior temporal lobe areas is most predictive of auditory comprehension deficits (Bates et al., 2003); however, as noted earlier, comprehension deficits in aphasia result predominantly from postphonemic processing levels. A majority of functional imaging studies targeting phonological processing in perception have highlighted regions in the posterior half of the STS (Hickok & Poeppel, 2007). Other studies, however, have reported *anterior* STS activation in perceptual speech tasks (Mazoyer et al., 1993; Narain et al., 2003; Scott et al., 2000; Spitsyna et al., 2006). These studies

involved sentence-level stimuli, raising the possibility that anterior STS regions may be responding to some other aspect of the stimuli such as its syntactic or prosodic organization (Friederici, Meyer, & von Cramon, 2000; Humphries, Binder, Medler, & Liebenthal, 2006; Humphries, Love, Swinney, & Hickok, 2005; Humphries, Willard, Buchsbaum, & Hickok, 2001; Vandenberghe, Nobre, & Price, 2002). The weight of the available evidence, therefore, suggests that the critical portion of the STS that is involved in phonological-level processes is bounded anteriorly by the antero-lateralmost aspect of Heschl's gyrus and posteriorly by the posteriormost extent of the Sylvian fissure (Hickok & Poeppel, 2007).

Phonological processing systems in speech recognition are bilateral but asymmetric

The claim that phonological processing is bilaterally organized for speech recognition tasks does not imply that the systems in both hemispheres are computationally identical. To the contrary, there is abundant evidence for differences in the way acoustic/speech information is processed in the two hemispheres (Abrams, Nicol, Zecker, & Kraus, 2008; Boemio, Fromm, Braun, & Poeppel, 2005; Giraud et al., 2007; Hickok & Poeppel, 2007; Zatorre, Belin, & Penhune, 2002). What is less clear is the computational nature of these differences. One view is that the difference turns on biases toward temporal (left-hemisphere) versus spectral (right-hemisphere) resolution (Zatorre et al., 2002). Another view holds that the two hemispheres differ in terms of their sampling rate, with the left hemisphere operating at a higher rate (25–50 Hz) and the right hemisphere at a lower rate (3–5 Hz) (Poeppel, 2003).² Yet another proposal, more specific to phonological processing, is that the left hemisphere processes phonemic information in a categorical fashion, whereas the right hemisphere may treat such information in a more continuous fashion (Liebenthal et al., 2005). We will not resolve these questions here. For our purposes, it is important to note that computational differences exist between the two hemispheres in the way that speech signals are processed during speech recognition, but that both are involved in the process, and both are largely capable of processing phonological information sufficiently well to access lexical-semantic information (Hickok & Poeppel, 2004). This analysis indicates that spoken word recognition involves parallel pathways (multiple routes) in the mapping from sound to meaning (Hickok & Poeppel, 2007). Although this conclusion differs from standard models of speech recognition (Luce & Pisoni, 1998; Marslen-Wilson, 1987; McClelland & Elman, 1986), it agrees nicely with the fact that speech contains redundant cues to phonemic information, as well as with behavioral evidence suggesting that the speech system can take advantage of these different cues

(Remez, Rubin, Pisoni, & Carrell, 1981; Shannon, Zeng, Kamath, Wygonski, & Ekelid, 1995).

Posterior language cortex in the left hemisphere is involved in phonological aspects of speech production

There is unequivocal evidence that posterior sensory-related cortex in the left, but not right, hemisphere plays an important role in speech production. For example, damage to the left posterior temporal lobe often results not only in comprehension deficits, but also in speech *production* deficits (A. Damasio, 1992; H. Damasio, 1991; Geschwind, 1971; Goodglass, 1993; Goodglass et al., 2001). Disruption to phonological systems appears to account for some of these production deficits. Damage to the left dorsal STG and/or the supramarginal gyrus/temporal-parietal junction is associated with conduction aphasia, a syndrome that is characterized by good comprehension, but with frequent phonemic errors in speech production, naming difficulties that often involve tip-of-the-tongue states (implicating a breakdown in phonological encoding), and difficulty with verbatim repetition (H. Damasio & Damasio, 1980; Goodglass, 1992).³ Conduction aphasia has classically been considered to be a disconnection syndrome involving damage to the arcuate fasciculus (Geschwind, 1965). However, there is now good evidence that this syndrome results from cortical dysfunction (Anderson et al., 1999; Hickok et al., 2000). The production deficit is load sensitive: errors are more likely on longer, lower-frequency words and verbatim repetition of strings of speech with little semantic constraint (Goodglass, 1992, 1993). Functionally, conduction aphasia has been characterized as a deficit in the ability to encode phonological information for production (Wilshire & McCarthy, 1996). Thus conduction aphasia provides evidence for the involvement of left posterior auditory-related brain regions in the phonological aspect of speech production. See also Wise et al. (2001).

Functional imaging evidence also implicates left superior posterior temporal regions in speech production generally (Hickok et al., 2000; Price et al., 1996) and phonological stages of the process in particular (Indefrey & Levelt, 2000, 2004). With respect to the latter, the posterior portion of the left planum temporale region, which is within the distribution of lesions associated with conduction aphasia, activates during picture naming and exhibits length effects (Okada, Smith, Humphries, & Hickok, 2003) and frequency effects (Graves, Grabowski, Mahta, & Gordon, 2007), and has a time course of activation, measured electromagnetically, that is consistent with the phonological encoding stage of naming (Levelt, Praamstra, Meyer, Helenius, & Salmelin, 1998).

Taken together, the lesion evidence and physiological evidence reviewed in this section make a compelling argument for the involvement of left posterior superior temporal regions in phonological aspects of speech production.

The left posterior planum temporale is part of an auditory-motor integration circuit

If left posterior superior temporal regions are involved in phonological aspects of speech *production*, there must be a mechanism for interfacing posterior and anterior brain regions. The need for such a mechanism has long been acknowledged, and in classical models was instantiated as a simple white matter pathway, the arcuate fasciculus (Geschwind, 1971). More recent proposals have argued, instead, for a *cortical* system that serves to integrate sensory and motor aspects of speech (Hickok et al., 2000, 2003; Hickok & Poeppel, 2000, 2004, 2007; Warren, Wise, & Warren, 2005), which is consistent with much research on sensorimotor integration systems studied in the context of the monkey visual system (Andersen, 1997; Colby & Goldberg, 1999; Milner & Goodale, 1995).

A series of studies over the last several years have identified a cortical network for speech and related abilities (e.g., music), which has many of the properties exhibited by sensorimotor networks studied in other domains. These properties include sensorimotor responses, connectivity with frontal motor systems, motor-effector specificity, and multi-sensory responses (Andersen, 1997; Colby & Goldberg, 1999). The speech-related network with these response properties includes an area (termed Spt) in the left posterior planum temporale region, that has been argued to support sensorimotor integration for speech (Hickok et al., 2003). We will review the evidence for this claim in the following paragraphs.

SPT EXHIBITS SENSORIMOTOR RESPONSE PROPERTIES A number of studies have demonstrated the existence of an area in the left posterior planum temporale that responds during both the perception and production of speech, even when speech is produced covertly (subvocally) so that there is no overt auditory feedback (Buchsbaum et al., 2001; Buchsbaum, Olsen, Koch, & Berman, 2005; Buchsbaum, Olsen, Koch, Kohn, et al., 2005; Hickok et al., 2003). Spt is not speech specific, however. It responds equally well to the perception and (covert) production by humming of melodic stimuli (Hickok et al.; Pa & Hickok, 2008).

SPT IS FUNCTIONALLY CONNECTED TO MOTOR SPEECH AREAS Spt activity is tightly correlated with activity in frontal speech-production-related areas, such as the pars opercularis (BA 44) (Buchsbaum et al., 2001), suggesting that the two regions are functionally connected. Furthermore, cortex in the posterior portion of the planum temporale (area Tpt) has a cytoarchitectonic structure that is similar to BA44. Galaburda writes that area Tpt “exhibits a degree of specialization like that of Area 44 in Broca’s region. It contains prominent pyramids in layer IIIc and a broad

lamina IV...the intimate relationship and similar evolutionary status of Areas 44 and Tpt allows for a certain functional overlap” (Galaburda, 1982, p. 442).

SPT ACTIVITY IS MODULATED BY MOTOR EFFECTOR MANIPULATIONS In monkey parietal cortex, sensorimotor integration areas are organized around motor effector systems (e.g., ocular versus manual actions in LIP and AIP; Andersen, 1997; Colby & Goldberg, 1999). Recent evidence suggests that Spt may be organized around the vocal tract effector system: Spt was less active when skilled pianists listened to and then imagined playing novel melodies than when they listened to and covertly hummed the same melodies (Pa & Hickok, 2008).

SPT IS SENSITIVE TO SPEECH-RELATED VISUAL STIMULI Many neurons in sensorimotor integration areas of the monkey parietal cortex are sensitive to inputs from more than one sensory modality (Andersen, 1997). The planum temporale, while often thought to be an auditory area, also activates in response to sensory input from other modalities. For example, silent lipreading has been shown to activate auditory cortex in the vicinity of the planum temporale (Calvert et al., 1997; Calvert & Campbell, 2003). Although these studies typically report the location as “auditory cortex” including primary regions, group-based localizations in this region can be unreliable. Indeed, a recent fMRI study using individual subject analyses has found that activation to visual speech and activation using the standard Spt-defining auditory-motor task (listen then covertly produce) are found in the same regions of the left posterior planum temporale (Okada & Hickok, 2009). Thus Spt appears to be sensitive also to visual input that is relevant to vocal tract actions.

In summary, Spt exhibits all the features of sensorimotor integration areas as identified in the parietal cortex of the monkey. This finding suggests that Spt is a sensorimotor integration area for vocal tract actions (Pa & Hickok, 2008), placing it in the context of a network of sensorimotor integration areas in the posterior parietal and temporal/parietal cortex, which receive multisensory input and are organized around motor-effector systems (Andersen, 1997). Although area Spt is not language specific, it counts sensorimotor integration for phonological information as a prominent function.

Verbal short-term memory relies on auditory-motor integration networks

Verbal short-term memory is often held to comprise at least two components: a storage component of some form and a mechanism for active maintenance of this information. In Baddeley’s model, for example, the storage mechanism is the

“phonological store,” a dedicated buffer, and active maintenance is achieved by the “articulatory rehearsal” mechanism (Baddeley, 1992). The concept of a sensorimotor integration network, as outlined previously, provides an independently motivated neural circuit that may be the basis for verbal short-term memory (Buchsbaum, Olsen, Koch, & Berman, 2005; Hickok et al., 2003; Hickok & Poeppel, 2000; see also Aboitiz & García V., 1997; Jacquemot & Scott, 2006). Specifically, on the assumption that the proposed sensorimotor integration circuit is bidirectional (Hickok & Poeppel, 2000, 2004, 2007), one can equate the storage component of verbal short-term memory with sensory representations in the superior temporal lobe (the same STS regions that are involved in sensory/recognition processes), and one can equate the active maintenance component with frontal articulatory systems: the sensorimotor integration network (Spt) allows articulatory mechanisms to maintain verbal information in an active state (Hickok et al., 2003). In this sense, the basic architecture is similar to Baddeley’s, except that there is a proposed computational mechanism (sensorimotor transformations in Spt) mediating the relation between the storage and active maintenance components. This view differs from Baddeley’s, however, in that it assumes that the storage component is not a dedicated buffer but an active state of networks that are involved in perceptual recognition (Fuster, 1995; Ruchkin, Grafman, Cameron, & Berndt, 2003). Because our evidence suggests that the proposed sensorimotor integration network is not specific to phonological information (Hickok et al.), we also suggest that the verbal short-term memory circuit is not specific to phonological information, a position that is in line with recent behavioral work (Jones, Hughes, & Macken, 2007; Jones & Macken, 1996; Jones, Macken, & Nicholls, 2004). For a thorough discussion of these issues, see Buchsbaum and D’Esposito (2008).

A theoretical framework: The dual-stream model

The processing of phonological information in speech recognition, speech production, and short-term memory involves partially overlapping, but also partially distinct, neural circuits. Speech recognition relies primarily on neural circuits in the superior temporal lobes bilaterally, whereas speech production and verbal short-term memory rely on a frontoparietal/temporal circuit that is left-hemisphere dominant. As noted earlier, this divergence of processing streams is consistent with the fact that phonological information plays a role in (1) accessing lexical-semantic representations on the one hand and (2) driving motor-speech articulation on the other. As lexical-semantic and motor-speech systems involve very different types of representations and processing mechanisms, it stands to reason that divergent pathways underlie the interface with phonological networks.

The dual-interface requirements with respect to phonological processing are captured neuroanatomically by the dual-stream model⁴ (figure 52.2) (Hickok & Poeppel, 2000, 2004, 2007). The model is rooted in dual-stream proposals in vision (Milner & Goodale, 1995) that distinguish between a ventral stream involved in visual object recognition (“what” stream) and a dorsal stream involved in visual-motor integration (sometimes called a “how” stream). Accordingly, the dual-stream model proposes that a ventral stream, which involves structures in the superior and middle portions of the temporal lobe, is involved in processing speech signals for comprehension (speech recognition), whereas a dorsal

stream, which involves structures in the posterior dorsalmost aspect of the temporal lobe and parietal operculum, as well as the posterior frontal lobe, is involved in translating speech signals into articulatory representations in the frontal lobe. The suggestion that the dorsal stream has an auditory-motor integration function differs from earlier arguments for a dorsal auditory “where” system (Rauschecker, 1998) but has gained support in recent years (Scott & Johnsrude, 2003; Warren et al., 2005; Wise et al., 2001).

The dual-stream model can explain the double dissociations between syllable discrimination tasks and auditory comprehension tasks noted earlier on the assumption

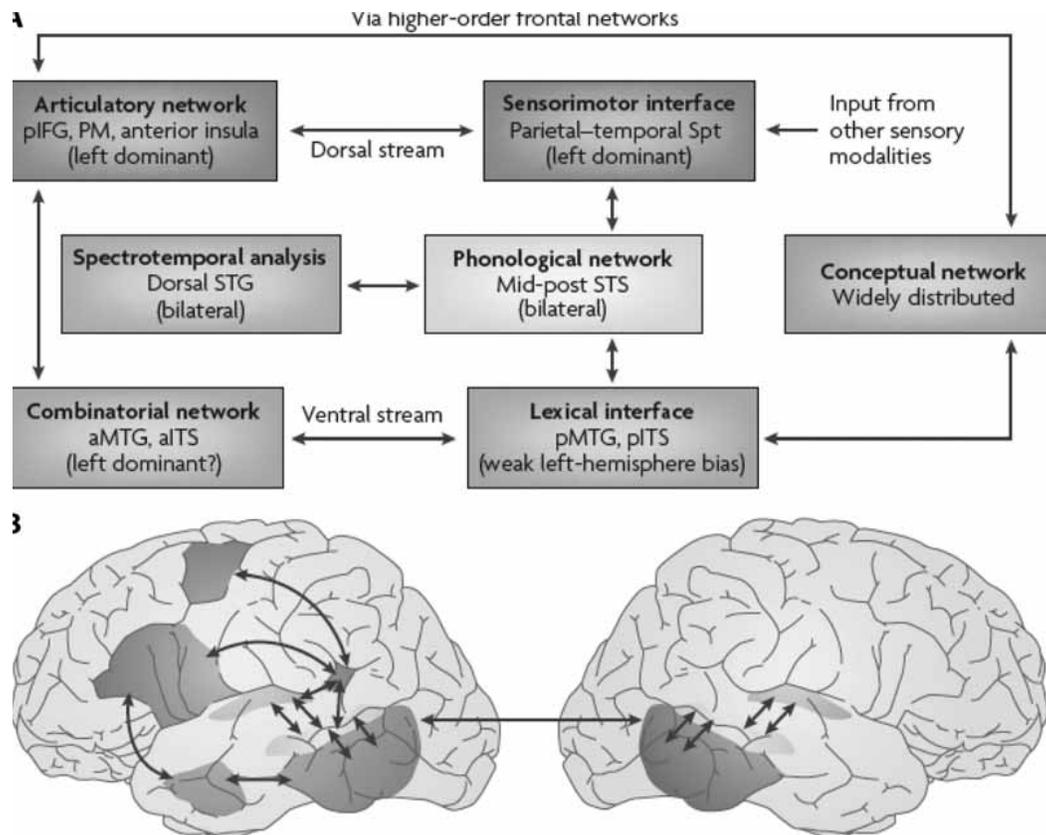

FIGURE 52.2 The dual-stream model of speech processing. (A) Schematic diagram of the dual-stream model. The earliest stage of cortical speech processing involves some form of spectrotemporal analysis, which is carried out in auditory cortices bilaterally in the supratemporal plane. These spectrotemporal computations appear to differ between the two hemispheres. Phonological-level processing and representation involves the middle to posterior portions of superior temporal sulcus (STS) bilaterally, although there may be a weak left-hemisphere bias at this level of processing. Subsequently, the system diverges into two broad streams, a dorsal pathway (blue) that maps sensory or phonological representations onto articulatory motor representations, and a ventral pathway (red) that maps sensory or phonological representations onto lexical-conceptual representations. (B) Approximate anatomical locations of the dual-stream model components, specified as precisely as available evidence allows. Regions shaded green depict areas on the dorsal surface of the

STG that are hypothesized to be involved in spectrotemporal analysis. Regions shaded yellow in the posterior half of the STS are implicated in phonological-level processes. Regions shaded red represent the ventral stream, which is bilaterally organized with a weak left-hemisphere bias. The more posterior regions of the ventral stream, the posterior middle and inferior portions of the temporal lobes, correspond to the *lexical interface*, which links phonological and semantic information, whereas the more anterior locations correspond to the hypothesized *combinatorial network*. Regions shaded blue represent the dorsal stream, which is strongly left-dominant. The posterior region of the dorsal stream corresponds to an area in the Sylvian fissure at the parietal-temporal boundary (area Spt), which is hypothesized to be a *sensorimotor interface*, whereas the more anterior locations in the frontal lobe, likely involving Broca’s region and a more dorsal premotor site, correspond to portions of the articulatory network. (Figure reproduced from Hickok & Poeppel, 2007.) (See color plate 64.)

that syllable discrimination relies to a greater extent on dorsal stream circuitry (Burton, Small, & Blumstein, 2000) (explaining the association with frontal lesions), whereas speech recognition tasks rely to a greater extent on ventral stream circuitry. The involvement of dorsal stream circuitry in syllable discrimination tasks makes sense given that discrimination of serially presented speech information requires some degree of verbal short-term memory. In addition, in contrast to the typical view that speech processing is mainly left-hemisphere dependent, the model suggests that the ventral stream is bilaterally organized (although with important computational differences between the two hemispheres); thus the ventral stream itself comprises parallel processing streams. This approach would explain the failure to find substantial speech recognition deficits following unilateral temporal lobe damage. The dorsal stream, however, is strongly left-dominant, explaining why production deficits are prominent sequelae of dorsal temporal and frontal lesions, as well as explaining why left-hemisphere injury can substantially impair performance on syllable discrimination tasks (Hickok & Poeppel, 2000, 2004, 2007).

On mirror neurons and motor theories of perception

Evidence we have reviewed suggests a tight connection between systems involved in speech perception and speech production, and the dual-stream model captures this association in the form of the dorsal processing stream that mediates this relation. The idea that perception and production systems in speech are functionally interrelated is not new, as it was an integral component of Wernicke's language model of 1874 (Wernicke, 1874/1969). The motor theory of speech perception also highlighted important links between perception and production, but with quite a different spin. Whereas Wernicke emphasized the role of perceptual systems in guiding speech production, the motor theory proposed the reverse, that motor speech systems were the foundation for speech perception (Liberman & Mattingly, 1985). Although the motor theory had lost favor among most speech/language scientists, the discovery of "mirror neurons" (di Pellegrino, Fadiga, Fogassi, Gallese, & Rizzolatti, 1992; Gallese, Fadiga, Fogassi, & Rizzolatti, 1996) has triggered a resurgence of interest in motor theories of perception generally (Iacoboni et al., 2005; Rizzolatti, Fadiga, Gallese, & Fogassi, 1996), and the motor theory of speech perception in particular (Rizzolatti & Arbib, 1998). Mirror neurons are cells found in monkey frontal cortex that respond both during the execution of motor acts and during the perception of others performing similar motor acts. It has been suggested that mirror neurons are the basis for action understanding, including the perception/understanding of speech (Rizzolatti & Arbib, 1998).

Despite the current popularity of motor theories of speech perception, there is strong evidence that the theory is incorrect. Motor theories of speech perception make a clear prediction: disruption of the motor systems involved in speech production should produce a substantial disruption of speech recognition. This prediction is falsified by the common occurrence of patients with large left frontal lesions who have profound impairments in the ability to produce speech, yet have well-preserved ability to comprehend speech at the lexical level (i.e., severe Broca's aphasics) (Goodglass, 1993; Goodglass et al., 2001). This finding demonstrates clearly that speech recognition can be achieved without the motor-speech system's involvement. However, damage to sensory-related speech areas regularly produces deficits in speech production, such as the paraphasic errors found in the fluent speech of Wernicke and conduction aphasics (Goodglass, 1993; Goodglass et al., 2001). Thus the evidence confirms Wernicke's conceptualization of the relation between sensory and motor speech systems, namely, that sensory systems are necessary for speech production, but motor-speech systems are not necessary for speech recognition (Hickok & Poeppel, 2000, 2004, 2007). Put differently, the relation between sensory and motor speech systems is better characterized by a *perceptual theory of speech production* than a *motor theory of speech perception*.

A strong version of a motor/mirror-neuron theory of speech perception is clearly untenable. At the same time, it is quite clear that motor knowledge can influence perception (Galantucci, Fowler, & Turvey, 2006), as the McGurk effect clearly demonstrates (McGurk & MacDonald, 1976). These effects do not imply, however, that speech perception requires the involvement of motor systems, only that motor knowledge can influence or constrain the acoustic analysis of speech, for example, by means of top-down, or predictive, coding mechanisms (van Wassenhove, Grant, & Poeppel, 2005). The proposed sensorimotor integration network provides a neural basis for this influence of motor knowledge on speech perception.

Summary

Phonological processing is a heterogeneous, task-dependent construct, and the neural systems that support phonological processing are similarly heterogeneous and task dependent. There is a fundamental distinction between the processes and neural circuits involved in tasks that involve motor-related systems compared with tasks that primarily involve lexical-semantic systems leading to task-related double dissociations within the context of "phonological processing." There is also a substantial amount of interaction between sensory- and motor-related aspects of phonological processing, as well as evidence for shared resources, such as phonological systems in the STS. The neuroanatomical framework

provided by the dual-stream model captures the distinctions between phonological tasks, as well as provides a basis for sensorimotor interactions.

ACKNOWLEDGMENTS This work was supported by NIH grant DC03681.

NOTES

1. Similar processes appear to operate in visual-manual languages (signed languages) suggesting that the association with sound per se may not be a defining feature of phonology (Emmorey, 2002).
2. These two proposals may not be incompatible as there is a relation between sampling rate and spectral versus temporal resolution (Zatorre, Belin, & Penhune, 2002).
3. Although conduction aphasia is often characterized as a disorder of repetition, it is clear that the deficit extends well beyond this one task (Hickok et al., 2000). In fact, Wernicke first identified conduction aphasia as a disorder of speech production in the face of preserved comprehension (Wernicke, 1874/1969). It was only later that Lichtheim introduced repetition as a convenient diagnostic tool for assessing the integrity of the link between sensory and motor speech systems (Lichtheim, 1885).
4. Note that this model is not intended as a psycholinguistic model. Nor are the boxes/brain areas intended to correspond to boxes in any existing psycholinguistic model of speech production or recognition. Instead it is a neuroanatomical outline of the brain regions involved in some linguistic operations, such as speech recognition/comprehension, speech production, and phonological working memory.

53 Morphological Processes in Language Production

KEVIN A. SHAPIRO AND ALFONSO CARAMAZZA

ABSTRACT Morphology refers to the set of linguistic processes that govern the composition of words from stored units called morphemes, which encode information about meaning and grammatical properties. Neuropsychological studies suggest that morphological operations can be spared or impaired in the setting of acquired brain damage. Moreover, specific patterns of breakdown in morphology have revealed major principles underlying the neural architecture of language. Here we make the case that the language production system has at least three components with discrete neural substrates: one component that represents lexical concepts and is organized according to meaning; a second component that processes morphological information linked to grammatical function; and a third component that converts lexical and morphological representations into specific output forms.

The basic unit of meaning in language is the morpheme, a type of cognitive representation that corresponds either to a lexical concept (a root, like *think*), to an abstract modifier that can be used to generate new lexical concepts with distinct meanings (a derivational morpheme, like *re-* or *-able*), or to a property relevant to the grammatical rules of a language (a functional morpheme, like the preposition *of* or the past tense marker *-ed*). Morphology—the system of rules that governs the construction of words from individual morphemes—is the engine that drives much of language’s combinatorial productivity, bridging the gap between the conceptual, grammatical, and phonological levels of representation. Generative morphological rules are also extremely versatile, allowing speakers to express practically unlimited nuances of meaning (*unthinkable*, *redirected*, *antidisestablishmentarians*, etc.) using a fixed set of stored representational elements.

Languages differ widely in the way that morphological structure is realized in the phonological message. In English and many other languages, morphemes may be either phonologically unbound, in the sense that they can be produced

separately from other morphemes (for example, prepositions), or bound, meaning that they cannot be produced in isolation (like the markers of plural number and past tense). Bound functional morphemes are called inflections. In Mandarin Chinese and other so-called isolating languages, functional morphemes are, as a rule, unbound; for example, the perfective aspect marker *le* in the sentence *wǒ mǎi le sānběn shū* (“I bought three books”) indicates that the action expressed by the verb *mǎi* (buying) has been completed.

This difference in phonological expression should not be taken to imply that English is morphologically “richer” than Chinese or “poorer” than a language like classical Hebrew, which marks verbs for both aspect and agreement with the subject (in *qaniti šloša s^ofarim*, the verb *qaniti* is a first-person singular perfective form). Rather, such variation provides rich fodder for the study of morphological processing, insofar as speakers of different languages make different kinds of errors with morphology under demanding experimental conditions (Dick, Bates, & Ferstl, 2003) and present with different morphological impairments in the setting of brain damage (Bates, Friederici, & Wulfeck, 1987; Menn & Obler, 1990; Wulfeck, Bates, & Capasso, 1991). For example, Mandarin-speaking aphasic patients tend to omit functional morphemes (Packard, 1990), while Hebrew-speaking patients tend to make substitution errors with bound morphemes and omission errors with unbound functional morphemes (Friedmann & Grodzinsky, 1997).

Moreover, some theories posit the existence, in all languages, of morphemes that have no phonological content at all. In the phrase *two sheep*, for example, the plural marker is thought to be phonologically null. This is an exception for English, which generally marks plurals with the inflectional suffix *-s*, but is perhaps the rule for Mandarin, which has no marker for plurals per se (*shū* can mean either “book” or “books,” depending on the context). In any given language, there may be very many grammatical features that are encoded by such zero morphemes (Pesetsky, 1995). On this view, nearly every word produced by a speaker or comprehended by a listener is, in fact, an agglomeration of lexical and functional morphemes, which convey various kinds of information crucial for encoding and decoding the meaning of that word in the context of an utterance. In other words,

KEVIN A. SHAPIRO Department of Psychology, Harvard University, Cambridge; Department of Medicine, Children’s Hospital, Boston, Massachusetts

ALFONSO CARAMAZZA Department of Psychology, Harvard University, Cambridge, Massachusetts; Center for Mind/Brain Sciences, University of Trento, Rovereto, Italy

morphology is not an optional stage in the production and comprehension of language, but an obligatory one (see also Shapiro, Shelton, & Caramazza, 2000).

Morphological composition in the lexicon

If many words appear to be composed of more than one morpheme, then must all morphologically complex words be built from scratch every time they are produced? Or are complex forms stored in the mental lexicon, so that they can be retrieved as prebuilt units when needed in speech or in comprehension?¹

In some morphological domains, and particularly in the domain of inflectional morphology, it seems unlikely that all forms are fully listed in the lexicon (Butterworth, 1983). Inflected words have meanings that are transparent and predictable from their component parts, and regular inflections can be productively applied to novel words and non-words that have no corresponding lexical representations (Berko Gleason, 1958; Goodglass & Berko, 1960). Furthermore, in some languages, the number of possible inflectional forms for any given word is so large as to render the full-listing hypothesis computationally infeasible. For example, in Finnish a noun may have as many as 2,000 distinct inflectional forms. Neuropsychological evidence also provides some support for the “online” nature of inflectional morphology: some patients appear to have selective problems with morphological inflection (Laine, Niemi, Koivuselkä-Sallinen, & Hyönä, 1995; Miceli & Caramazza, 1988), and others display different patterns of errors with lexical and inflectional morphemes (Miceli, Capasso, & Caramazza, 2004).

Some derivational processes are also likely to take place online, like the generation of novel derived forms with transparent meanings (*undigitizable*, *misunderestimate*) and productive lexical compounding, as in the Mandarin *wǒ mǎi shū le* (analogous to the English “I went book-buying”) (Butterworth, 1983; Cutler, 1981; Vannest & Boland, 1999). For conventional derived words (like *conventional* and *composition*), however, the question is much more controversial (McQueen & Cutler, 1998). According to one set of theories, the lexicon has a root- (or stem-) based organization, meaning that the root is the basic unit that is stored in memory; derived forms must be produced by composition online (Forster, 1976; Taft, 1979; Taft & Forster, 1975). Other theories hold that common derived forms are stored as units, though they may be linked to other representations within the same derivational family (*compose*, *composure*, *composite*, *composition*, *decompose*, and so on) (Caramazza, Miceli, Silveri, & Laudanna, 1985). A third kind of model proposes that only derived words that are highly frequent (as well as inflected forms that are highly frequent) are stored as units; low-frequency forms must be constructed or parsed online

(Luzzatti, Mondini, & Semenza, 2001). The tendency to store derived forms in toto, as opposed to storing them in a decomposed manner, may vary across languages (Vannest, Bertram, Järvikivi, & Niemi, 2002).

The data available to distinguish between these cognitive models are equivocal, and there is very little evidence from cognitive neuroscience on the processing of morphologically derived words. Electrophysiological data suggest that morphological relationships between words affect lexical access at an earlier stage than phonological relationships (Pykkänen, Feintuch, Hopkins, & Marantz, 2004), lending support to the general idea that morphological structure is represented in the lexicon but not distinguishing between the competing proposals about morphological decomposition. From this point forward we will generally be concerned with the cognitive neuroscience of productive morphological processes, and especially of morphological inflection.

Neural basis of productive morphological processes

Although morphological processing plays a central role in language, morphology has received comparatively little attention from cognitive neuroscientists. Much of what is known about morphology from a neuroscientific perspective comes from the study of brain-damaged patients who have difficulties in producing and understanding morphologically complex words. Impairment with the use of functional morphemes is classically observed in patients with lesions affecting the left inferior frontal lobe (Goodglass & Berko, 1960; Menn & Obler, 1990) and is considered a defining characteristic of agrammatic aphasia. By contrast, patients with posterior perisylvian lesions often show preservation of functional and derivational morphemes despite impairment in access to lexical roots. Such patients may produce apparently morphologically complex neologisms like *persessing* and *deborodation* (Buckingham & Kertesz, 1974; Caplan, Kellar, & Locke, 1972; Semenza, Butterworth, Panzeri, & Ferreri, 1990).

This generalization about anterior and posterior aphasics is not ironclad, however, as some patients with anterior lesions also appear to have preserved knowledge about functional morphology in the face of significant impairments in lexical access. For example, patient HG could produce *achooing* and *looming* but not *sneezing* or *weaving*, and she was also able to produce inflected nonwords in phrases like *he wugs* (Shapiro & Caramazza, 2003b). Patients with acquired “deep” dyslexia, which can arise as a sequela of heterogeneous and diffuse lesions in the left hemisphere, also characteristically make morphological errors in reading aloud (e.g., *initiative* for *initiate*) (Patterson, 1980).

On the one hand, the observation that morphological elements in language can be spared or impaired selectively in aphasia suggests that morphological rules rely on neural

circuits distinguishable from those that underly other aspects of language, like phonology and syntax. This suggestion coincides both with dominant linguistic theories and with psycholinguistic models of sentence processing, which postulate the independence of morphology from phonology and syntax on the basis of evidence like the differential involvement of lexical and functional morphemes in slips of the tongue (e.g., *it waits to pay*) (Garrett, 1980; Levelt, 1989; Schwartz, 1987).

On the other hand, it is not obvious that all morphological errors in aphasia are actually attributable to deficits in morphological knowledge as such. It has been argued that the morphological errors made in reading by acquired dyslexic patients are not morphological in origin at all, but rather are actually semantic errors or visual errors (Badecker & Caramazza, 1987; Castles, Coltheart, Savage, Bates, & Reid, 1996; Funnell, 1987; Plaut & Shallice, 1993). This proposal has been notoriously difficult to refute, although there is evidence to suggest that such patients do not systematically produce morphological forms that are more frequent or more imageable (Rastle, Tyler, & Marslen-Wilson, 2006). Similar doubts exist about the nature of morphological errors in naming, repetition, and spontaneous speech. In a study of repetition errors in 26 aphasic patients, Miceli and colleagues (2004) demonstrated that aphasic patients who make morphological errors invariably also make phonological errors, implying either that the neural circuits important for morphology are distinct but grossly inseparable from regions involved in phonological processing, or that what appear to be morphological errors are in fact errors of phonology.

In this case, there is some evidence to support both positions. Neuroimaging studies have found that the left inferior prefrontal cortex is recruited in a wide variety of linguistic and nonlinguistic tasks, including the processing of grammatical gender (Miceli et al., 2002), phonological processing (Heim & Friederici, 2003; Heim, Opitz, Muller, & Friederici, 2003; Indefrey & Levelt, 2000), and phonological working memory (Hickok & Poeppel, 2007; Paulesu, Frith, & Frackowiak, 1993). These diverse results suggest that the left anterior perisylvian region may contain populations of neurons that are heterogeneous in function. It may be that any brain lesion that is large enough or severe enough to disrupt morphological processes will also disrupt phonological processes—and perhaps other cognitive functions as well. Alternatively, perhaps it is the case that functional morphemes are especially vulnerable to impairment because of the extra demands they place on the phonemic processor. Kean observed that agrammatic patients tend to omit functional morphemes that are phonologically less salient (Kean, 1978, 1979). Both children and some aphasic patients fare more poorly with inflections that are phonologically more complex (Berko Gleason, 1958; Shapiro & Caramazza,

2003a; Bird, Lambon-Ralph, Seidenberg, McClelland, & Patterson, 2003; Joanisse & Seidenberg, 1999; Patterson, Lambon-Ralph, Hodges, & McClelland, 2001).

An intermediate possibility is that morphology is neither an autonomous function nor a wholly owned subsidiary of phonology, but rather a confederation of processes that operate at the interstices of language, ensuring that abstract syntactic representations with particular grammatical and structural features can be matched with specific, contextually appropriate lexical representations, and that these lexical representations in turn can be converted into phonological strings. Morphological deficits in aphasia may arise when one of these interfaces is compromised by damage at a particular level of language processing. For instance, patients who have difficulty with lexical access may be prone to making paragrammatic substitution errors in either functional or derivational morphology (Caplan et al., 1972; Kohn & Melvold, 1999; Laine et al., 1995; Miceli & Caramazza, 1988; Semenza et al., 1990). Such patients may make relatively few phonological errors, especially if their errors in other language production tasks are not primarily phonological—as was true for patient HH described by Laine and colleagues, who produced paralexias involving both functional morphemes and root (or stem) morphemes (e.g., *pesä+lla* “on the base” was read as *maila+sta* “from the bat”). Interestingly, this patient’s lesion largely spared the left inferior prefrontal cortex, but may have involved subcortical connections between the left frontal lobe and posterior perisylvian areas that were also damaged.

Some patients appear simply to ignore morphemes that are not lexical roots, even when access to phonological information appears to be intact (Tyler, Behrens, Cobb, & Marslen-Wilson, 1990); in these cases, the deficit may also occur at the level of lexical retrieval. However, patients with postlexical processing deficits may have particular difficulty with functional morphemes, which are often unstressed and can require the resyllabification of words and phrases (Kean, 1978). Likewise in comprehension, patients of this type may have difficulty parsing functional affixes (Tyler & Cobb, 1987). Others still may present with morphological impairments that are linked to the ability to use particular kinds of syntactic information (Goodglass & Berko, 1960), such as information about tense (Friedmann & Grodzinsky, 1997; Miceli, Silveri, Romani, & Caramazza, 1989) or knowledge about a specific grammatical category (Laiacina & Caramazza, 2004; Shapiro & Caramazza, 2003a; Tsapikini, Jarema, & Kehayia, 2002).

The question of how morphology interacts with other subcomponents of language, as well as with domain-general mechanisms in cognitive processing, has proven to be a fruitful field of research in this otherwise relatively uncultivated domain of cognitive neuroscience. We will discuss two examples in the sections that follow. First, there is the

controversy over the representation of phonologically regular and irregular morphological forms (like *ducks* and *geese*, respectively), which addresses a question at the interface of morphology and phonology: namely, how are abstract morphological features converted to phonological information? Second, there is the debate about whether the brain distinguishes between categories of words, like nouns and verbs, by virtue of their abstract morphosyntactic properties. Both topics demonstrate that the neuroscientific investigation of morphological processing can generate findings and novel hypotheses that are relevant not only to the biology of language, but also to the understanding of cognition more broadly.

The regular/irregular debate

As we saw with the example *two sheep*, a morphologically marked grammatical feature (like past tense) may be expressed phonologically in more than one way within a language. When this is the case, there is usually only a small set of regular morphophonological transformations that can be applied productively to novel words (e.g., *one google/many googles*); the other transformations tend to be frozen and nonproductive (e.g., *goose/geese* but not *google/*geegle*). This discrepancy has led many to propose that regular and irregular forms are processed by separate cognitive and, by extension, neurobiological mechanisms (Pinker, 1991).

At first glance, this proposal appears to be supported by the existence among aphasic patients of double dissociations in processing regular and irregular morphology (Marslen-Wilson & Tyler, 1997; Tyler, deMornay-Davies, et al., 2002; Tyler, Randall, & Marslen-Wilson, 2002; Ullman et al., 1997); see figure 53.1. The evidence for such dissociations has been challenged, however, on the grounds that they are reducible to phonological factors (Bird et al., 2003; Braber, Patterson, Ellis, & Ralph, 2005; Lambon-Ralph, Braber, McClelland, & Patterson, 2005) or to a combination of phonological and semantic deficits (Joanisse & Seidenberg, 1999; Patterson et al., 2001): in other words, regular words are more susceptible to errors because they involve transformations that are phonologically more complex, not because they are processed by a different route than regular morphological transformations. Coincidentally, it has been reported that patients with impairments in regular morphology tend to have lesions in left inferior prefrontal regions (Ullman et al., 1997)—a part of the brain which, we have seen, is also thought to be important for phonological processing.

Whether the single-route account can successfully explain all cases of regular/irregular dissociations is a matter of some debate, and there appear to be at least some anterior aphasic patients for whom a selective deficit in irregular morphology co-occurs with a deficit in phonological processing, contrary

to what this account would seem to predict (Miozzo, 2003). The dual-route account, by contrast, is often (albeit not of necessity) linked with a different hypothesis about the functional role of the left inferior frontal cortex. Ullman and colleagues have proposed that the processing of regular forms depends on a frontal-striatal circuit that is engaged more generally in the representation of procedural memory, not necessarily limited to language (Pinker & Ullman, 2002; Ullman et al., 1997; Ullman, 2001, 2004; Ullman et al., 2005). However, irregular forms are said to depend on temporal lobe structures that are important for the representation of declarative memory.

The declarative/procedural hypothesis is attractive in that it situates a linguistic dissociation within the context of a general model in cognitive neuroscience. However, the empirical data have so far been mixed. To begin with, the putative link between frontal lobe damage and impairments in regular morphological processing is tenuous at best. Although some patients with anterior lesions have selective deficits for regular morphological transformations, and some patients with temporal lobe damage have more difficulty with irregular transformations (Tyler, deMornay-Davies, et al., 2002; Tyler, Randall, et al., 2002; Ullman et al., 1997), there are numerous counterexamples of patients with frontal lobe damage who have greater difficulty with irregular words (de Diego Balaguer, Costa, Gallés, Juncadella, & Caramazza, 2004; Penke, Janssen, & Krause, 1999; Shapiro & Caramazza, 2003a). Neuroimaging studies of regular and irregular inflection have not clarified the issue: some have failed to elucidate distinctions in the cortical regions activated by regular and irregular stimuli (Sahin, Pinker, & Halgren, 2006), others have shown that irregular words elicit greater activity in prefrontal regions (de Diego Balaguer et al., 2006; Desai, Conant, Waldron, & Binder, 2006), and still others seem to indicate that regular words produce greater activation in both frontal and temporal regions (Beretta et al., 2003; Tyler, Stamatakis, Post, Randall, & Marslen-Wilson, 2005).

This confusion may be due in part to the fact that not all regular/irregular dissociations arise at the same level of language processing. As Druks observes, the regular/irregular distinction is relevant only in the domain of morphophonology, and so the dissociation predicted by the procedural/declarative hypothesis should be evident only when rule-based morphophonological processing is emphasized (Druks, 2006). A corollary is that deficits at other levels may also interact with the processing of regular and irregular word forms. For at least one of the patients who exhibited a dissociation not in line with the procedural/declarative model, the locus of impairment appeared to be not morphophonological, but morphosyntactic: the patient produced regular forms better than irregular forms, but only when the stimuli were inflected verbs (Shapiro & Caramazza, 2003a). This result reinforces the observation that the left inferior

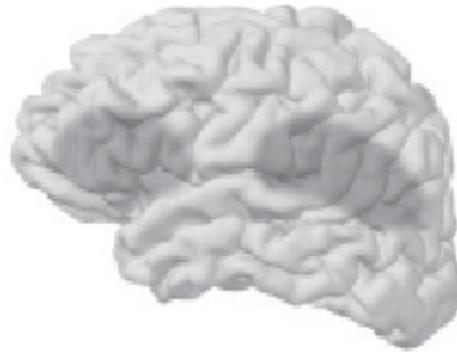

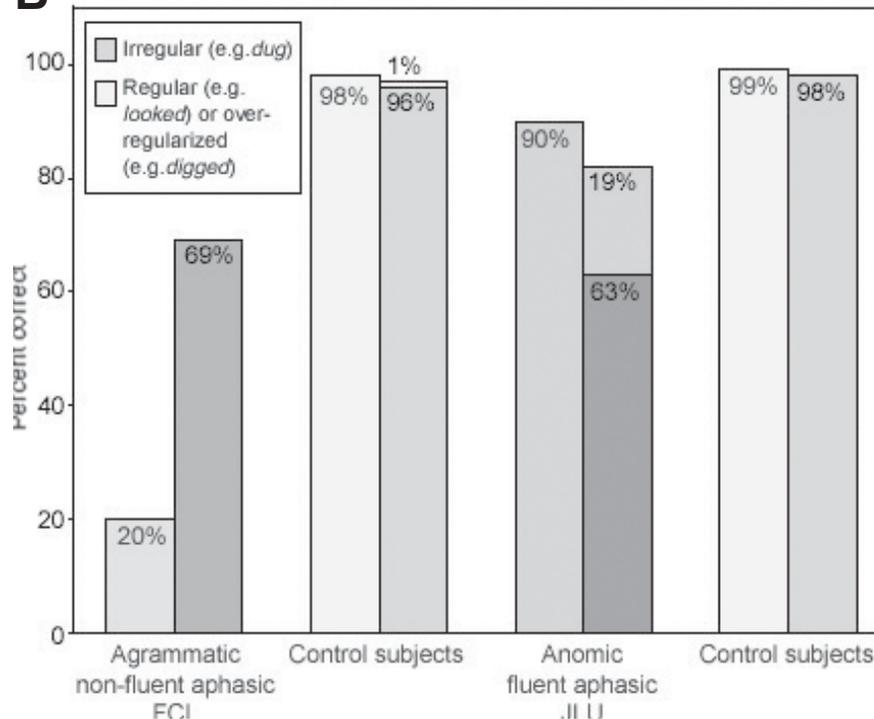

A**B**

FIGURE 53.1 A neuropsychological dissociation in processing regular and irregular verb forms. (A) The approximate lesion sites of patient FCL (red area, left anterior perisylvian regions), who had symptoms of agrammatism, and patient JLU (green area, left temporoparietal region), who had symptoms of anomia. (B) Results of verb inflection tests showed that the agrammatic patient had more trouble inflecting regular verbs (lighter bars) than irregular verbs

(darker bars), whereas the anomic patient had more trouble inflecting irregular verbs—and overapplied the regular suffix to many of the irregulars (light green bar on top of dark green bar). The performance of age- and education-matched control subjects is shown in the gray bars. (Reprinted from Pinker & Ullman, 2002.) (See color plate 65.)

prefrontal cortex is functionally heterogeneous. Not all patients with lesions in this area may be expected to have the same pattern of linguistic performance, and activation of this region in neuroimaging paradigms may be particularly sensitive to the demands of the task that is employed.

A second anatomical claim of the procedural/declarative hypothesis is that the basal ganglia, and specifically the striate nuclei (the caudate and putamen), are crucial for the processing of grammatical rules. Studies of patients with early Huntington's disease, which first affects the caudate, have shown that these patients are indeed impaired in producing morphologically complex word forms (Gordon & Illes, 1987) and making rule-based judgments about such

forms (Teichmann, Dupoux, Kouider, & Bachoud-Lévi, 2006). They may make more errors than control subjects in the production of regularly inflected words (Longworth, Keenan, Barker, Marslen-Wilson, & Tyler, 2005), though the latter finding appears to be subtle and task dependent. Some neuroimaging experiments corroborate the idea that the caudate nuclei are particularly active in the detection of syntactic anomalies, including anomalies signaled by morphological structure (Forkstam, Hagoort, Fernandez, Ingvar, & Petersson, 2006; Lieberman, Chang, Chiao, Bookheimer, & Knowlton, 2004; Moro et al., 2001). The evidence therefore seems, on balance, to support a role for the caudate in the application of linguistic rules. By contrast, patients with

nonstriatal basal ganglia lesions, like those with Parkinson's disease, do not reliably display either regular/irregular effects (Longworth et al.) or difficulties with syntactic rules (Reber & Squire, 1999; Small, Lyons, & Kemper, 1997; Witt, Nühsman, & Deuschl, 2002).

Grammatical categories and morphological processes

It has long been observed that some patients with aphasia have more difficulty producing nouns than verbs, while others show the opposite dissociation (Goodglass, Klein, Carey, & Jones, 1966; Luria & Tsvetkova, 1967; Miceli, Silveri, Villa, & Caramazza, 1984). This dissociation is particularly relevant to the discussion of morphological knowledge, since nouns and verbs can be distinguished formally by virtue of the fact that they undergo different kinds of morphological operations. For example, nouns in English are marked for number and possession, while verbs are marked for tense and subject agreement. The differential distribution of morphological operations over nouns and verbs may also facilitate the acquisition of grammatical categories in the course of language development (Maratsos & Chalkley, 1981).

In some cases, "grammatical" category deficits may not be grammatical in origin at all; instead, they may be attributable to impairments in access to specific kinds of semantic information associated more with words of one category than another. For example, many verbs refer to actions; a selective deficit in verb production could, therefore, result from damage to brain regions involved in representing knowledge about actions. Likewise, an apparent noun deficit could result from an underlying impairment in retrieving semantic knowledge about concrete objects (Damasio & Tranel, 1993; McCarthy & Warrington, 1985).

Still, some patients have deficits that cannot readily be explained by positing a breakdown in access to semantic knowledge. A number of patients with deficits in noun or verb production are particularly impaired in producing morphologically inflected words when they clearly belong to one grammatical category (Laiacona & Caramazza, 2004; Shapiro & Caramazza, 2003a; Shapiro et al., 2000; Tsapkini et al., 2002), even when, in some cases, they are able to produce exactly the same strings when the context indicates that they belong to the other category (Shapiro & Caramazza, 2003a; Shapiro et al.). For example, patient RC, described by Shapiro & Caramazza (2003a), was able to produce the phrase *these judges*, but not the phrase *he judges*. This deficit extended even to the production of morphologically inflected neologisms (e.g., *these wugs* versus *he wugs*).

The fact that these patients also have difficulties with the affected category in production tasks that do not explicitly involve morphological inflection—like picture naming and delayed repetition—cannot be taken as *prima facie* evidence

against a morphological locus for their deficits; to the contrary, it reinforces the idea that morphological processing is an essential step in all lexical output (Shapiro et al., 2000). Moreover, a category-specific impairment in morphological inflection is not the simple consequence of any deficit that appears to affect noun or verb production: some patients have difficulty producing words of one category without any evident impairment in morphology (Shapiro & Caramazza, 2003b).

What brain regions subserve the morphological processing of nouns and verbs? The data on this score are limited, as the patients who have clear grammatical impairments are few in number and have lesions that are too extensive and ill-defined to allow for meaningful comparisons. However, it has been shown that when neurologically intact subjects perform morphological transformation tasks following transcranial magnetic stimulation, a processing deficit for verbs emerges only when the stimulation is targeted to a focal area of the left middle frontal gyrus, situated near the triangular portion of Broca's area (Cappelletti, Fregni, Shapiro, Pascual-Leone, & Caramazza, 2008; Shapiro, Pascual-Leone, Mottaghy, Gangitano, & Caramazza, 2001); see figure 53.2. This area is included within the lesion of patient RC (Shapiro & Caramazza, 2003a).

Curiously, neuroimaging studies have offered little, if any, support for the notion that this part of the brain distinguishes nouns from verbs on the basis of morphology. In most previous studies, differences in activation between nouns and verbs have been observed not in the middle frontal gyrus but in the left inferior frontal gyrus, or Broca's area (Longe, Randall, Stamatakis, & Tyler, 2007; Perani et al., 1999; Sahin et al., 2006; Tyler, Bright, Fletcher, & Stamatakis, 2004). Although this area is also included within the lesions of patients with apparent verb deficits, in most cases the lesions are much more extensive than the area of activation (figure 53.3). Moreover, Tyler and colleagues (Longe et al., 2007; Tyler et al.) have argued that the increased activation they observed for verbs in this region does not reflect categorical specificity as such, but rather, the greater complexity of verb morphology as compared to noun morphology. For example, they point out that verb inflection in English may be bound up with the computation of long-distance syntactic dependencies, like agreement with the subject of a sentence. It is indeed likely that the inferior frontal gyrus is sensitive to any variation in processing demands, but this may be more a property of particular stimuli than of the English language in general: nouns with low-frequency and atypical inflectional forms activate this area more than do verbs (Sahin et al.). When noun and verb stimuli are carefully matched for difficulty, targeted suppression of Broca's area with transcranial magnetic stimulation results in a category-general delay in processing, but no category-specific effects (Cappelletti et al., 2008).

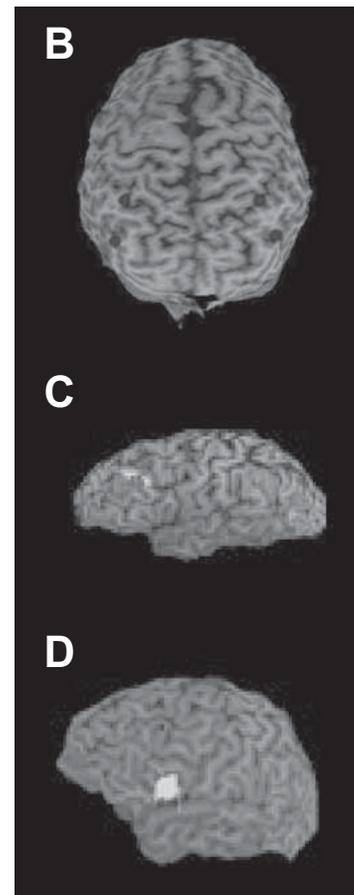

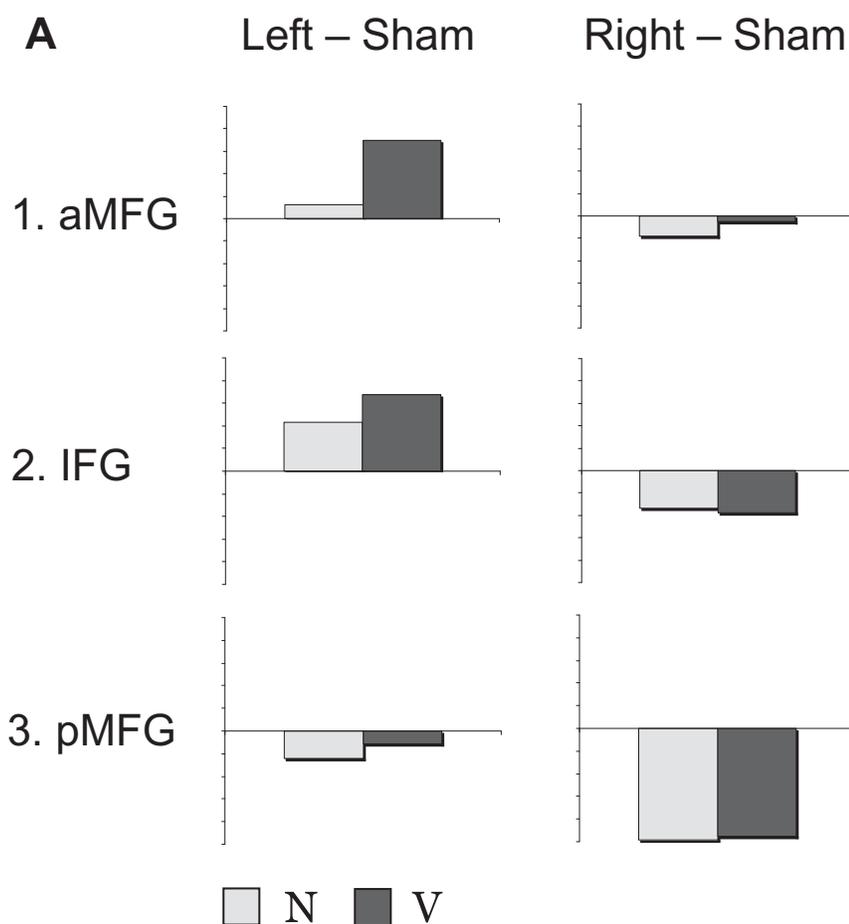

FIGURE 53.2 Results of the rTMS experiment reported by Cappelletti et al. (2008), showing a selective disruption in verb processing following stimulation to the left anterior frontal gyrus. (A) The mean difference in reaction times to nouns and verbs with repetitive TMS compared to sham stimulation in three areas: the anterior middle frontal gyrus (aMFG), inferior frontal gyrus (IFG),

and posterior middle frontal gyrus (pMFG). (B) The sites of stimulation to the IFG and pMFG. The remaining panels demonstrate the stereotactic application of TMS to the left pMFG (C) and left IFG (D). (Modified from Cappelletti, Fregni, Shapiro, Pascual-Leone, & Caramazza, 2008.) (See color plate 66.)

We propose that the left inferior frontal gyrus represents a common pathway for the production of words bearing functional morphemes that specify grammatical information relevant to one category or another. In other words, this area (perhaps along with the striate nuclei of the basal ganglia) may be important for the conversion of morphological elements into phonological segments. The process of selecting syntactically appropriate functional morphemes may be handled by different upstream regions, like the left anterior middle frontal gyrus for verbs. These morphosyntactic regions, in turn, must normally receive information from the lexicon, with the constraint that only words meeting certain requirements should be processed as nouns or verbs—allowing us to say, for example, that *he rose to smell* or *he smelled a rose*, but not *he has been rising up the place all afternoon*.

The hypothesis of a neuroanatomical dissociation between grammatically based morphological processes and form-based morphological processes also has the virtue of

accounting for certain striking phenomena that have hitherto been somewhat difficult to reconcile with other theories about the organization of language in the brain: namely, the finding that some aphasic patients exhibit grammatical category deficits that are restricted to either spoken or written output (Caramazza & Hillis, 1991; Hillis & Caramazza, 1995; Hillis, Tuffiash, & Caramazza, 2002; Hillis, Wityk, Barker, & Caramazza, 2003; Rapp & Caramazza, 2003). Perhaps the clearest example of this kind of modality specific deficit is the case of patient KSR, who produced verbs better than nouns in speech, but nouns better than verbs in writing (Rapp & Caramazza, 2002). That such patients are able to produce the same stimuli in one modality but not in another strongly implies that the patients' problems do not arise at the semantic level of representation. Instead, it has been proposed that the cortical regions responsible for storing and accessing lexical representations are segregated along lines of both modality and grammatical category, so that brain

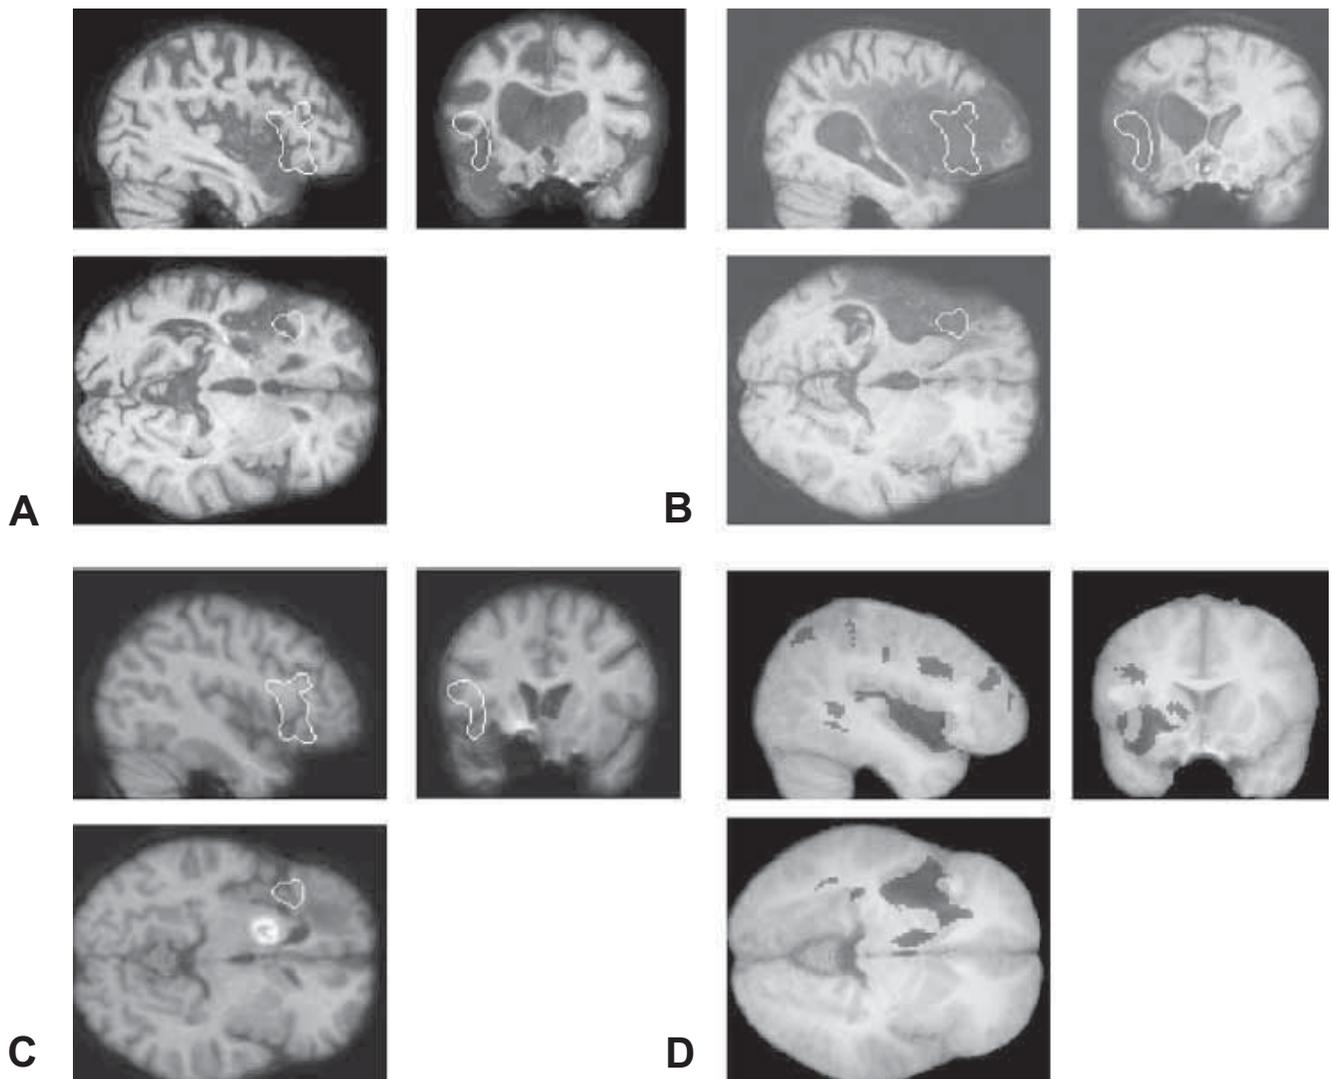

FIGURE 53.3 The area found by Tyler and colleagues (2004) to be more active for inflected verbs than inflected nouns in an fMRI semantic judgment paradigm, compared to the lesion sites of three aphasic patients with deficits in processing regularly inflected verb forms in a priming task. (A–C) T1-weighted MR images of three patients with an outline of the activation found in the verbs-nouns contrast superimposed on them. (D) A mean of the spatially

normalized T1 images of the 12 subjects in the fMRI experiment overlaid with the lesion overlap of the three patients in A–C. Lesion overlap is shown in blue, the significant activation found in the verbs-nouns contrast is in yellow, and the overlap between common lesion volume of the three patients and the activation is in green. (Reprinted from Tyler, Bright, Fletcher, & Stamatakis, 2004.) (See color plate 67.)

damage might selectively affect access to orthographic verb representations, for example.

While this proposal is not logically impossible, it is somewhat difficult to reconcile with the fact that these patients' lesions tend to be relatively large, and the areas implicated—like the left posterior inferior frontal and precentral gyri in two patients unable to write verbs (Hillis et al., 2003)—are unlikely candidates for modality-specific lexical stores. However, if we suppose that morphosegmental processes (in phonology and orthography) are dissociable from lexical retrieval and morphosyntactic feature selection, an alternative explanation becomes available. It may be that modality-specific grammatical-class deficits are manifestations of

disconnections between morphosyntactic processors, segregated by grammatical category, and morphosegmental processors, which may be segregated by modality.

Precisely what brain areas are important for category-specific morphosyntactic processes and for the representation of phonological and orthographic segments is, of course, a matter that requires much further investigation. With respect to morphosyntactic processing, the rTMS studies reviewed here suggest that the anterior portion of the left middle frontal gyrus may be crucial for verbs (Cappelletti et al., 2008; Shapiro et al., 2001). The data for nouns are even more severely limited: the lesion data implicate either the left inferior frontal lobe or the inferior parietal lobe

(Shapiro et al., 2000), although none of the frontal areas tested with rTMS was found to be crucial for nouns. What is clear, however, is that some components of the neural circuitry for language production are sensitive to information about grammatical category, while others are dedicated to the processing of particular kinds of output. We believe that this hypothesized division of labor, with the ultimate goal of constructing morphemes into producible and comprehensible words, may provide a productive framework for investigating the neurobiological mechanisms by which language operates.

NOTE

1. In this chapter we are concerned primarily with language production: in other words, how do speakers produce morphologically complex words? Of course, an analogous problem exists in the domain of comprehension: how do listeners access the meaning of morphologically complex words? We make the assumption here that the lexicon is unitary—that is, that the same kinds of lexical representations are accessed in production and comprehension. It follows that theories about morphological composition in the lexicon, even those based empirically on evidence from comprehension tasks, should also apply to language production.

54 Ventral and Dorsal Contributions to Word Reading

LAURENT COHEN AND STANISLAS DEHAENE

ABSTRACT The core component of expert reading is the fast and accurate perception of single words by the visual system, an ability that results from years of intensive learning. We propose an integrated view of the contributions of the ventral and dorsal streams to this process, associating brain imaging in normal subjects and studies of brain-damaged patients. Together, these two sources of data indicate that fluent reading results from a tight collaboration of both pathways. In the left occipitotemporal cortex, the Visual Word Form system allows for the fast, invariant, and parallel encoding of well-formed letter strings. The occipitoparietal pathway makes an important contribution to reading through attention orienting, word selection, and within-word serial decoding under nonoptimal reading conditions.

The acquisition of reading by children rests on a delicate tuning of the visual system and of the verbal system, and on the elaboration of novel interactions between these two preexisting domains. As a result of this long and effortful process, adult readers are able to scan pages of text in a fast and orderly manner, identifying a flow of words that are each fixated only for a fraction of a second, immediately accessing their sound and meaning, and building up at the same time an integrated interpretation of the text. The core component of this remarkable process is the fast and accurate perception of single words by the visual system. A prerequisite for access to a word's sound and meaning is the identification of its component letters and of their order, an abstract representation that has been called the Visual Word Form (Besner, 1989; Paap, Newsome, & Noel, 1984; Warrington & Shallice, 1980).

In past years, research has concentrated on the contribution of the left ventral visual system to word-identification processes. However, like any complex visual task, reading is most likely achieved through a collaboration of the two components of the cerebral visual system—that is, the ventral occipitotemporal “what” stream and the dorsal

occipitoparietal “where” stream (Ungerleider & Mishkin, 1982). In this chapter we propose an integrated view of the contributions of the ventral and dorsal streams to single-word reading. We systematically associate information from brain imaging in normal subjects and contributions from studies of brain-damaged patients with varieties of acquired “peripheral” dyslexias—that is, reading deficits resulting from impaired visual processing, as opposed to language-related “central” dyslexias. Together, these two sources of data indicate that fluent reading results from a tight collaboration of the ventral and dorsal visual pathways, with the occipitotemporal route dominating for expert reading of known words and the occipitoparietal pathway making an essential contribution to reading under dysfluent, unfamiliar, or degraded conditions.

Word processing in the ventral visual pathway

WORD PERCEPTION AS OBJECT PERCEPTION Over the last decades, studies in monkeys and, more recently, functional imaging in humans have shown that object recognition is achieved through neuronal hierarchies located in the ventral occipitotemporal pathway (figure 54.1). Moving from area V1 to inferotemporal (IT) cortex, converging neurons show an increasing invariance to position and scale, an increasing size of the receptive fields, and an increasing complexity of the neurons' optimal stimuli (M. Booth & Rolls, 1998; Riesenhuber & Poggio, 1999; Rolls, 2000; Serre, Oliva, & Poggio, 2007; Ullman, 2007). Connections include bottom-up and top-down projections within the ventral stream (Felleman & Van Essen, 1991), as well as projections to and from more remote frontal and parietal regions subserving attentional control (Kastner & Ungerleider, 2000).

We proposed that the ability to read words stems from this general ability of the ventral stream to identify complex multipart objects. According to the local combination detector, or LCD, model (Dehaene, Cohen, Sigman, & Vinckier, 2005), words are encoded through a posterior-to-anterior hierarchy of neurons tuned to increasingly larger and more complex word fragments, such as visual features, single letters, bigrams, quadrigrams, and possibly whole words.

STANISLAS DEHAENE INSERM, Cognitive Neuro-Imaging Unit, Gif sur Yvette; Collège de France, Paris, France

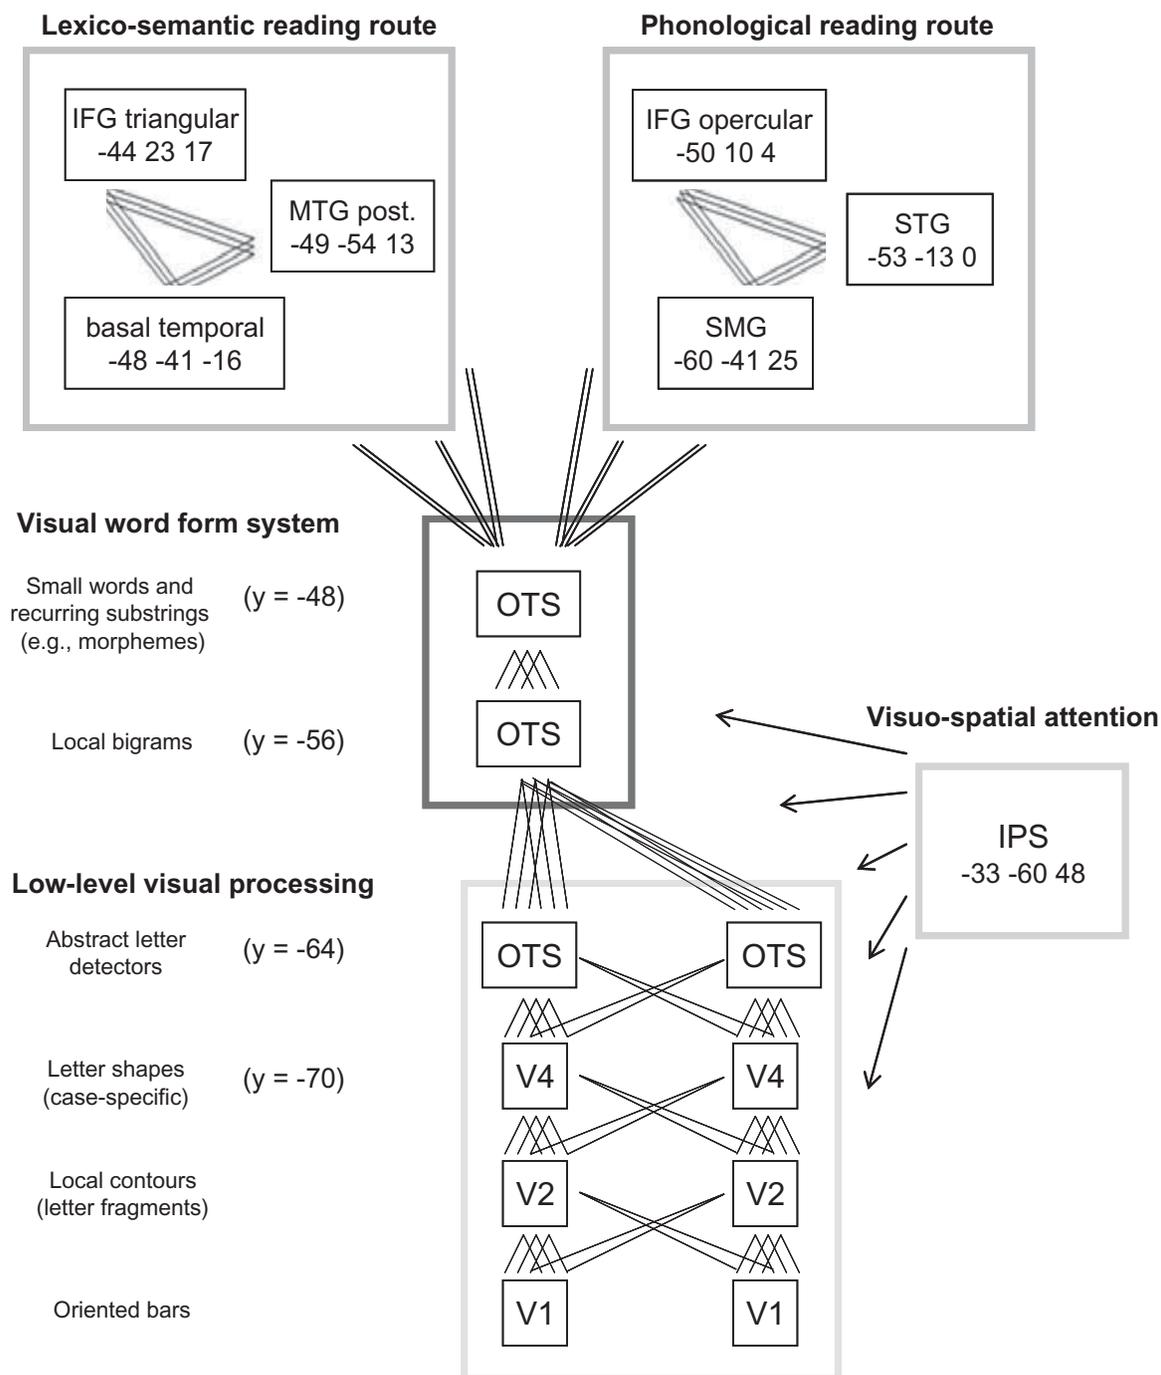

FIGURE 54.1 Synthetic schema of the reading system, merging propositions from Dehaene, Cohen, Sigman, and Vinckier (2005) and Cohen and colleagues (2003). Low-level processing is achieved in each hemisphere for the contralateral half of the visual field (yellow). Information converges on the left-hemispheric Visual Word Form system, where an invariant representation of letter strings is computed (red). The dorsal visual stream exerts a top-down attentional control on the hierarchy of ventral areas (blue). The ventral visual system then feeds the lexicosemantic and

phonological reading routes (green). The proposed normalized coordinates for the lexicosemantic and phonological reading routes are from a meta-analysis of 35 PET and fMRI studies (Jobard, Crivello, & Tzourio-Mazoyer, 2003), and the coordinates of the visuospatial attention system are from Gitelman et al. (1999). IFG: inferior frontal gyrus; MTG: middle temporal gyrus; SMG: supra-marginal gyrus; OTS: occipitotemporal sulcus; IPS: intraparietal sulcus. (See color plate 68.)

This system reaches its optimal level of expertise only after years of practice. Through perceptual learning mechanisms, neurons within the ventral pathway become progressively attuned to the regularities of the writing system at all hierarchical levels. This hierarchy must also take into account the need to interact with downstream codes for phonological, morphological, and lexical knowledge of words (Goswami & Ziegler, 2006). Eventually, the adult pattern of performance—that is, fast and invariant word recognition with little influence of the number of letters—is thought to reflect the parallel encoding of letter strings through a fast bottom-up hierarchy of converging detectors.

EARLY VISUAL PROCESSING OF PRINTED WORDS

Retinotopic processing Letters are first processed in the hemisphere contralateral to their location in the visual field, probably in increasingly invariant format, through areas V1 to V4. Those areas, located approximately between Talairach coordinates (TC) $y = -90$ and $y = -70$, are modulated by physical parameters such as word length (Whiting et al., 2003) and visual contrast (Mechelli, Humphreys, Mayall, Olson, & Price, 2000), stimulus degradation (Helenius, Tarkiainen, Cornelissen, Hansen, & Salmelin, 1999; Jernigan et al., 1998), and stimulus rate and duration (Price & Friston, 1997; Price, Moore, & Frackowiak, 1996). Accordingly, the P150 wave evoked by word reading is only sensitive to the physical repetition of stimuli in a masked priming paradigm (Petit, Midgley, Holcomb, & Grainger, 2006).

Perceptual asymmetry It has long been recognized that words are read more easily when they are displayed in the right visual field (RVF) than in the left visual field (LVF) (for reviews see Ducrot & Grainger, 2007; Ellis, 2004). By continuously varying fixation point inside and outside words, Brysbaert, Vitu, and Schroyens (1996) showed that the RVF advantage is closely related to another behavioral asymmetry, namely, that in the optimal reading position, gaze position falls left of word center (Nazir, 2000; O'Regan, Levy-Schoen, Pynte, & Brugailiere, 1984), so that most of the word falls in the RVF. Thus the visual reading span of about 10 letters (Rayner & Bertera, 1979) is not distributed equally across both hemifields, as letter-identification performance decreases more slowly with eccentricity in the RVF than in the LVF (Nazir, Jacobs, & O'Regan, 1998). In addition to higher accuracy and shorter latencies, the RVF advantage is characterized by parallel letter identification, as indexed by constant reading latencies irrespective of word length. The absence of a word-length effect is restricted to words displayed in the optimal viewing position, or fully within the sector of the RVF closest to the fovea. Outside of those conditions, a length effect emerges. Accordingly, when words extend across central fixation, only their left part

induces a length effect (Lavidor & Ellis, 2002; Lavidor, Ellis, Shillcock, & Bland, 2001).

The RVF advantage is a complex phenomenon, for which several compatible mechanisms have been put forward: degradation of information resulting from right-to-left inter-hemispheric transfer of LVF letters; better perceptual learning in the most stimulated sector of the visual field (Nazir, 2000; Nazir, Ben-Boutayab, Decoppet, Deutsch, & Frost, 2004); and rightward attentional bias. As to the ultimate causes of such perceptual or attentional asymmetries, they may involve left-hemispheric lateralization of language (M. Kinsbourne, 1972), left-to-right reading habits (Deutsch & Rayner, 1999; Lavidor & Whitney, 2005; Mishkin & Forgy, 1952), and the fact that the beginning of words is more informative than their end and should therefore be kept close to fixation, as acuity drops steeply away from the fovea (e.g., O'Regan et al., 1984).

Nazir and colleagues (Nazir, 2000; Nazir et al., 2004) emphasized the role of perceptual learning in the genesis of the RVF advantage, as a result of the most frequent perception of words in this sector of the visual field. Along those lines, it is plausible that expert word perception, like other instances of overpracticed perceptual abilities, is restricted to the trained region of the visual field and results from increased activation in retinotopic cortex, with increasing reliance on its more posterior sectors (Sigman et al., 2005). Congruent with this view, Cohen and colleagues (2002) found a left extrastriate region (TC $-24 -78 -12$) only responsive to RVF stimuli, which showed stronger activation by alphabetic strings than by checkerboards, while no such difference was observed in corresponding right extrastriate areas. Moreover, transcranial magnetic stimulation (TMS) inhibition of the left (but not of the right) occipital cortex induces a length effect for words displayed in the RVF (Skarratt & Lavidor, 2006). This effect occurs when TMS is applied 80 ms after word presentation, supporting the localization of the interference to the posterior visual cortex.

Moreover, priming tasks with split-field stimuli suggest that alphabetic strings are encoded in a format less dependent on physical shape and case when they are viewed in the RVF than in the LVF (Burgund & Marsolek, 1997; Marsolek, Kosslyn, & Squire, 1992; Marsolek, Schacter, & Nicholas, 1996), possibly reflecting general processing asymmetries in the visual system (Burgund & Marsolek, 2000; Marsolek, 1995; Sawamura, Georgieva, Vogels, Vanduffel, & Orban, 2005). Accordingly, using a masked priming paradigm, Dehaene and colleagues (2001) have evidenced case-specific physical repetition priming in the right extrastriate cortex (though similar regions were also present in left extrastriate at a lower threshold) (for similar effects with object perception see Koutstaal et al., 2001).

Overall, such data support the idea that the posterior sector of the left ventral pathway develops superior

perceptual abilities for contralateral strings of letters (as indexed by measures of accuracy, speed, parallelism, and invariance), explaining at least the perceptual component of the RVF advantage.

Pathology: Reading with hemianopia or with apperceptive agnosia

The asymmetric role of posterior visual cortex in reading is supported by the pattern of reading impairments resulting from left versus right hemianopia. Reading is highly dependent on the integrity of the central visual field. As unilateral lesions affecting the retrochiasmatic visual tract up to primary visual cortex result in scotomas sparing at least half of the fovea, the ensuing reading impairments are relatively mild. Only right hemianopia without sparing of foveal vision induces noticeable reading difficulty (Zihl, 1995). First, the visual span of such patients is reduced, and they may require several fixations in order to perceive long words. Second, patients lose the reading advantage specific to the normal RVF. Accordingly, they show an influence of word length on reading latencies, as normal subjects do with words displayed in their LVF (Cohen et al., 2003). Third, perception in the right parafoveal field, in an area spanning about 15 letters (Rayner & McConkie, 1976), is important for preparing the accurate landing of the gaze on subsequent words (Serenio & Rayner, 2003). Therefore hemianopic patients make abnormally short and numerous saccades when reading word sequences (Leff et al., 2000; Zihl, 1995).

Finally, patients with so-called apperceptive agnosia (Humphreys & Riddoch, 1993; Lissauer, 1890) following (generally bilateral) lesions of intermediate visual areas such as V2 and V4 are impaired at word reading just as they are at identifying other types of shapes and objects (Heider, 2000; Michel, Henaff, & Bruckert, 1991; Rizzo, Nawrot, Blake, & Damasio, 1992).

INVARIANT REPRESENTATION OF LETTERS AND THE VISUAL WORD FORM AREA After percolating through retinotopic cortex, visual word information converges on the sector of ventral cortex anterior to V4, ranging approximately from TC $y = 60$ to $y = -40$, a region with larger receptive fields and greater capacity of invariance (figure 54.2). This region receives afferences from both visual hemifields (Tootell, Mendola, Hadjikhani, Liu, & Dale, 1998) and shows repetition suppression by object images across changes in size, position, and orientation (Grill-Spector et al., 1999), and across a change of exemplar within a category (Koutstaal et al., 2001). Accordingly, we proposed that, during reading, part of this region (which we labeled as the Visual Word Form Area, or VWFA) is responsible for the computation of an invariant representation of letter identities (Cohen et al., 2000). Both this proposed labeling and the functional properties of this region have given rise to enduring

controversies (Price & Devlin, 2003; Wright et al., 2007), which we tried to clarify by applying to the VWFA the distinctive notions of reproducible localization, partial regional selectivity, and functional specialization (for review and discussion see Cohen & Dehaene, 2004).

Specialization within the ventral stream

1. *Reproducible localization.* Reading-related activations are reproducibly located within the occipitotemporal sulcus lateral to the left fusiform gyrus (VWFA), with only a few millimeters of intersubject variability (Cohen et al., 2002; Jobard, Crivello, & Tzourio-Mazoyer, 2003). The VWFA is activated by visual words irrespective of their position in the visual field (Cohen et al., 2000). An associated electrical or magnetic signature is detected about 170–200 ms after stimulation (e.g., Cohen et al., 2000; Marinkovic et al., 2003; Tarkiainen, Helenius, Hansen, Cornelissen, & Salmelin, 1999).

The remarkable topographical reproducibility of the VWFA may result from its optimal positioning within gradients biasing the a priori organization of the visual cortex, such as a posterior-to-anterior increase in perceptual invariance (Grill-Spector et al., 1998; Lerner, Hendler, Ben-Bashat, Harel, & Malach, 2001) and a mesial-to-lateral increase in preference for foveal versus peripheral stimuli (Hasson, Levy, Behrmann, Hendler, & Malach, 2002). A further reason for the localization of the VWFA, particularly for its usual left lateralization, may be the availability of more direct connections to other language-related sites involved in phonological or lexical processing (Cai, Lavidor, Brysbaert, Paulignan, & Nazir, 2008; Cohen, Jobert, Le Bihan, & Dehaene, 2004; Epelbaum et al., 2008; Mahon & Caramazza, 2009).

2. *Partial regional selectivity.* The VWFA is activated by alphabetic strings relative to fixation but often also relative to complex nonalphabetic stimuli such as faces or geometrical patterns (e.g., Cohen et al., 2002; Puce, Allison, Asgari, Gore, & McCarthy, 1996). However, the difference in activation between words relative to visual objects is variable across studies, and may even be inverted, depending on a number of experimental parameters (e.g., Wright et al., 2007). This lack of absolute regional selectivity may be taken as a sensible argument against the use of the VWFA label, as this region may well be involved in processing nonalphabetic visual objects. However, selectivity may be detectable only at a higher spatial resolution. Thus intracranial recordings occasionally showed P150 or N200 waves elicited exclusively by letter strings, as compared to a variety of control stimuli such as phase-scrambled strings, flowers, faces, or geometrical shapes (Allison, McCarthy, Nobre, Puce, & Belger, 1994; Allison, Puce, Spencer, & McCarthy, 1999). Moreover, some left inferotemporal lesions (see the subsection “Pathology: Pure alexia”) yield massive alexia

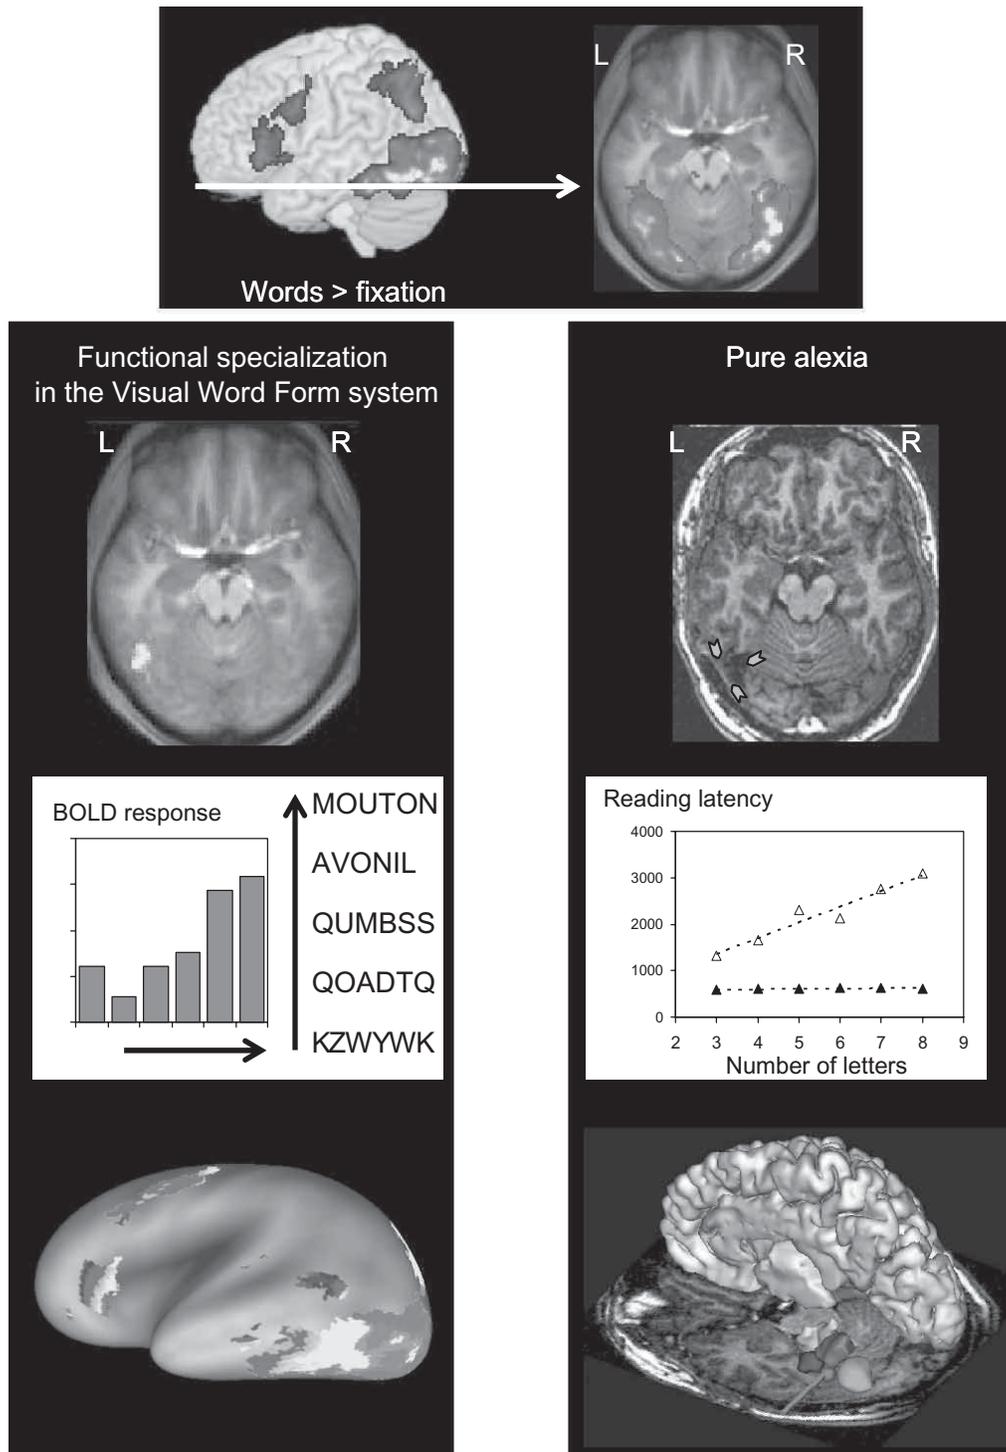

FIGURE 54.2 Word processing in the ventral pathway. *Top panel:* Activations induced by printed words relative to a fixation baseline in the left hemisphere (left) and in the bilateral ventral visual pathway (right). *Left panel:* The VWF system shows a linear increase of activation (top) by letter strings forming closer statistical approximations to orthographically legal strings (middle). This functional specialization increases progressively in more anterior regions within the VWF system (bottom). (Left panel adapted from Vinckier et al., 2007.) *Right panel:* Surgical lesion in the left ventral

cortex responsible for pure alexia (top). Whereas before surgery word reading was fast and constant irrespective of word length, after surgery the patient showed slow letter-by-letter reading (middle). In the same patient, the 3D image shows the relative position of the VWFA (blue), of other category-dependent fMRI activation clusters before surgery, of the brain lesion (green), and of intracerebral electrodes (magenta). (Right panel adapted from Gaillard et al., 2006.) (See color plate 69.)

affecting even single letters, contrasting with the spared recognition of complex multipart objects, faces, or digit strings, demonstrating that the VWFA, even if activated by a wide range of stimuli, may evolve to be *necessary* only to word recognition.

3. *Functional specialization.* The issue of selectivity is independent of the hypothesis of a functional specialization of the VWFA (figure 54.2). On top of their preexisting object coding properties, neurons in the VWFA develop elaborate functional specialization as they get attuned to arbitrary features of the subject's script. As the clearest instance of functional specialization, activation of the VWFA is stronger when the script is familiar than when it is unfamiliar (e.g., Hebrew versus alphabetic strings; Baker et al., 2007) or created *de novo* (Price, Wise, & Frackowiak, 1996). Moreover, using masked repetition priming, it was shown that the VWFA represents words in a format invariant for the upper- versus lowercase distinction (e.g., radio versus RADIO), another arbitrary culture-dependent feature of writing systems (Dehaene et al., 2004, 2001). Finally, within the subjects' familiar script, the VWFA is activated more strongly by letter strings forming closer statistical approximations to orthographically legal strings (including real words), showing that the VWFA incorporates constraints on letter combinations, which are specific to the familiar language (Binder, Medler, Westbury, Liebenthal, & Buchanan, 2006; Cohen et al., 2002; Vinckier et al., 2007).

4. *Internal structure of the Visual Word Form system.* According to the LCD model, the anteroposterior extension of the VWFA (about 20 mm) should reflect its heterogeneous and hierarchically organized structure. Dehaene and colleagues (2004), using a subliminal priming design, showed that the type of prime-target similarity that causes fMRI priming varies according to the anterior-posterior location in left occipitotemporal cortex, with an increasing invariance for position and case change, and probably greater reliance on larger-size units such as bigrams or quadrigrams. More recently, Vinckier and colleagues (2007) tested whether a hierarchy of detectors of increasingly larger word fragments is present in the left occipitotemporal cortex. The frequency of letters, bigrams, and quadrigrams was manipulated, yielding a range of stimuli with an increasing structural similarity to real words. The more anterior an area was within the Visual Word Form region, the more sensitive it was to the frequency of complex components, revealing a gradient-like spatial organization *within* the VWFA (see Grainger and Holcomb, *in press*, for a review of ERP data relevant to the fragmentation of orthographic processing).

Pathology: Pure alexia Impairments affecting the Visual Word Form system correspond to the syndrome of pure alexia, as described in the 19th century (Binder & Mohr, 1992; Damasio & Damasio, 1983; Dejerine, 1892; see figure 54.2).

Pure alexia is an acquired and selective reading deficit occurring in previously literate patients. Patients typically have entirely preserved production and comprehension of oral language, and they can write normally either spontaneously or to dictation. However, they show various degrees of impairment of word reading. The critical cortical lesions generating pure alexia overlap with the VWFA as defined with functional imaging (Cohen et al., 2003; Gaillard et al., 2006). Pure alexia may also follow deafferentation of an intact VWFA following left-hemispheric white matter lesions (Cohen, Henry, et al., 2004; Epelbaum et al., 2008). Posterior callosal lesions cause a selective deafferentation of the VWFA from the right occipital cortex, yielding alexia restricted to the LVF (Cohen et al., 2000, 2003; Molko et al., 2002; Suzuki et al., 1998).

In the most severe cases, known as global alexia, patients cannot identify single letters, let alone whole words (Dalmás & Dansilio, 2000; Dejerine, 1892). Such patients may or may not have access to abstract letter identities, as tested for instance in a cross-case letter-matching task (Miozzo & Caramazza, 1998; Mycroft, Hanley, & Kay, 2002). More often, patients show relatively preserved letter identification abilities and develop letter-by-letter reading strategies, as if only the most finely tuned mechanisms of word perception were affected, those allowing for rapid and parallel identification of letter strings. As an indication of this effortful reading strategy, patients show a large increase in the number and the duration of fixations per word relative to normals and even to patients with hemianopic dyslexia (Behrmann, Shomstein, Black, & Barton, 2001). There is some evidence that in letter-by-letter readers, residual letter identification can be subtended by right-hemispheric regions symmetrical to the VWFA or by spared patches of left-hemispheric ventral cortex (Bartolomeo, Bachoud-Levi, Degos, & Boller, 1998; Cohen, Henry, et al., 2004; Gaillard et al., 2006).

Finally, some patients show better-than-chance performance in purely implicit reading tasks such as lexical or semantic decision, contrasting with the apparent inability to identify printed words (Coslett & Saffran, 1989; Coslett, Saffran, Greenbaum, & Schwartz, 1993). Implicit reading has been most clearly evidenced with Arabic numerals, which can be compared accurately even when explicit reading is grossly impaired (Cohen & Dehaene, 1995, 2000), probably revealing effective right-hemispheric identification processes.

Contribution of the dorsal pathway

The operation of the ventral stream during word reading is modulated by attentional influences, originating from parietal regions, that may impinge on all processing levels from striate cortex (Chawla, Rees, & Friston, 1999; Somers, Dale,

Seiffert, & Tootell, 1999) to ventral occipitotemporal areas (Kastner, De Weerd, Desimone, & Ungerleider, 1998; see figures 54.1 and 54.3). In order to make sense of the variety of reading impairments that may follow parietal lesions, we will distinguish somewhat artificially three contributions of attentional control to single-word reading: orienting to the region of space where the target word is displayed, filtering out irrelevant words present in the vicinity of the target, and serially attending to letters or word fragments whenever

letters cannot be effectively processed in parallel over the whole string.

ORIENTATION OF ATTENTION Spatial attention modulates the efficiency of the visual processing of alphabetic stimuli. Thus words are better recognized when they appear in a region of the visual field to which attention has been directed by a previous cue (McCann, Folk, & Johnston, 1992), and subliminal letters have a priming effect on subsequent

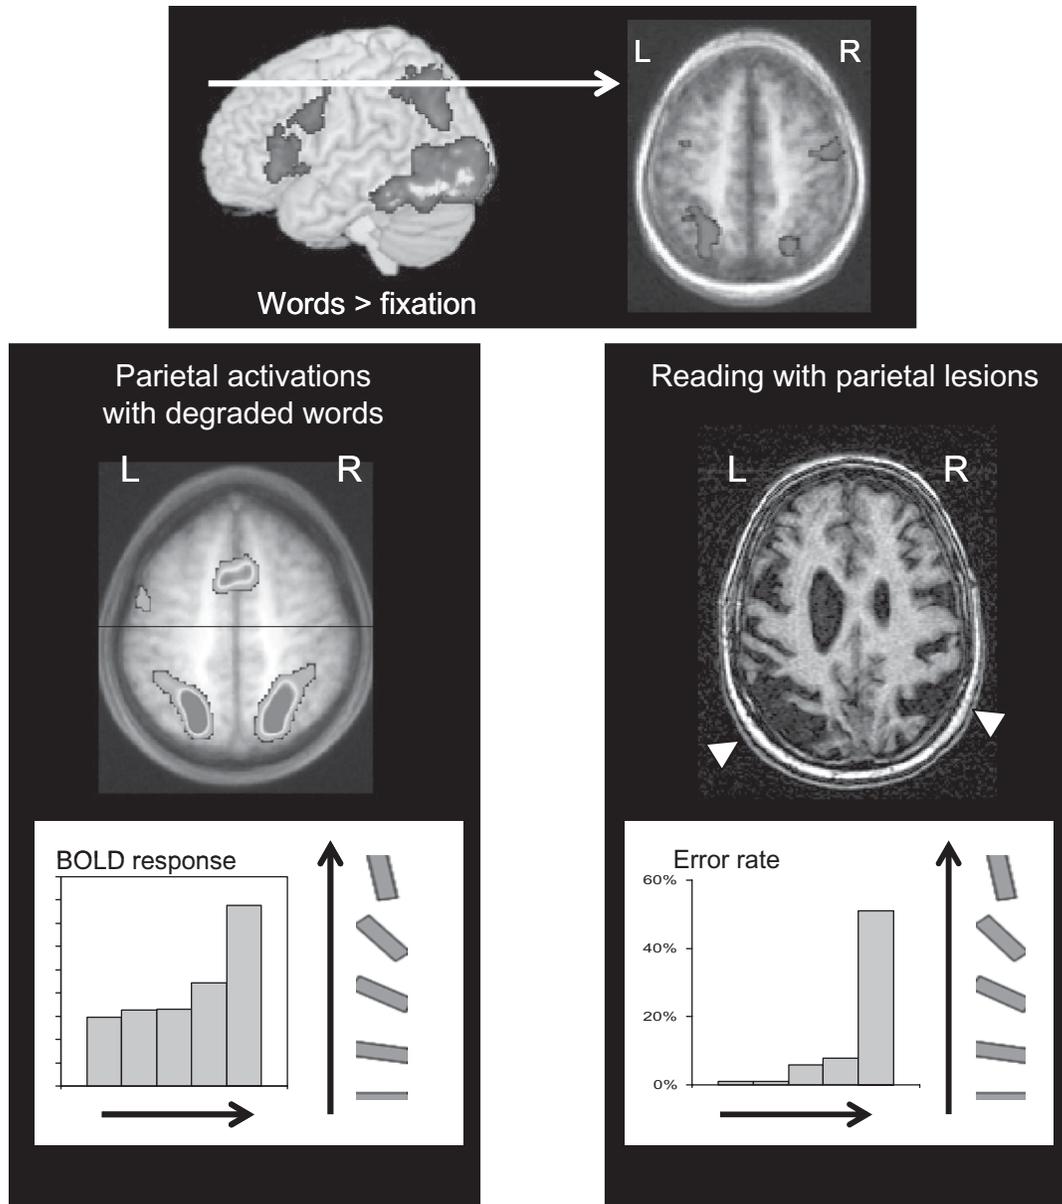

FIGURE 54.3 Contribution of the dorsal pathway to word reading. *Top panel:* Activations induced by printed words relative to a fixation baseline in the left hemisphere (left) and in the bilateral dorsal visual pathway (right). *Left panel:* The bilateral intraparietal cortex shows a nonlinear increase of activation with word degradation, correlated with reaction times (top). For instance, activations increased steeply for words rotated by more than 45° (bottom).

(Left panel adapted from Cohen, Dehaene, Vinckier, Jobert, & Montavont, 2008.) *Right panel:* In a patient with bilateral parietal atrophy and spared ventral cortex (top), there was a severe reading impairment above a similar threshold of rotation angle, demonstrating the role of parietal cortex whenever display degradation exceeds the range of invariance in the ventral cortex. (Right panel adapted from Vinckier et al., 2006.) (See color plate 70.)

targets only when they are displayed at an attended location (Marzouki, Grainger, & Theeuwes, 2007). As mentioned before, the RVF advantage may partly result from a rightward bias of attention. Ducrot and Grainger (2007) showed that exogenous spatial cuing has no impact on the (asymmetrical) reading performance for words displayed only slightly off fixation, suggesting that in the central field, the RVF advantage is mostly perceptual. In contrast, cuing was very effective for more peripheral words and tended to reduce the RVF advantage. In a study of lateralized word reading, Cohen and colleagues (2002) found larger activations for RVF than for LVF words in the left precuneus and thalamus, with no activations for the opposite contrast, likely reflecting the attentional component of the RVF advantage.

Pathology: Neglect dyslexia The defining feature of neglect dyslexia is the existence of a left-right spatial gradient in the rate of reading errors far exceeding the normal RVF advantage (for an overview and references see Riddoch, 1990). Following the general pattern of hemispatial neglect, it is much more common to observe left than right neglect dyslexia, although a number of right-sided cases have been reported. Neglect dyslexia is generally associated with signs of neglect outside the domain of reading, although patients with seemingly isolated neglect dyslexia have been reported. Neglect is thought to result from associated impairments of both nonlateralized and lateralized components of attentional/spatial processing (Husain & Rorden, 2003). The latter may depend on saliency maps of the opposite hemispace subtended by each posterior parietal lobe (Medendorp, Goltz, Vilis, & Crawford, 2003; M. Sereno, 2001). Assuming that those lateralized maps contribute to the top-down modulation of the ventral visual stream, one may expect that distinct varieties of neglect dyslexia may arise, depending on the side of the lesion, the affected parietal structure, the ventral regions that are deprived of attentional modulation, and so on. Indeed, there are numerous clinical observations to illustrate this fractionation of neglect dyslexia (Riddoch, 1990).

Neglect errors typically affect the leftmost letters when patients read single words, and the leftmost side of the page when they read connected text. However, those two types of errors can be to some extent doubly dissociated, suggesting that neglect dyslexia is not a homogeneous syndrome (Costello & Warrington, 1987; Kartsounis & Warrington, 1989). This fractionation is best illustrated by the case of patient JR, who suffered from bilateral occipitoparietal lesions (Humphreys, 1998). When presented with words scattered on a page, he omitted the rightmost words, but his reading errors affected the leftmost letters of the words that he picked out. Likewise, he showed left neglect when he was asked to read single words, while he showed right neglect when trying to name the component letters of the same stimuli. This pattern suggests that JR's left lesion yielded

right neglect in situations of competition between objects, while his right lesion yielded left neglect in situations of competitions between the parts of an object.

A clarifying framework was proposed by Hillis and Caramazza (1995), who suggested that the varieties of neglect dyslexia may be attributed to spatial attentional biases acting on one or more of progressively more abstract word representations derived from Marr's theory of object perception (Marr, 1982): a peripheral retinocentric feature representation, a stimulus-centered letter-shape level, and a word-centered graphemic representation akin to the Visual Word Form (for a review of supportive data see Haywood & Coltheart, 2000). Thus, in a deficit at the retinocentric level, error rate for a given letter should depend on its position in the visual field relative to central fixation and not on its rank within the target word. In contrast, in a deficit at the stimulus-centered level, error rate should depend on the distance from the center of the word irrespective of the position of the word in the visual field. Naturally, both parameters may be relevant in some if not in the majority of patients. More remote from neglect in its usual sense, neglect at the graphemic level yields errors affecting one end of words irrespective of their spatial position or orientation. Thus patient NG made errors with the last letters (e.g., hound → house) when reading standard words, but also vertical words and mirror-reversed words, as well as when naming orally spelled words and when performing other lexical tasks such as spelling (Caramazza & Hillis, 1990). Note, however, that there are alternative accounts of word-centered neglect dyslexia, in frameworks that refute the existence of object-centered neural representations (Deneve & Pouget, 2003; Mozer, 2002).

Finally, letter strings that are neglected in explicit reading tasks may nevertheless be processed to higher representation levels. This possibility is suggested by preserved performance in lexical decision (Arduino, Burani, & Vallar, 2003), by the fact that erroneous responses often tend to have the same length as the actual targets (K. Kinsbourne & Warrington, 1962), or by higher error rates observed with nonwords than with real words (Sieroff, Pollatsek, & Posner, 1988). The interpretation of such findings is still debated (Riddoch, 1990), but it is plausible that neglected words can be partially processed in the ventral visual pathway in the absence of conscious awareness, as has also been shown in normal subjects (Dehaene et al., 2001; Devlin et al., 2003) and with other types of visual stimuli such as faces or houses in neglect patients (Rees et al., 2000).

SELECTION OF ONE SINGLE WORD For optimal reading, not only should the attention window encompass the target word, but it should also be narrow enough to exclude other neighboring words. In normal subjects it is possible to force a spread of attention over two words, by briefly

presenting two words side by side, and specifying only afterward which of the two should be reported (Davis & Bowers, 2004; Treisman & Souther, 1986). This procedure degrades performance and induces reading errors that are analogous to those observed in the pathological condition known as attentional dyslexia (for qualifications to this analogy see Davis & Bowers, 2004).

Pathology: Attentional dyslexia The hallmark of attentional dyslexia is the contrast between preserved reading of isolated words and high error rates when the target is surrounded by other words (for a review see Davis & Coltheart, 2002). It is generally attributed to an impaired attentional selection of one among several concurrent stimuli (Shallice, 1988). This induces (1) an inaccurate processing of the target (substitutions, additions, or deletions of letters) as a result of the competition by surrounding words and (2) intrusion of distracters into later stages of processing (letter migrations from the flanking words into the response to the target).

Such ideas are in good agreement with imaging data in normals, showing that when multiple objects are presented simultaneously, they exert mutual inhibition, resulting in decreased ventral visual activations (Kastner et al., 1998). Directing attention toward one of the stimuli compensates this reduction of activity. Moreover, the activation induced by distracters in areas T4 and TEO is reduced in proportion to the attention that is paid to the target, and it is inversely correlated with frontoparietal activations (Pinsk, Doniger, & Kastner, 2004). It is thus plausible that in attentional dyslexics, impaired selection abilities, which are unmasked in the presence of flanker words, cause both visual errors due to a weakened representation of the target and letter migrations due to an excessive activation of distracters.

The phenomenon of flanker interference also prevails when patients are asked to read single letters surrounded by other letters. This finding leads to the paradoxical observation that patients may be good at reading isolated words but not at naming their component letters. More generally, interference seems to occur only between items of the same category. In their seminal article Shallice and Warrington (1977) showed that flanking letters but not flanking digits interfered with letter identification. Similarly, there is no mutual interference between letters and whole words (E. K. Warrington, Cipolotti, & McNeil, 1993). One may note that in some patients the interference between letters is the same whether the target and flankers are printed in the same case or not (Shallice & Warrington, 1977; E. K. Warrington et al.), suggesting that the impairment impinges on visual areas that already show high-level invariance, such as the VWFA. Still, the irrelevance of case changes for attentional selection is not absolute. Indeed, letter migrations between words may be reduced by using different typographic cases

(Saffran & Coslett, 1996), suggesting that low-level visual features may help to focus the attention on the target word and to discard distracters.

In brief, attentional dyslexia may be due to insufficient attentional focusing on one among several concurrent letters or letter strings represented in the Visual Word Form system. Note that the few cases of attentional dyslexia with sufficient lesion data consistently point to a left parietal involvement (Friedmann & Gvion, 2001; Mayall & Humphreys, 2002; Shallice & Warrington, 1977; E. K. Warrington et al., 1993). Such asymmetry may relate to a left-hemispheric bias for object-oriented attention (Egley, Driver, & Rafal, 1994), or more generally to the left dominance for language.

ATTENDING TO PARTS OF WORDS AND SERIAL DECODING As an outcome of perceptual learning, in expert readers the ventral visual pathway gets attuned to the perception of normal print: horizontally aligned words presented in the foveal region in a usual font are identified in a fast and parallel manner. There are, however, a number of circumstances in which this optimal encoding is either unavailable or inappropriate to the task at hand, as revealed by slower reading speed and by the emergence of a linear increase of reading latencies with word length. We suggest that this length effect reflects a failure of parallel letter processing in the ventral pathway and indicates the deployment of serial attention to letters or groups of letters (for an alternative account see Whitney, 2001; Whitney & Lavidor, 2004). Serial reading would involve parietal structures driving spatial-attentional processes (Gitelman et al., 1999; Husain & Rorden, 2003; Kanwisher & Wojciulik, 2000; Mesulam, 1999) and a modulation by this top-down attention of ventral occipitotemporal structures coding for word fragments (Chawla et al., 1999; Kastner et al., 1998; Somers et al., 1999).

Departure from parallel reading as indexed by the emergence of a length effect occurs in many conditions: (1) in children whose reading expertise is still incompletely developed, with an effect of word length persisting until about the age of 10 (Aghababian & Nazir, 2000); (2) in pure alexic patients who develop letter-by-letter reading following left ventral lesions, a strategy that is associated with parietal activations (Gaillard et al., 2006); (3) in normal subjects attempting to read words degraded by means of contrast reduction (Legge, Ahn, Klitz, & Luebker, 1997), of mIxEd case printing (Lavidor, 2002; Mayall, Humphreys, Mechelli, Olson, & Price, 2001), of vertical display (Bub & Lewine, 1988), and of lateral display in the LVF (Lavidor & Ellis, 2002); and (4) in normal subjects reading aloud pseudo-words, which probably requires the serial left-to-right conversion of graphemes into phonemes (Weekes, 1997). Interestingly, patients with semantic dementia who suffer from a progressive dissolution of lexical knowledge show a length effect even when reading real words (Cumming,

Patterson, Verfaellie, & Graham, 2006). This abnormal length effect is due to reduced top-down lexical support for word identification, compelling patients to process real words as pseudowords.

We recently studied the mechanisms involved in reading degraded words (Cohen, Dehaene, Vinckier, Jobert, & Montavont, 2008; see figure 54.3). We presented adult readers with words that were progressively degraded in three different ways (word rotation, letter spacing, and displacement to the visual periphery). Behaviorally, we identified degradation thresholds above which reading difficulty increased nonlinearly, with the concomitant emergence of a length effect. Functional MRI activations were correlated with reading difficulty in bilateral occipitotemporal and parietal regions, reflecting the strategies required to identify degraded words. A core region of the intraparietal cortex was engaged in all modes of degradation. Supporting the current interpretation, the same region is also activated, and its interactions with other parts of the reading network increase, when subjects are required to pay attention to letters within nondegraded words (Bitan et al., 2005; J. Booth et al., 2002). Furthermore, in the ventral pathway, word degradation led to an amplification of activation in the posterior Visual Word Form Area at a level thought to encode single letters. We also found an effect of word length restricted to highly degraded words in bilateral occipitoparietal regions.

Pathology: Spatial dyslexia and Balint's syndrome Balint's syndrome, a consequence of bilateral dorsal parietal lesions, includes simultanagnosia, which prevents the binding of objects with a stable localization in space and the computation of their relative positions, and ocular apraxia, which precludes an accurate control of saccades toward peripheral targets (Rizzo & Vecera, 2002). The most salient impact of this disorder on reading is an inability to read connected text as a result of chaotic scanning of the display. The patients' gaze wanders randomly from word to word, and the relative position of words cannot be appreciated. However, patients can read accurately each of the disconnected words on which they land.

While the identification of optimally printed words is not substantially affected, patients may have major difficulties reading words presented in unusual formats, such as vertically arrayed or widely spaced letters. These difficulties disrupt the automatic binding of letters into single visual objects, and therefore require a scanning of component letters, which Balint patients cannot do. Due to impaired scanning, patients may also be unable to report one letter out of a string, even with optimally displayed real words (Baylis, Driver, Baylis, & Rafal, 1994). A similar account explains why Balint patients are impaired at reading pseu-

dowords, for which grapheme-to-phoneme conversion requires the sequential inspection of graphemes. For instance, a patient could read accurately 29 out of 30 briefly presented words, while she identified only 4 out of 30 pseudowords (Coslett & Saffran, 1991).

We recently studied a simultanagnosic patient with bilateral parietal atrophy (Vinckier et al., 2006; see figure 54.3). She was excellent at reading normally printed foveal words, but she was severely impaired at reading words that were mirror reversed, or rotated by angles larger than 50°, or whose letters were separated by at least two blank spaces, or words displayed in her left hemifield. According to the present hypothesis, above those critical thresholds—that is, when stimulus degradation exceeds the perceptual tolerance of the ventral system—reading normally requires the intervention of the parietal lobes to pilot the attention-driven exploration of stimuli (for a congruent observation see Hall, Humphreys, & Cooper, 2001). Parietal lesions did not allow the patient to resort to such strategy. This study was congruent with an imaging study reviewed before (Cohen et al., 2008): overlapping parietal regions were activated in normal subjects and lesioned in the patient, and the same degree of word degradation boosted parietal activations in normals and caused a drop in the patient's performance.

Because of her parietal lesions, this patient also presented with orientation agnosia (e.g., Priftis, Rusconi, Umiltà, & Zorzi, 2003). She was thus unable to discriminate normally oriented words or pictures of objects from the same rotated stimuli. However, while she was unable to discriminate pictures of objects from their mirror-reversed images, she could do so easily with reversible pseudowords. For instance, “boup” and “quod” appeared to her as distinct items, although they are mirror images of each other. The ventral pathway builds up a mirror-invariant representation of common objects (Logothetis & Pauls, 1995; Rollenhagen & Olson, 2000), which requires the intervention of explicit orientation analysis dependent on parietal cortex in order to discriminate mirror images. In contrast, the default invariance for mirror symmetry is “unlearned” by the ventral pathway in the particular case of reading, since reading requires the accurate discrimination of mirror-symmetric shapes (e.g., “p” versus “q”).

Interfacing with the verbal system

As the result of a collaboration between ventral and dorsal routes, detailed visual information about letter strings is ultimately conveyed to downstream language areas. In this section, we briefly point out some open issues pertaining to the relationships of the visual system with the language-related components of word processing, including phonology and the lexicon.

MULTIPLE OUTLETS FROM THE VENTRAL STREAM Assuming that word fragments of various sizes are identified in the ventral stream, one may expect that rich direct and indirect projections should exist toward areas involved in lexical, semantic, motor, or phonological processes. However, the pathways leading from the VWFA to all components of the reading network are not precisely defined. The macaque equivalent of the VWFA putatively falls within the IT complex, which projects to the inferior parietal lobule and the anterior temporal lobe, in addition to occipital and interhemispheric connections (Schmahmann & Pandya, 2006). Moreover, there may be a specifically human development of projections from the inferior temporal cortex to language-related superior temporal, parietal, and frontal regions, through the arcuate fasciculus (Catani, Jones, & ffytche, 2005; Epelbaum et al., 2008) and the inferior fronto-occipital fasciculus (Catani, Howard, Pajevic, & Jones, 2002), respectively.

Following the observation of alexia with agraphia, Dejerine (1892) suggested that the next step following visual word processing should be the angular gyrus, which he postulated to be the “visual center of letters.” Indeed, the angular gyrus is among the regions that are modulated during reading tasks, even if it often remains below the baseline level of activation (Binder et al., 2003; Binder, Medler, Desai, Conant, & Liebenthal, 2005), and there is functional connectivity between the angular gyrus and the left fusiform gyrus at coordinates matching the VWFA (Horwitz, Rumsey, & Donohue, 1998). There is also correlated activity in the VWFA and in left inferior frontal areas (Bokde, Tagamets, Friedman, & Horwitz, 2001). A further potential output pathway is to temporal regions anterior to the VWFA. These regions, which have been difficult to image with functional MRI because of magnetic susceptibility artifacts, are probably involved in supramodal semantic processing (for a review see Giraud & Price, 2001; Kreiman, Koch, & Fried, 2000; Lambon Ralph, McClelland, Patterson, Galton, & Hodges, 2001).

Finally, it is possible that different segments of the Visual Word Form system feed distinct language-related processes by projecting to distinct areas. Thus Mechelli and colleagues (2005) found that during reading the posterior fusiform cortex, which codes for single letters according to the LCD model, was coupled with the superior premotor cortex, possibly in relation to letter-to-articulation transcoding, while the anterior fusiform cortex, presumably coding for large word fragments, was coupled with Broca’s pars triangularis, possibly in relation to lexicosemantic access. Accordingly, the former coupling increased during pseudoword reading, whereas the latter increased during exception word reading. In a similar vein, Grainger proposed on the basis of behavioral data that two types of orthographic code are computed: a coarse code used to rapidly access semantic information

and a finer-grained code used to access phonology from orthography (Grainger & Holcomb, in press).

PHONOLOGICAL IMPACT ON VISUAL REPRESENTATIONS One potential shortcoming of the LCD model is that it focuses primarily on the acquisition of visual expertise in reading—that is, how the ventral visual system eventually incorporates orthographic regularities (see figure 54.1). However, it is likely that word phonology also influences orthographic representations in the visual system. Early letter-to-sound mapping is thought to be crucial for reading acquisition, which may constrain the eventual structure of the orthographic code in adults (Goswami & Ziegler, 2006; Ziegler & Goswami, 2005).

The impact of phonology on visual processing emerges from the comparison between scripts that differ in terms of orthographic transparency—that is, the regularity of grapheme-phoneme conversion rules. According to the LCD model, transparency should be reflected in the size of the units encoded by occipitotemporal neurons. In “transparent” writing systems such as Italian or the Japanese kana script, the letter and bigram levels should suffice for grapheme-phoneme conversion. In an “opaque” script, however, such as English or kanji, a larger-size visual unit, more anterior along the visual hierarchy, should be used. Compatible with this idea, stronger and more anterior activation is observed in the left occipitotemporal region in English than in Italian readers (Paulesu et al., 2000), and, at a slightly more mesial location, during kanji than during kana reading in Japanese readers (Ha Duy Thuy et al., 2004; Nakamura, Dehaene, Jobert, Le Bihan, & Kouider, 2005).

However, evidence of an influence of phonology on visual processing within a given writing system is less clear. There are numerous behavioral demonstrations of an impact of phonology on the processing of printed words, as well as of cross-modal word activations in parietal and superior or lateral temporal regions (e.g., J. Booth et al., 2002; Cohen, Jobert, Le Bihan, & Dehaene, 2005; van Atteveldt, Formisano, Goebel, & Blomert, 2004). Still there is little evidence that some of those effects reflect the operation of the visual system per se, rather than of later speech-related processes. For instance, Grainger, Kiyonaga, & Holcomb (2006) showed that by 225 ms after the presentation of a target word preceded by a masked prime, ERPs distinguished homophone pseudoword primes, as compared to nonhomophone controls (e.g., *bakon-BACON* versus *bafon-BACON*). Although this time window is roughly compatible with processing in the Visual Word Form system, the anterior topography of this effect does not support an occipitotemporal source. The contribution of phonological structure to word encoding in the visual system is thus largely open to empirical research.

Conclusion

The present review emphasizes that fluent reading results from an intimate collaboration of multiple areas forming a distributed network. Although the VWFA clearly plays an essential role in expert reading, the recent literature has tended to forget that the dorsal spatial-attentional system also makes a major contribution through attention orienting, word selection, and within-word serial decoding. Adult readers probably rely on serial attentive reading under relatively rare conditions; but we speculate that young readers, in whom the word length effect is particularly large, rely heavily on the dorsal route early during the laying down of the grapheme-phoneme decoding stage. Although phonological sources of developmental reading impairments have received vast attention, our analysis suggests that occipitoparietal impairments are also very likely to have an impact on developmental dyslexia, as indeed suggested by recent research (Bosse, Tainturier, & Valdois, 2007; Lassus-Sangosse, N'Guyen-Morel, & Valdois, 2008; Valdois, Bosse, & Tainturier, 2004). In the future, developmental neuroimaging paradigms should be developed to directly image the ventral and dorsal routes as children learn to read.

55 The Neural Basis of Syntactic Processing

DAVID CAPLAN

ABSTRACT Syntactic structures are unique mental representations that relate the meanings of words to one another. Understanding of the neural basis for syntax consists mostly of information about the areas in which these structures are assigned and used to determine meaning in the process of comprehension, together with electrophysiological correlates of these processes. This chapter briefly reviews deficit-lesion correlations and neurovascular studies that are relevant to the first of these topics. Both these sources of data suggest that the brain does not support syntactic processing in an abstract fashion but as part of performing the task that is the purpose of the comprehension process and that these task-related syntactic operations are supported by multiple brain areas.

Marr (1982) articulated a useful framework for describing cognitive functions. In this system, a cognitive function is described at three levels: a level at which the representations of the information in the cognitive domain are described (the representational level), a level at which the operations that compute these representations are described (the algorithmic level), and a level at which the neural mechanisms that support the storage of the representations and the activity of the operations that compute them are described (the neural level). In this chapter, I briefly review syntactic processing using this framework to organize the presentation. Readers may find that more space is devoted to the representational and algorithmic levels than is the case in other chapters. If so, this emphasis reflects my sense that these levels are less well understood by neurologically oriented cognitive neuroscientists in this domain than may be the case in other cognitive areas.

Syntactic representations and their processing

Sentences convey information beyond that which is conveyed by words alone. This information, collectively known as the propositional content of a sentence, includes who is initiating and receiving an action (thematic roles), which adjectives are assigned to which nouns (attribution of modification), which words refer to the same items (co-reference),

and other similar information, mostly relating to the relationships between items, actions, and properties referred to by the words in a sentence. Propositions are the source of much of the information that is stored in semantic memory. In addition, because propositions can be true or false, they can be used to reason, including making inferences, and to plan actions. Without propositions, language would consist of designating items, actions, and properties of items and actions—a significant functional capacity, to be sure, but far less rich and useful than that which language affords because it includes propositions.

For sequences of words to convey propositional relationships in a flexible manner—one that allows unlikely or impossible relationships to be expressed—it is necessary that the meanings of words be combinable into propositions in some way that does *not* correspond to likely events. That is, combinatory possibilities have to be available to allow the sequence of words “man dog bite” to be associated with the proposition that a man is biting a dog, and not vice versa. Humans use the ability to refer to unlikely and false events when they lie, when they consider hypothetical situations, and in other circumstances. The principles that allow these functions are the syntactic structures of language.

Syntactic structures need not be complex to permit unlikely propositions to be expressed: a simple active form (“The man is biting the dog”) would suffice for this basic purpose. But syntactic structures are much more complex than this one requirement imposes, and the complexity adds to the semantic information they allow language to convey. Features of syntax such as embedding allow *propositions*, not merely *words*, to be related to one another. The sentence “The man who chased the girl fell down” expresses a relationship between two propositions—the man chased the girl, and the man fell down. The syntactic structure known as a relative clause allows these two propositions to apply to the same man. Similarly, complement structures allow us to express propositional attitudes: “John believed/disagreed/expected/feared that it would rain” expresses a variety of states of mind that *John* is in vis-à-vis the proposition that it will rain. Syntactic structures are needed to allow these sorts of relations between propositions to be conveyed.

DAVID CAPLAN Department of Neurology, Massachusetts General Hospital, Boston, Massachusetts

In addition to propositional information, syntactic structures also express discourse-level information. The sentences “It was the policeman who shot the robber” and “It was the robber who the policeman shot” convey the same thematic roles, but the first sentence makes the policeman the topic and the second makes the robber the topic. To convey *both* propositional and discourse information, it must be possible to express the same proposition in different forms—whence another functional role for a complex syntax.

The most widely accepted theories of syntactic structures view them as hierarchically organized sets of syntactic categories, over which configurational relations are defined that determine these propositional aspects of meaning (figure 55.1). Different syntactic relations determine different aspects of meaning. In “The boy who chased the dog fell,” *the dog* has no semantically consequential syntactic relation to *fell*. In the sentence “The boy who chased the dog caught him,” the very similar (though not identical) relation of *the dog* to *him* allows *the dog* to serve as the antecedent of *him*. Similarly, *the boy* is the syntactic subject of both sentences and plays a thematic role around the verb *fell* in both, but cannot be the antecedent of *him* in “The boy who chased the dog caught him.”

Basic questions in linguistics revolve around the details of these structures. In the model developed by Chomsky (1995), for instance, syntactic structures are formed by merging lexical categories into higher-level phrasal categories, copying many categories into grammatical positions that need to be filled, using the resulting structure to determine meaning, and deleting the categories in their positions of origin to determine the phonological form of the sentence. Other theories (e.g., Goldberg, 1995, 2006) do not postulate “underlying” syntactic structures: the structure that is “visible” on the surface is the only one generated.

It is beyond the scope of this essay to discuss the differences between these theories in detail, but it is important to provide the reader with some idea of the sorts of issues involved in deciding between alternative conceptions of syntactic structures. As an oversimplified introduction, consider

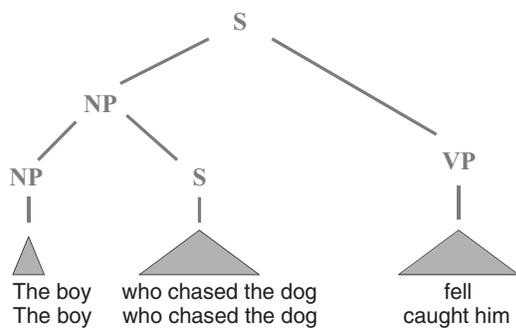

FIGURE 55.1 Schematic representation of hierarchical syntactic structure.

the important issue of whether the surface form of a sentence completely captures its syntactic structure. Chomsky has long argued that such models miss important generalizations about how syntactic relations are related to meaning. For instance, in general, verbs assign a thematic role to their objects, but there are many sentences in which this is not the case when we consider the surface syntactic form—for example, sentences with object-extracted relative clauses (“The boy who the dog chased fell”), questions (“Who did the dog chase?”), indirect questions (“The boy knew who the dog chased”), passives (“The boy was chased by the dog”), and other structures. In all these cases, Chomsky postulates that *the boy* (or *who*) appears in the position of the object of the verb *chase* at some level of syntactic structure and moves to its surface position, leaving a copy of its former self to which the thematic role is assigned. However, Goldberg and many others have argued that the surface forms of sentences introduce particular semantic properties that are not found in a plausible “underlying” syntactic form. For instance, many linguists in the Chomskian tradition have argued that the “ditransitive” construction (e.g., “John tossed Mary a bottle opener”) is derived from a “dative” structure (e.g., “John tossed a bottle opener to Mary”) in which the thematic roles of agent, theme, and goal follow the more common (“canonical”) English linear order. Goldberg, however, points out that the ditransitive has semantic properties not found in the dative—it requires an animate recipient, for instance: one cannot say, “John tossed the counter a bottle opener”, but “John tossed a bottle opener to the counter” is perfectly acceptable—and thus the correct syntactic theory recognizes surface constructions that are associated with aspects of propositional meaning, not surface structures that are derived from underlying representations. The reader can appreciate that it is not possible to develop detailed models of how syntactic information is represented and processed in the brain without knowing what syntactic representations are, and therefore that these disagreements present challenges to understanding the neural basis for syntactic processing. Models of the neural basis for representing and processing syntactic structure have dealt with this uncertainty by either adopting a particular theory or by investigating phenomena that are thought to be basic to syntactic representations and processing regardless of how they are expressed in a theory.

To conclude this section on syntactic representations, we note that a related, but secondary, question is the extent to which syntactic structures differ from representations in other cognitive domains such as mathematics and music (including “languages” naturally used by and taught to animals). Suffice it to say that, although when considered at a sufficiently abstract level, representations proposed in these other areas share features with syntax, virtually all models of the syntax of natural human languages postulate

structures that differ in fairly important ways from those postulated in these other domains. Certainly the contribution of syntactic relations between words to meaning differs from the contribution of the rules relating elements in these other domains to meaning, because of the differences in the meanings conveyed by sentences and these other representational systems.

Most models of sentence comprehension maintain that “parsing” and “interpretive” operations assign syntactic structures and use them to determine aspects of meaning in the process of understanding a sentence. These models have articulated principles whereby parsing rules apply. For instance, in the sentence “The boy wanted to go to the game yesterday,” *yesterday* preferentially modifies *to go* not *wanted*, suggesting a general principle of attaching new phrases to the last incomplete phrase in a developing syntactic structure. Sentence interpretation relies on more than just syntactic structure and word meanings; information about the frequency with which constructions appear, the plausibility of the meaning of a sentence, and other factors affect the ease of syntactic analysis and comprehension (MacDonald, Pearlmuter, & Seidenberg, 1994). For instance, “While the man ate the hot dog burned in the fire” is harder to structure and interpret than “While the man ate the wood burned in the fire,” because *the hot dog*, but not *the wood*, is a plausible theme of *ate*, which reinforces an ultimately incorrect structure. The principles affecting structure building and these other factors interact online (as sentences are analyzed syntactically and assigned meaning). Recent studies provide evidence that features of the nonlinguistic environment in which a sentence is uttered (e.g., the nature of items visible to a listener) enter into these interactions (Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995).

This chapter will review studies that provide data relevant to the neural basis of parsing and interpretive operations. Only results of deficit-lesion correlations in patients with focal lesions and neurovascular activation studies in normal subjects will be covered. Some other potential sources of data (intraoperative stimulation, subdural electrode placement, transcranial magnetic stimulation, magnetoencephalography, intraoperative and subdural recordings, optical imaging) have not been extensively used for these studies; for review of electrophysiological studies, see Hagoort, Baggio, and Willems (chapter 56 in this volume). Only studies of comprehension will be reviewed, as there is more work in this area than in production.

Deficit-lesion correlation studies of syntactic processing

The logic underlying the use of deficits to explore the neural basis of syntactic processing is that, if a patient’s performance can be analyzed as being due to a deficit in a syntactic operation (plus residual abilities and any compensatory strat-

egies that apply), the deficit is due to the lesion the patient has sustained. The corollary of this statement is that the integrity of the lesioned area/neural process is necessary for the operation to take place. To apply deficit-lesion analyses to the problem of localization of syntactic operations, it is therefore necessary to characterize the deficits in patients, their lesions, and the relations between the two.

Two basic views of deficits affecting syntactically based comprehension have been articulated. The first is that individual parsing or interpretive operations are selectively affected by brain damage. The second is that patients lose the ability to apply what have been called “resources” to the task of assigning and interpreting syntactic structure. The first of these deficits may be likened to a student not being able to calculate π to eight decimal places in his/her head because s/he does not know the formula for calculating π . The second may be likened to a student knowing the formula but not being able to hold the intermediate products of computation in mind. Exactly what prevents the application of such knowledge is unclear, but most models of cognitive processes include limitations of this sort.

The hallmark of a deficit affecting syntactic operations is the combination of abnormally low (or chance) performance in understanding sentences that require a syntactic analysis to be understood—semantically reversible sentences that cannot be understood by the application of simple heuristics such as the assignment of thematic roles to nouns following a simple pattern (e.g., “The boy who the girl pushed is tall”)—and the retained ability to understand “semantically irreversible” sentences with the same syntactic structures, that is, sentences in which the meaning can simply be inferred from the meanings of the words and knowledge about likely relations between them (e.g., “The book that the girl read is long”) (Caramazza & Zurif, 1976). Researchers who advocate “specific deficit” accounts of aphasic disturbances in this area have claimed that this pattern occurs for representations and processes specified in linguistics and psycholinguistic models. Some of these deficits are said to be very specific. For instance, the “trace deletion hypothesis” (Grodzinsky, 2000) maintains that individual patients cannot process sentences that Chomsky’s theory maintains contain a certain type of moved items (the term “trace deletion hypothesis” refers to an earlier version of Chomsky’s theory in which these items were moved and left a “trace,” not copied). The claim is that some patients have lost the ability to connect certain moved (or, now, copied) noun phrases to their “traces” in sentences such as those mentioned previously (relative clauses, questions, indirect questions, passive), with the consequence that these noun phrases are not assigned thematic roles. At the other end of the spectrum, some researchers have suggested that certain aphasics have deficits that apply to a large set of related operations, such as the operations that map all syntactic structures

onto propositional meaning (the “mapping hypothesis”—Linebarger, Schwartz, & Saffran, 1983).

Evidence for such deficits would come from the finding that a patient had an impairment restricted to processing the sentences that required that structure or operation to be understood. Proponents of these models have argued that there are data from aphasia of this sort, but there are three important limitations to such data.

First, the data usually consist of one measure of performance—usually accuracy. To my knowledge, there are three studies in the literature—Tyler (1985), Caplan and Waters (2003), and Caplan and colleagues (2007a)—in which both accuracy and response-time (RT) data have been reported on the same sentences in aphasic patients. Without both accuracy and RT data, it is impossible to rule out speed-accuracy trade-offs as the source of selective impairments, or to know if a patient’s problem is manifest only in a longer time that s/he requires to process a syntactic structure. The same three studies are among the few in which online and end-of-sentence measures have been gathered on the same sentences in the same patients. Online data are critical in many ways. For instance, a patient may show normal online performance and an impairment in performing a task; this finding would suggest that the patient assigns the normal structure and interpretation of a sentence of a certain type but fails to use the meaning s/he extracts normally—because of limitations on how long it can be retained, because alternative interpretations (some of which may be activated in the course of normal comprehension) are not inhibited, or for other reasons. In situations such as these, it would not be correct to say that the patient has a deficit in assigning or interpreting the syntactic structure in question.

Second, patients have usually been tested on only one task that requires comprehension, most often sentence-picture matching. However, it is well documented that performance may dissociate over tasks (Cupples & Inglis, 1993; Caplan, Waters, & Hildebrandt, 1997). Caplan, DeDe, and Michaud (2006) and Caplan and colleagues (2007a) studied 42 aphasic patients and found only two in which the same deficit appeared in sentence-picture matching and object manipulation. An inability to perform accurately on a set of sentences in one comprehension task cannot be taken as a reflection of an impairment of a syntactic operation if the patient can perform accurately on those sentences in another comprehension task.

Third, important linguistic controls have usually not been run that would show that the deficit is restricted to the structures claimed. For instance, the trace deletion hypothesis (Grodzinsky, 2000) maintains that patients with the deficit in question are able to co-index items other than traces, such as pronouns. Thus a patient who has this deficit would not be able to connect *the boy* to the “trace (t)” in “The boy who the man pushed t bumped him,” but s/he should

be able to connect *the man* to the *him* in this sentence. Accordingly, the patient should not know who pushed whom, but should know that the boy bumped the man. None of the papers in the literature that have been taken as supporting the trace deletion hypothesis have reported patients’ performance on both sentences with “traces” and sentences with pronouns (or other referentially dependent items, such as reflexives—see Caplan, 1995; Caplan et al., 2007a, for discussion).

Much of the evidence for specific syntactic deficits is based not upon the performance of individual patients but upon the performance of small groups of patients with certain diagnoses drawn from the traditional clinical literature on aphasia, such as Broca’s aphasia or agrammatic aphasia. It is sometimes claimed that some of the objections that we have raised are answered by these group data. For instance, Grodzinsky (2000) has argued that some agrammatic patients have shown integrity of processing pronouns, answering questions about the adequacy of linguistic controls. In the view of this writer, these studies do not address the issues raised. For instance, although some agrammatic patients have shown normal performances on sentences with pronouns (Grodzinsky, Wexler, Chien, Marakovitz, & Solomon, 1993), these patients have not also been tested on sentences with “traces,” so we do not know if they show the deficit specified by the “trace deletion hypothesis.” Empirical data show that not all patients with a clinical diagnosis of Broca’s aphasia or agrammatism have problems with sentences containing “traces” (Swinney & Zurif, 1995; Zurif, Swinney, Prather, Solomon, & Bushell, 1993; Blumstein et al., 1998; see Berndt, Mitchum, & Haendiges, 1996; Drai & Grodzinsky, 1999, Caramazza, Capitani, Rey, & Berndt, 2001; Caplan, 2001a, 2001b, for discussion), so there is a need to verify the presence of both deficits on a patient-by-patient basis.¹

Turning to the hypothesis that deficits of aphasic syntactic comprehension should be characterized as reductions of processing capacity, four arguments have been made in support of this suggestion: (1) the finding that some patients can understand sentences that contain certain structures or operations in isolation but not sentences that contain combinations of those structures and operations (Caplan & Hildebrandt, 1988; Hildebrandt, Caplan, & Evans, 1987); (2) the finding that, in large groups of patients, as patients’ performances deteriorate, more complex sentence types are affected more than less complex ones (Caplan, Baker, & Dehaut, 1985; Caplan et al., 2007a); (3) the fact that, in factor analyses of performance of such patient groups in syntactic comprehension tasks, first factors on which all sentence types load account for the majority of the variance (Caplan et al., 1985, 2007a; Caplan, Hildebrandt, & Makris, 1996); (4) the claim that simulations of the effect of resource reductions on syntactic comprehension in normal subjects

through the use of speeded presentation (Miyake, Carpenter, & Just, 1994), concurrent tasks (King & Just, 1991), and other methods mimic aphasic performance.

These arguments are also not ironclad. The argument that some patients can understand sentences that contain certain structures or operations in isolation but not sentences that contain combinations of those structures and operations suffers from the same limitations of the database that we discussed earlier: it is based on a single performance measure (accuracy) in a single task (enactment). Testing the second result—that as patients' performances deteriorate, more complex sentence types are affected more than less complex ones—risks circularity unless the effects of resource reduction are modeled and measured separately from comprehension on sentences of the sort that are used to test the effects of complexity. Three studies have addressed this issue in different ways: two (Caplan et al., 1985; Caplan et al., 2007a) have found this pattern; the third, a smaller study, did not (Dick et al., 2001). The data regarding interference effects in normal subjects are complex. Interactions of load and syntactic complexity, and of these factors with subject groups that differ in processing resource capacity, are critical pieces of evidence that would support this model, but these interactions only occur under special circumstances (see Caplan & Waters, 1999; Caplan et al., 2006, for reviews), reducing the strength of this argument. The finding that first factors on which all sentence types load account for the majority of the variance is an extremely robust finding, regardless of the task over which factors are extracted or whether they are extracted over several tasks (DeDe Caplan, 2006; Caplan et al., 2007a). The hypothesis that reductions of processing capacity are sources of aphasic syntactic comprehension deficits fares better, in my view, than the hypothesis that individual patients have specific deficits.²

Accepting the view that what is to be correlated with lesion parameters is either some measure of performance that captures a deficit a patient has with a particular syntactic structure or operation, or some measure of performance that captures the “amount” of resources available to a patient, what do studies of deficit-lesions correlation show about the way the brain is organized to support parsing and interpretation? Four models of brain organization for syntactic processing have been suggested, based on data of this sort. Localizationist models are represented by Grodzinsky (2000), who claims that Chomskian traces are coindexed in Broca's area; variable localization models by ourselves (Caplan, 1994; Caplan et al., 2007b); invariant evenly distributed models by Dick and colleagues (2001) and Damasio and Damasio (1992); and invariant unevenly distributed models by Mesulam (1990, 1998). Most of these models have been articulated as applying to specific operations, but the evidence can often be interpreted in terms of reductions in the resource system that underlies parsing and

interpretation. For instance, unless the proper control studies are done (discussed previously), performances that are interpreted as failures to “co-index traces” can be seen as due to reductions in processing resources that lead to failures to comprehend sentences that contain “traces.”

We must begin with a major caveat about lesion-deficit studies: the vast majority of these studies do not examine lesions quantitatively. Many are based on the assumption that Broca's or nonfluent patients have “anterior” lesions and Wernicke's, fluent, conduction, and anomic patients have “posterior” lesions, whereas the reality is far more complicated (Mohr et al., 1978; Vanier & Caplan, 1989). A number of studies summarize radiological reports and/or display lesions, usually on a single transverse section of the brain imaged with computer tomography or magnetic resonance, and emphasize the area in which lesions in patients with certain types of performances (analyzed as deficits of particular types) overlap. Such analyses do not investigate many questions. For instance, neither the most direct prediction made by distributed models (that lesion size correlates with performance level) nor the claim that the insertion of traces into syntactic structures occurs in Broca's area has ever been tested on the basis of radiological data by advocates of these models (Mesulam, 1990; Damasio & Damasio, 1992; Dick et al., 2001; Grodzinsky, 2000).

To my knowledge, there are only six studies in the literature in which radiological images have been analyzed and related to sentence comprehension in aphasics. Three are based on instruments that do not examine syntactic processing: Karbe and colleagues (1989), who used the Western Aphasia Battery, which does not characterize deficits in a linguistically or psycholinguistically specific way; Kempler, Curtiss, Metter, Jackson, and Hanson (1991), who used the Token Test, which confounds syntactic processing with short-term memory requirements; and Dronkers, Wilkin, Van Valin, Redfern, and Jaeger (2004), who used the CYCLE, which does not separate lexical from syntactic errors. Two studies used appropriate measures to test syntactic processing but had other limitations. Tramo, Baynes, and Volpe (1988) presented reversible sentences in a sentence-picture matching task, but studied only one contrast (active and passive sentences) and only reported three cases. Caplan and colleagues (1996) studied 25 sentence types testing many aspects of syntactic processing, but only 18 patients were studied, lesions were identified subjectively, and scans were normalized along a single linear dimension in the anterior-posterior plane only, likely leading to significant inaccuracies in the estimates of percents of regions of interest (ROIs) that were lesioned. Other problems are found in many of the studies that also used inappropriate test instruments (see Caplan et al., 2007b, for discussion). In all these studies, analyses were limited to examining the effect of lesions in individual locations; only Caplan and colleagues

(1996) considered the effect of size of lesion or the relative effects of lesions in multiple regions on performance.

Caplan and colleagues (2007b) began to address these issues. We studied 42 right-handed native English-speaking aphasic patients with single left-hemisphere strokes and 25 age- and education-matched controls. Patients were tested in object manipulation, sentence-picture matching, and grammaticality judgment tasks, the latter two with whole-sentence auditory and word-by-word self-paced auditory presentation (“auditory moving windows”; Ferreira, Henderson, Anes, Weeks, & McFarlane, 1996). In each task, three syntactic operations were tested: passivization, object relativization, and co-indexation of a reflexive. First-factor scores of principal components analyses of performance on each task were taken as reflections of resource availability of each patient in each task, and differences in accuracy, response time, and listening times for words in critical positions (corrected for word length and frequency) in experimental and baseline sentences served as measures of syntactic processing ability for particular structures.

Thirty-two patients and 13 controls matched for age and education underwent magnetic resonance (MR) and positron emission tomography (PET) scanning. The relation between lesions and deficits was investigated by regressing MR and PET measures of the extent of the lesion in each of seven ROIs against the measures of syntactic processing mentioned earlier. The results showed that percent lesion volume on MR and mean PET counts/voxel in several small regions accounted for a significant amount of variance in performance measures. For instance, percent MR lesion in the inferior parietal lobe, the anterior inferior temporal lobe, and the superior parietal lobe, and PET counts/voxel in Broca’s area accounted for a significant amount of variance in first-factor scores for all tasks combined and for object manipulation; different patterns of predictor variables were found for other dependent variables. Since the number of cases was small, a simpler analytic approach was also used: the range of performance in patients with lesions within 0.25 standard deviation of the mean lesion size in four regions (the entire left hemisphere, the left hemisphere cortex, the perisylvian association cortex, and the combination of the perisylvian association cortex, the inferior anterior temporal lobe, and the superior parietal lobe) was examined. In each case, performances covered a wide range of total performance; in some cases almost the entire range, and in one case the entire range, of performance was found.

These results provide strong evidence against models that maintain that the operations or resources involved in assigning and interpreting specific sentence types are invariantly localized in one brain area. If this were the case, measures of lesion extent in only one area should have predicted the magnitude of a deficit. Similarly, these results argue against models that maintain that these functions are evenly

distributed across large contiguous brain areas, such as the left-hemisphere cortex or the perisylvian association cortex. If this were the case, lesions of equal size in areas such as those considered should have led to similar magnitudes of a deficit. The data are consistent with the view that localization of these operations and resources varies across individuals. They are also consistent with the idea that the functions being measured are unevenly distributed throughout sets of apparently otherwise unrelated cortical areas, either with the same pattern of unevenness in all individuals (“invariant uneven distribution”) or with different patterns of uneven distribution in different individuals (“variable uneven distribution”). The evidence that would discriminate between these models is not available (see Caplan et al., 2007b, for discussion).

An important finding in this study is that the patterns of significant effects of lesion sites differed for different tasks. This suggests that lesions cause deficits in operations or resource systems that are deployed in certain tasks, not operations or resource systems that are used to assign and interpret syntactic structures in an amodal, abstract, fashion. This conclusion is consistent with the finding of Caplan and colleagues (2006) that deficits affecting the same operation on two tasks are very rare. They suggest that the brain is organized such that regions support syntactic operations in particular tasks.

Functional neuroimaging studies of syntactic processing

Functional neuroimaging has supplanted deficit-lesion correlations as the principal source of information regarding the neural organization that supports syntactic processing in sentence comprehension. Functional neuroimaging in intact individuals provides different information about functional neuroanatomy than deficit-lesion correlations, namely, information about (a subset of) the neural areas and processes that are normally sufficient to support a function.

As with deficit-lesion correlations, functional neuroimaging studies can be divided into those that investigate specific operations and those that examine the “processing resource” system that supports these functions. We will review these areas in turn (for more extensive reviews of this literature see Grodzinsky & Freiderici, 2006; Caplan, 2006, 2007).

In a line of research that parallels his work in aphasia, Grodzinsky and his colleagues have suggested that fMRI studies implicate left posterior inferior frontal gyrus (Broca’s area) as the site responsible for co-indexing traces. Ben-Shachar, Hendler, Kahn, Ben-Bashat, and Grodzinsky (2003) contrasted object-relativized sentences (sentence 1), in which this operation occurs, with complements (sentence 2), in which it does not, in a grammaticality judgment task ([t] = trace; identical subscripts indicate referential co-indexation).

1. I helped the girl_i that Mary saw [t_i] in the park.

2. I told Mary that the girl ran in the park.

BOLD signal increased in left inferior frontal gyrus (IFG) and bilateral superior temporal sulcus (STS) in sentence 1 compared to sentence 2. Ben Shachar, Palti, and Grodzinsky (2004) found increased BOLD signal in the left IFG, in the left ventral precentral sulcus, and bilaterally in superior temporal gyrus (STG) (marginally on the right) in the contrast of embedded *wh*-questions (sentences 3 and 4) against yes/no questions (sentence 5) in a verification task:

3. The waiter asked which tourist_i [t_i] ordered the alcoholic drink in the morning.

4. The waiter asked which alcoholic drink_i the tourist ordered [t_i] in the morning.

5. The waiter asked if the tourist ordered the alcoholic drink in the morning.

These studies are the only studies to date that contrast sentences with and without the co-indexation of a “trace,” and they yield activation in more than one region.

Bornkessel and Schlesewsky (2006) have published a major position paper on a neurologically based model of parsing and sentence interpretation. They argue that the linear order of noun phrases is mapped onto thematic roles in Broca’s area and that deviations from the usual mapping lead to increased activity in this area. The mapping is determined by both general features of language and cognition (e.g., animate nouns are more likely to be agents than inanimate nouns) and language-specific grammatical features (e.g., case marking is more important in determining thematic roles in a language that has a great deal of visible case marking, such as German, than in a language that does not, such as English). The model is groundbreaking in that it is the first detailed model of aspects of sentence comprehension that is based primarily upon neurological data, mostly event-related potential studies. It is worth noting, however, that the model only deals with a small aspect of sentence processing—assigning the two most basic thematic roles (prototypical agents and themes) in the simplest syntactic structures (single sentences). As noted, the model mostly deals with ERP data, but the anatomical hypotheses are partially based on fMRI studies; I shall briefly review these here.

As noted, the model focuses on the role of Broca’s area in mapping noun phrases onto thematic roles. The first critical study of this topic was Bornkessel, Zysset, Friederici, von Cramon, and Schlesewsky (2005), in which participants verified the meaning of German sentences with verb-final complement clauses in which word order, morphological case ambiguity, and verb class (transitive/dative object experiencer) were varied. Bornkessel and colleagues found that, for sentences with subject-before-object word order, sentences with dative-object-experiencer verbs produced greater

BOLD signal in left pars opercularis than sentences with transitive verbs and vice versa for sentences with object-before-subject word order. This finding is consistent with the conclusion that this part of Broca’s area is involved in mapping the linear order of thematic roles onto the hierarchy of thematic roles. However, the picture is quite complicated. Grewe and colleagues (2005) found that an increase in BOLD signal in left IFG associated with a less common word order (object before subject) was not present when the first noun phrase was a pronoun. Since pronouns preferentially occur in first position in the German middle field, the authors interpreted this result as evidence that particular language-specific syntactic features override the usual effect of word order. However, the result could also indicate that the object-before-subject word order does not always lead to activation in left IFG. Grewe and colleagues (2007) also failed to find that noun animacy had the effects that the theory predicts: an increase in BOLD signal that occurred with object-before-subject order was not greater when the object was inanimate. This finding contradicts the hypothesis in Grewe and colleagues (2006) and Bornkessel and Schlesewsky (2006) that left IFG is activated by sentences that require mapping noun phrases (NPs) that violate the animacy principle onto thematic roles. Another issue is that, as in the studies of BOLD signal associated with processing “traces,” brain areas other than left IFG have been activated in these studies. In the Bornkessel and colleagues (2005) study, the left STS and inferior parietal sulcus (IPS) showed the same pattern as left IFG, for morphologically unambiguous sentences. Thus the hypothesis that left IFG supports a general function of “decoding the prominence relations between arguments,” and that it is the only brain area to do so, is not well established.

The processing resource system underlying parsing and interpretation has been studied in functional neuroimaging studies that examine the difference between object- and subject-extracted structures (e.g., “The boy who the girl chased fell”; “The boy who chased the girl fell”). Object extraction is more demanding than subject extraction and is thought to require more “resources” than subject extraction, for many reasons. These studies use a variety of sentences—cleft sentences, relative clauses, conjoined sentences, *wh*-questions, complement clauses, main clauses, topicalization, and dative shifts in English, German, Dutch, Japanese, and Hebrew. There is great variability in the areas activated in these studies. In Just, Carpenter, Keller, Eddy, and Thulborn (1996), this contrast activated frontal and temporal perisylvian cortex bilaterally. In Stromswold, Caplan, Alpert, and Rauch (1996), left IFG was activated. Cooke and colleagues (2001) found increased BOLD signal in bilateral inferior temporal lobe in this contrast. In other studies of ours (Caplan, Alpert, & Waters, 1998, 1999; Waters, Caplan, Stanczak, & Alpert, 2003), activation was seen variably in

medial anterior structures (cingulate, middle frontal, and superior frontal gyri) and other areas (right IFG, left thalamus, left superior parietal lobe). There was no effect of the object/subject-extraction contrast in studies by Fiebach, Vos, and Friederici (2004), Fiebach, Schlesewsky, and Lohmann (2005), Indefrey, Hagoort, Herzog, Seitz, and Brown (2001), or Ben-Shachar and colleagues (2003).

Fiebach and colleagues (2004, 2005) considered several reasons for this variability: differences in sensitivity of imaging technology, tasks, the particular structures in which extraction occurred (indirect questions; relative clauses), languages, and subjects (high and low span). To these we can add differences in presentation modality, design (blocked versus event related), normalization methods, modeling of the hemodynamic response, and how the significance of activation was determined (fixed versus random-effects models; omnibus analyses versus preselected ROIs). There is an important point about these factors, however: none of them other than the use of inadequately powerful statistical methods could reveal BOLD signal effects that are not present in a contrast, and therefore, unless many of these studies have used inadequate statistical methods and are reporting false positive effects, there are a large number of areas that are activated by these contrasts, suggesting some type of nonlocalizationist model for the neural structures that provide the resources utilized in parsing and interpreting these sentences. However, two factors that we have not mentioned thus far could account for much of this variation and potentially salvage a localization model. The first is the possibility that ancillary cognitive operations (“strategies”) co-occur with parsing and interpretation (Page, 2006) and are the source of some of the BOLD signal effect found in these studies. The second are task-stimulus interactions. We will consider these factors briefly.

First, strategies may have affected neurovascular effects. We investigated this possibility in a verification task (Caplan, Chen, & Waters, 2008). We presented sentences for 4 seconds, followed by a fixation point for 2 seconds, followed by a probe in an active form. We separated BOLD signal into an “early” set of timed repetition (TR) intervals associated with processing the target and a “late” set associated with processing of the probe. In the early TR intervals, there were a few areas of paradoxically greater BOLD signal for syntactically simple compared to complex sentences. This result may have occurred because participants responded to the easier sentences more quickly. In later TR intervals, BOLD signal increased in four left perisylvian locations—the inferior frontal gyrus, the middle frontal gyrus, the inferior parietal sulcus, and the middle temporal gyrus—and in a variety of other areas in response to the complex sentences. This finding strongly suggests that many areas of activation in this task are due to retaining syntactic representations or a representation from which syntactic representations were constructed in

memory. Some of the activity associated with sentence contrasts in the literature cited previously may thus be a result of retaining these representations, not constructing them. Strategies of this sort may have led to BOLD signal effects associated with sentence contrasts in other studies, leaving open the possibility that the resource system that supports parsing and interpretation itself is localized in one area.

Second, performing a task affects parsing and interpreting specific sentences, and the interaction of performing a task and parsing and interpretation may result in the BOLD signal associated with a sentence contrast. Let us take plausibility judgment as an example. There is strong evidence that subjects assess the plausibility of thematic assignments incrementally as syntactic constituents are constructed and interpreted (e.g., Trueswell, Tanenhaus, & Garnsey, 1994; Pearlmuter & MacDonald, 1995). These assessments of plausibility can be used incrementally to weight responses in a plausibility judgment task (Garnsey, Tanenhaus, & Chapman, 1989; Boland, Tanenhaus, Garnsey, & Carlson, 1995). There is a complete isomorphism between the assignment of thematic roles and this function. For example, more thematic roles are assigned at the embedded verb of object-extracted sentences than at any point in subject-extracted sentences, and therefore more plausibility judgment weighting can occur there as well. BOLD signal differences between sentences might thus reflect different processing loads associated with incremental plausibility judgment in different sentences, not different demands of task-independent parsing and interpretation of different sentence types.

To see if this might be the case, we compared BOLD signal responses to the same sentences in two tasks: plausibility judgment and nonword detection (Caplan et al., 2008). The plausibility-judgment task led to widespread activation in the contrast of syntactically complex and simple sentences. In nonword detection, participants viewed the same plausible sentences containing only real words as they saw in the plausibility-judgment task, and an equal number of sentences in which a word had been replaced by an orthographically and phonologically legal nonword. Nonword detection showed a very different pattern of BOLD signal effects. For sentences containing only real words—the same sentences as the plausible sentences that were analyzed in the plausibility-judgment task—there was an increase in BOLD signal located only in left BA 44. The behavioral data showed that subjects not only searched each stimulus for nonwords but also processed the sentences as sentences. The results thus suggest that, in plausibility judgment, the BOLD signal effects largely resulted from the incremental weighting of the response selection mechanism by plausibility information that was activated online. In contrast, left BA 44 may be the area in which task-independent operations that are used in the more complex but not the simpler sentences are localized.

These considerations suggest that, once the effects of strategies and task-sentence type interactions are eliminated, specific parsing and interpretation operations may yet be supported by a limited number of brain areas, perhaps only one. Other data show that the picture is more complicated, however (Caplan & Waters, 2007). We used the same correct sentences used in the plausibility and nonword-detection tasks, containing only real words, in a third task—font-change detection. Participants saw these sentences and foils consisting of grammatically correct, meaningful sentences containing only real words, one of which appeared in a slightly different font from the others, and were required to indicate whether a sentence had a font change. Analyses of the behavioral data again showed that subjects processed sentences as sentences. For sentences containing only words without font changes—the same grammatical, plausible sentences that were analyzed in the plausibility-judgment task and in the nonword-detection task—there was an increase in BOLD signal, but it was located in the left supramarginal gyrus (left BA 39), not left IFG. There were no areas activated in both nonword detection and font-change detection, and no functional connectivity between the areas activated in the two tasks. These results indicate that different parsing and interpretive operations were applied in the two tasks—a result that was confirmed by the finding that the effects of the position of a nonword or a word with a font change on detection response times differed. Thus, although individuals do assign and interpret syntactic structures even when these structures are completely irrelevant to task performance, the task they are performing still affects which operations they deploy. To identify the neural basis of particular parsing operations thus requires knowing what parsing and interpretive operations are applied in a task, as well as knowing that neurovascular effects are not due to strategies or task-sentence type interactions.

Concluding comments

The past 15 years have seen great changes in models of parsing and sentence interpretation. For close to three decades (roughly 1965–1995), heavily influenced by Chomsky's views regarding the domain specificity of syntactic representations and Fodor's (1972) concept of modular cognitive processes, researchers studying syntactic processing made the assumption that parsing and interpretive operations were task independent, and that the use of the products of the interpretive process to perform tasks occurred independently of the assignment of syntactic structure and propositional meaning. Correspondingly, deficit-lesion correlations were interpreted as providing evidence for the location of neural tissue that supports task-independent syntactic operations. Most functional neuroimaging studies of syntactic processing have been interpreted within the same framework.

In the past decade or so, evidence has accrued that this view is inaccurate in important respects. It may be that there are task-independent parsing and interpretive operations, but there is very strong evidence that the assignment of syntactic structure interacts at the earliest possible moment with other types of information in the process of assigning sentence structure and meaning, such as the assessment of how plausible certain meanings are, the activation of meanings based upon nongrammatical heuristics, the assignment of structure and meaning based upon the frequency of occurrence of particular constructions or sequences of words, and so on (MacDonald et al., 1994). Though all these operations could be regarded as part of a larger, integrated process that assigns sentence meaning, the problem still remains of isolating the operations that assign the grammatically licensed syntactic structure of a sentence and use it to determine the meaning of the sentence (recall that it is this structure that allows sentences to convey unlikely information, to express complex relations between items and propositions, and to convey both propositional and discourse-level information). Even more unexpectedly from a “modular” point of view, task demands appear to influence parsing and interpretation online; for instance, how one attaches the prepositional phrase in a sentence such as “Put the toy on the rug . . .” depends upon how many toys are in an array that is being inspected and where these toys are located (Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). The application of parsing and interpretive operations thus may differ in different tasks, and, more seriously from the point of view of identifying the neural basis of these operations, differences in how a task is performed as a function of the sentences that are being presented may be responsible for differences in neural activity associated with sentence contrasts and for deficits that affect performance on one sentence type in a given task. Finally, many tasks involve strategic use of cognitive operations, such as subvocal rehearsal, that are applied to a greater extent when an individual is presented with more complex sentences. These ancillary cognitive operations must also be eliminated from consideration if the neural basis of parsing and interpretation is to be identified. The results of recent studies of patients and neurovascular responses to syntactic contrasts have led to some findings that suggest that these questions are important to consider.

With respect to task dependency of deficits and activation, recent lesion studies have shown that deficits affecting particular parsing operations or the resource system that supports them are affected by task, and the same is true of activation associated with sentence contrasts. These results indicate that most of the data obtained thus far regarding parsing and interpretation may identify brain regions that support a combination of parsing and interpretation and performance of particular tasks. Areas of the brain that are always activated by a syntactic contrast regardless of task are

candidates for the neural substrate of parsing and interpretive operations that are applied regardless of task. Though there are hints in the literature that such areas exist, evidence of this sort is sparse. Two examples that we have reviewed are evidence that the operations that relate the prominence of a noun phrase to its thematic role and those that relate a “moved” constituent to its underlying position invariably involve left IFG. I have argued that the evidence for such invariant activation is at best suggestive.

A feature of recent lesion studies is that they have shown that deficits are associated with lesions in multiple unrelated brain areas and are not predicted by the size of lesions in larger brain areas that are reasonably thought to be possible substrates for parsing and interpretation. Similarly, the activation studies that provide the best evidence for invariant activation of an area across tasks have activated several brain areas. These findings suggest an unorthodox view of the way syntactic operations or the resource system that supports them are related to the brain. The standard view is that a given elementary cognitive operation is invariantly distributed over an area of the brain, either large or small. The results cited earlier are not consistent with this model—they are consistent with the view that the functions identified in these studies are localized in different brain regions in different individuals or distributed across diverse brain areas. I shall end this chapter with a comment on the implications of this possibility.

Properties of neurons such as cytoarchitectonics, receptotomics, connectivity, and other genetically determined features determine the computational capacities of an area of the brain. Invariant localization of a cognitive operation would result from these computational capacities being determined by the *specific* neurological features of particular brain areas. In contrast, variable localization or distribution of a function across diverse brain areas would result from these computational capacities being determined by the neurological features that are *common* to several brain areas, coupled with some factor that determines which of the brain areas that have these features supports a function. Suppose, for instance, that any part of the six-layer association isocortex that is connected to primary auditory koniocortex at a synaptic distance of three or less is capable of supporting parsing operations, and that which area actually supports a particular operation depends upon the history of exposure to particular operations. This capability would surely lead to variable localization of such operations or to a state of affairs in which such operations were supported by multiple, possibly otherwise unrelated, areas of cortex.

These possibilities significantly complicate the picture that needs to be considered regarding the neural organization for syntactic processing (and possibly other aspects of language), but such complication is not necessarily a bad

thing. Syntactic operations are among the most abstract naturally occurring species-specific operations that develop in all normal humans, and we would be wise to consider a broad range of possibilities regarding their neural basis. An encouraging feature of current work is that the tools to gather relevant data and to develop models are greatly expanded compared to only a few years ago. We shall see where their use leads.

NOTES

1. In addition to this issue, the reliance on clinical syndromes to identify patients with particular processing deficits runs into other problems. One is that most syndromes are very poorly defined, often referring to patients with “relatively intact” performance on one very general type of task (e.g., “comprehension”) and “relatively poor” or “impaired” performance on another (e.g., “speech production”); this problem leads to inconclusive debates about which patients have the deficit and fall within the syndrome. Another is that, in many instances, a clinical syndrome is defined by performances that have no obvious connection to the deficit being proposed. This is the case for the “trace deletion hypothesis,” which postulates a very specific comprehension disturbance in patients who have particular problems in sentence production (roughly, nonfluent speech, with omission of grammatical elements). In such cases, the relation between the production and comprehension problems needs to be specified. One possibility is that the connection is functional: that the deficit in one task leads to the deficit in the other. In many cases, such as the “trace deletion hypothesis,” this connection has not been suggested; it has not been established in any case in which the classic syndromes are the basis for identification of patients in which a deficit in syntactic comprehension is hypothesized to occur. The alternative is that a lesion that produces one deficit also produces the other. A great deal of confusion has been generated by not distinguishing these two ways that syndromes can be related to hypotheses about specific deficits.
2. An important question is, What, exactly, are “resources”? Seen in the most general terms possible, resources are features of (a model of) a cognitive system that allow certain operations to occur and set limits on their occurrence, but do not themselves enter into computations and are not representations. An example would be the presence and number of hidden units in a Boltzmann machine, whose existence extends the computational power of one-level “perceptrons” and whose number affects the types of generalizations that the system achieves. Cognitive functions that might provide resources for parsing and interpretation include working memory (Miyake et al., 1994), phonological short-term memory (Baddeley, 1986; Caramazza, Basili, Koller, & Berndt, 1980; but see Caplan & Waters, 1990), factors that determine speed of processing (rates of activation and decay: Haarmann & Kolk, 1991, 1994; Haarmann, Just, & Carpenter, 1997), factors that affect weights in connectionist systems (Dell, Schwartz, Martin, Saffran, & Gagnon, 1997), and factors that affect the efficiency of lexical processing, which can affect syntactic processing (see Caplan & Waters, 1990, for discussion). All these factors have been considered as a resource in which reduction affects parsing and

interpretation, but none have been definitely shown to play this role. Deficits in a short-term semantic memory system are thought to lead to quite specific, different disturbances in comprehension (Martin & He, 2004).

56 Semantic Unification

PETER HAGOORT, GIOSUÈ BAGGIO, AND ROEL M. WILLEMS

ABSTRACT Language and communication are about the exchange of meaning. A key feature of understanding and producing language is the construction of complex meaning from more elementary semantic building blocks. The functional characteristics of this semantic unification process are revealed by studies using event-related brain potentials. These studies have found that word meaning is assembled into compound meaning in not more than 500 ms. World knowledge, information about the speaker, co-occurring visual input, and discourse all have an immediate impact on semantic unification and trigger electrophysiological responses that are similar to those triggered by sentence-internal semantic information. Neuroimaging studies show that a network of brain areas, including the left inferior frontal gyrus, the left superior/middle temporal cortex, the left inferior parietal cortex, and, to a lesser extent, their right-hemisphere homologues are recruited to perform semantic unification.

Ultimately, language is the vehicle for the exchange of meaning between speaker and listener, between writer and reader. The unique feature of this vehicle is that it enables the assembly of complex expressions from simpler ones. The cognitive architecture necessary to realize this expressive power is tripartite in nature, with levels of form (sound, graphemes, manual gestures in sign language), syntax, and meaning as the core components of our language faculty (Jackendoff, 1999, 2002; Levelt, 1999). The principle of compositionality is often invoked to characterize the expressive power of language at the level of meaning. The most strict account of compositionality states that the meaning of an expression is a function of the meanings of its parts and the way they are syntactically combined (Fodor & Lepore, 2002; Heim & Kratzer, 1998; Partee, 1984). In this account, complex meanings are assembled bottom-up from the meanings of the lexical building blocks by means of the combinatorial machinery of syntax. This process is sometimes referred to as simple composition (Jackendoff, 1997). That this is not without problems can be seen in adjective-noun constructions such as “flat tire,” “flat beer,” “flat note,” and so on (Keenan, 1979). In all these cases, the meaning of “flat” is quite different and strongly context dependent. For this and

other reasons, simple composition seems not to hold across all possible expressions in the language (for a discussion of this and other issues related to compositionality, see Baggio, van Lambalgen, & Hagoort, in press). One of the challenges for a cognitive neuroscience of language is to account for the functional and neuroanatomical underpinnings of online meaning composition.

In linking the requirements of the language system as instantiated in the finite and real-time machinery of the human brain to the broader domain of cognitive neuroscience, three functional components are considered to be the core of language processing (Hagoort, 2005). The first is the *memory* component, which refers to the different types of language information stored in long-term memory (the mental lexicon) and to how this information is retrieved (lexical access). The *unification* component refers to the integration of lexically retrieved information into a representation of multiword utterances, as well as the integration of meaning extracted from nonlinguistic modalities; this component is at the heart of the combinatorial nature of language. Finally, the *control* component relates language to action, and is invoked, for instance, when the correct target language has to be selected (in the case of bilingualism) or for handling turn taking during conversation. In principle, this MUC (memory, unification, control) framework applies to both language production and language comprehension, although details of their functional anatomy within each component will be different. The focus of this chapter is on the unification component.

Classically, psycholinguistic studies of unification have focused on syntactic analysis. However, as we saw, unification operations take place not only at the syntactic processing level. Combinatoriality is a hallmark of language across representational domains (cf. Jackendoff, 2002). Thus, also at the semantic and phonological levels, lexical elements are combined and integrated into larger structures (cf. Hagoort, 2005). In the remainder of this chapter, we will discuss semantic unification. Semantic unification refers to the integration of word meaning into an unfolding representation of the preceding context. This is more than the concatenation of individual word meanings, as is clear from the adjective-noun examples given earlier. In the interaction with the preceding sentence or discourse context, the appropriate meaning is selected or constructed, so that a coherent interpretation results.

PETER HAGOORT Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen; Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands

GIOSUÈ BAGGIO and ROEL M. WILLEMS Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen, Nijmegen, The Netherlands

Hereafter we will first discuss the functional characteristics of semantic unification as revealed by ERP and MEG studies. Next, results from fMRI studies will be discussed to identify the neural networks of semantic unification. In the remainder we will use the terms *unification* and *integration* interchangeably. However, in the last paragraph we propose to use the terms *integration* and *unification* for two different ways of combining information.

Functional characteristics of semantic unification

Insights into the functional characteristics of semantic unification have been especially gained through a series of event-related potential (ERP) studies. Most studies on semantic unification exploit the characteristics of the so-called N400 component in the ERP waveform. Kutas and Hillyard (1980) were the first to observe this negative-going potential with an onset at about 250 ms and a peak around 400 ms (hence the N400), whose amplitude was increased when the semantics of the eliciting word (i.e., *socks*) mismatched with the semantics of the sentence context, as in “He spread his warm bread with socks.”

Since its original discovery in 1980, much has been learned about the processing nature of the N400 (for extensive overviews, see Kutas & Federmeier, 2000; Kutas, Van Petten, & Kluender, 2006; Osterhout, Kim, & Kuperberg, 2007). In particular, as Kutas and Hillyard (1984) and many others have observed, the N400 effect does not depend on a semantic violation. For example, subtle differences in semantic expectancy, as between *mouth* and *pocket* in the sentence context “Jenny put the sweet in her mouth/pocket after the lesson,” can also modulate the N400 amplitude (Hagoort & Brown, 1994). Specifically, as the degree of semantic fit between a word and its context increases, the amplitude of the N400 decreases. This general relation between individual word meanings and the semantics of the context is independent of type of context. That is, it is found for a single-word context (Holcomb, 1993), for a sentence context (Kutas & Hillyard, 1980, 1984), and for larger discourses (van Berkum, Hagoort, & Brown, 1999). Because of such subtle modulations, the N400 is generally taken to reflect processes involved in the integration of the meaning of a word into the overall semantic representation constructed for the preceding language input (Brown & Hagoort, 1993; Osterhout & Holcomb, 1992). However, different views exist as to what brings about the N400 integration effect. Federmeier and Kutas (1999; Kutas & Federmeier, 2000) proposed that in addition to its sensitivity to context, the N400 is also sensitive to the ease of accessing information from semantic memory. As such, the N400 can be seen to reflect the organization of (lexical) meaning in semantic memory. According to this view, the N400 amplitude is modulated by the degree to which the context contains

retrieval cues for accessing or selecting the stored representation for a particular word meaning. Recent evidence in favor of this position was obtained in a study by DeLong, Urbach, and Kutas (2005). These authors found an N400 effect to an indefinite article (*an* versus *a*) that excluded the semantically expected continuation, such as in “the day was breezy so the boy went out to fly an . . .,” where *kite* would be the contextually expected noun. This result suggests a contextual pre-activation of the target word. However, other recent evidence is more compatible with a unification account. Li, Hagoort, and Yang (2008) investigated the neurophysiological response to manipulations of information structure. An important distinction at the level of semantic/conceptual structure is that between conceptual content and information structure. The latter refers to the division of the content of a sentence into information that is in the foreground or in the background (topic/focus; given/new). In many languages new information is accented, whereas old information is deaccented. Li and colleagues found that in Chinese the N400 to new, accented information was larger than the N400 to new, deaccented information, despite the fact that the accentuation was contextually appropriate, whereas the absence of an accent was not. The authors argue that this result is best explained by the recruitment of additional unification resources for information that is marked as more salient by accentuation.

One way to reconcile these different accounts of the N400 is by reference to different roles for the left and right hemispheres (Kutas & Federmeier, 2000; Federmeier, 2007). Federmeier and Kutas (1999) did a visual-half-field study in which participants read sentences such as “Every morning John makes himself a glass of freshly squeezed juice. He keeps his refrigerator stocked with (oranges/apples/carrots).” In this context, “oranges” is the expected continuation, “apples” is a violation but within the correct semantic category, and “carrots” is a violation that crosses the category boundary. The left-visual-field/right-hemisphere (LVF/RH) results showed a smaller N400 to oranges than to both within- and across-category violations, but no N400 difference for the two types of violation. In contrast, for the RVF/LH a reduced N400 was obtained not only for the predicted word (“orange”), but also in part for the within-category violation (“apple”) (see figure 56.1). This latter result can be explained as a consequence of a contextual prediction for the target concept. Owing to the organization of semantic memory, the within-category nontarget (“apple”) gets activated to some degree as well, resulting in a partially reduced N400. Predictive semantic processing might thus be a left-hemisphere processing mechanism, while the right-hemisphere contribution is presumably strictly postlexical in nature, only contributing to the integration of the word meaning from a lexical item that received bottom-up support on the basis of visual or acoustic input.

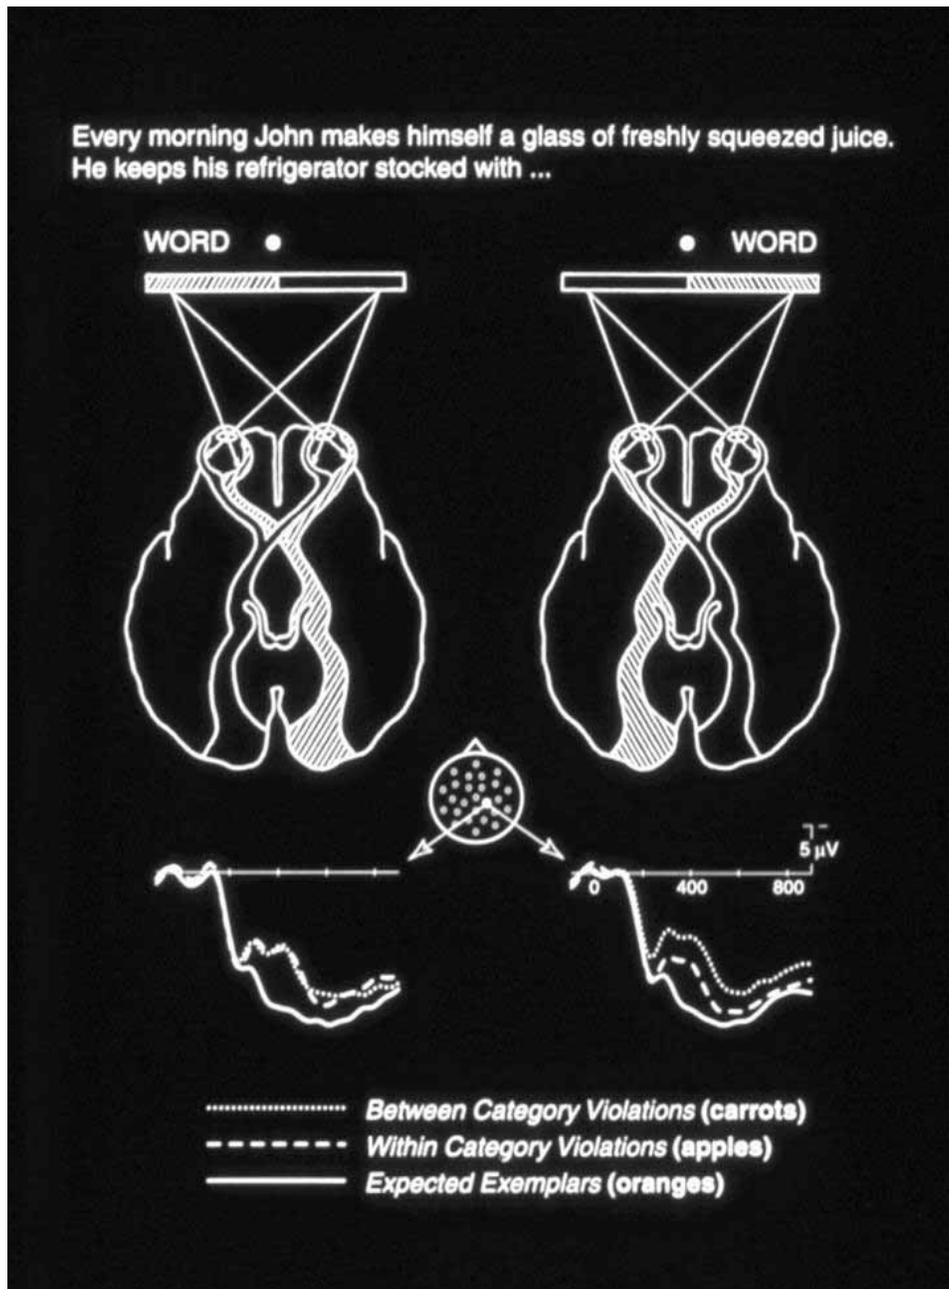

FIGURE 56.1 Participants read the sentences as in the example in a visual-half-field presentation design. Context words were presented at central fixation, whereas sentence-final target words (e.g., “oranges”) were presented to the left or right of fixation. As illustrated, words presented to the left visual field (LVF) travel initially to the right hemisphere (RH) and vice versa. ERPs are shown here from a representative (right medial central) site as indicated. The response to target words presented to the RVF (left hemisphere) (shown on right), yielded the same pattern as that observed with central fixation: expected exemplars (solid line) elicited smaller N400s than did violations of either type, but within-category violations (dashed line) also elicited smaller N400s than between-

category violations (dotted line). This pattern is indicative of a “predictive” strategy, in which semantic information associated with the expected item is preactivated in the course of processing the context information. The response to targets presented to the LVF/RH (shown on left), however, was qualitatively different: expected exemplars again elicited smaller N400s than violations, but the response to the two types of violations did not differ. This pattern is more consistent with a plausibility-based integrative strategy. Taken together, the results indicate that the hemispheres differ in how they use context to process semantic information in online language processing. (Reprinted with permission from Kutas & Federmeier, 2000.)

In recent years, the N400 and other language-relevant ERP effects have been exploited to test more specific ideas about the functional characteristics of semantic unification. These include the contribution of world knowledge, the processing of silent meaning, the integration of pragmatic information, and the syntax-semantics interface. We will discuss briefly each of these theory-driven issues.

WORLD KNOWLEDGE At least since Frege (1892; see Seuren, 1998), theories of meaning make a distinction between the semantics of an expression and its truth-value in relation to our mental representation of the state of affairs in the world (Jackendoff, 2002). For instance, the sentence “Bill Clinton is the 43rd president of the USA” has a coherent semantic interpretation, but contains a proposition that is false in the light of our knowledge that George W. Bush is the 43rd president. The situation is different for the sentence “The presidential helicopter is divorced.” Under default interpretation conditions, this sentence has no coherent semantic interpretation, since the predicate “is divorced” requires an animate argument. The difference between these two sentences points to the distinction that can be made between facts of the world (“world knowledge”) and facts of the words of our language, including their meaning (“linguistic knowledge”). Hagoort, Hald, Bastiaansen, and Petersson (2004) performed a combined EEG/fMRI study that compared the unification of linguistic knowledge with the unification of world knowledge. While participants’ brain activity was recorded, they read one of three versions of a sentence such as “The Dutch trains are *yellow/white/sour* and very crowded” (critical words are in italics). It is a well-known fact among Dutch people that Dutch trains are yellow, and therefore the first version of this sentence is correctly understood as true. However, the linguistic meaning of the alternative color term *white* applies equally well to trains as the predicate *yellow*. It is world knowledge about trains in Holland that makes the second version of this sentence false. This is different for the third version, where (under standard interpretation conditions) the core semantic features of the predicate *sour* do not fit the semantic features of its argument *trains*.

Figure 56.2 presents an overview of the results. As expected, the classic N400 effect was obtained for the semantic violations. For the world-knowledge violations, a clear N400 effect was observed as well. Crucially, this effect was identical in onset and peak latency, and very similar in amplitude and topographic distribution to the semantic N400 effect. This finding is strong empirical evidence that lexical-semantic knowledge and general world knowledge are both integrated in the same time frame during sentence interpretation. The results of this world-knowledge experiment provide further evidence against an account of unification in which first the meaning of a sentence is determined, and only then is its

meaning verified in relation to our knowledge of the world. Semantic interpretation is not separate from its integration with nonlinguistic conceptual knowledge.

Further evidence in favor of an enriched composition account comes from a study on the integration of information about the speaker. In interpreting a speaker’s utterance, we take not only the preceding utterances into consideration, but also our knowledge of the speaker. For instance, we might find it odd for a man, but not for a woman of a certain age, to say, “I think I am pregnant.” At some point during language comprehension, the listener combines the information that is represented in the content of a sentence with the information she has about the speaker. The question is: When exactly does the pragmatic information about the speaker have its impact on the unfolding interpretation of the utterance? This question was answered in a recent ERP study by van Berkum, van den Brink, Tesink, Kos, and Hagoort (2008). Participants listened to sentences, some of which contained a specific word at which the message content became at odds with inferences about the speaker’s sex, age, and social status, as inferred from the speaker’s voice.

If voice-based inferences about the speaker are recruited by the same early unification process that combines word meanings, then speaker inconsistencies and semantic anomalies should elicit the same N400 effect. This was indeed observed. Reliable effects of speaker inconsistency were already found in the 200–300-ms latency range after word onset. The same latency effect was obtained for the straightforward semantic anomalies. These findings therefore demonstrate that sense making depends on the pragmatics of the communicative situation right from the start.

As for compositionality, the results of the studies just reviewed may mean two things, depending on one’s views on the lexicon. One possibility is that the lexicon includes declarative memory in its entirety, and then simple composition seems enough to account for the similarity between the N400 effects. Alternatively, the lexicon includes invariant (i.e., linguistic) meanings only, and then enriched composition—the thesis that the lexicon is not the only source of semantic content—seems necessary to explain the observed N400 effects (Baggio et al., in press).

EVENT KNOWLEDGE AND DISCOURSE MODELS Unification of lexical representations ultimately results in a discourse model—that is, a representation making what is given as input true whenever possible (recall the Dutch trains examples). Events offer a vantage point for investigating the properties of discourse models, because natural languages have very sophisticated devices for characterizing time and causation. One of these devices is aspect. This is the linguistic marking of the internal profile of events. Ferretti, Kutas, and McRae (2007) found that readers have least difficulty

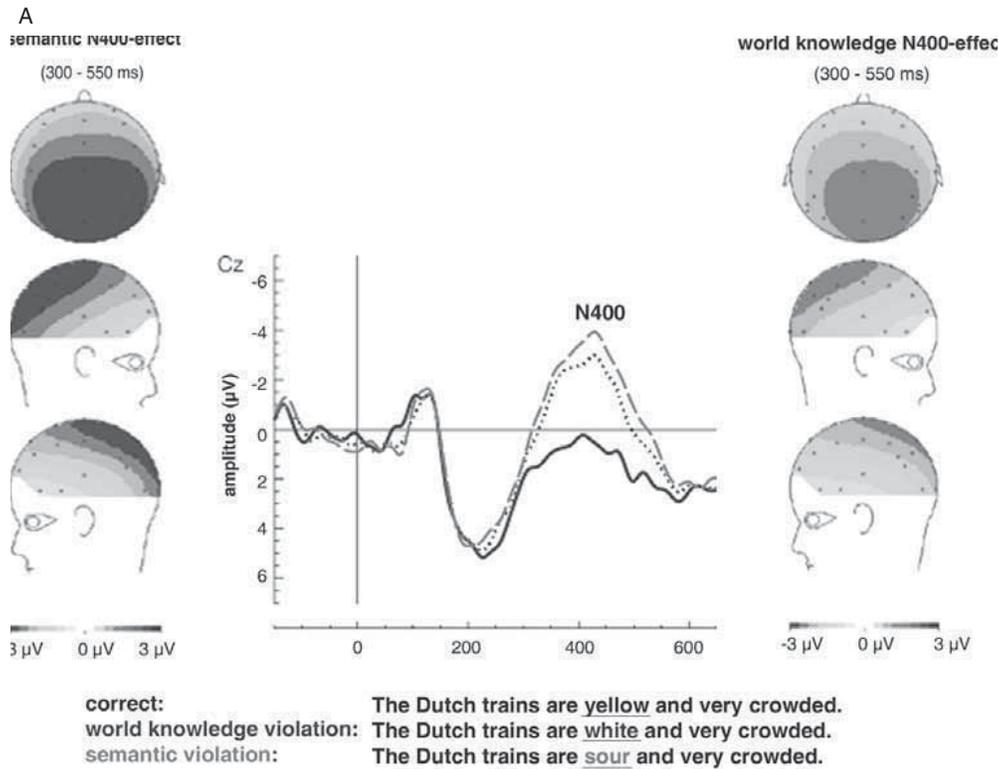

FIGURE 56.2 (A) Grand average ERPs for a representative electrode site (Cz) for correct condition (black line), world-knowledge violation (blue dotted line), and semantic violation (red dashed line). ERPs are time locked to the presentation of the critical words (underlined). Spline-interpolated isovoltage maps display the topographic distributions of the mean differences from 300 to 550 ms between semantic violation and control (left), and between world knowledge violation and control (right). (B) The common activation

for semantic and world-knowledge violations compared to the correct condition, based on the results of a minimum-T-field conjunction analysis. Both violations resulted in a single common activation ($P = 0.043$, corrected) in the left inferior frontal gyrus. The crosshairs indicate the voxel of maximal activation. (Reprinted with permission from Hagoort, Hald, Bastiaansen, & Petersson, 2004.) (See color plate 71.)

integrating locative nouns when the aspect of the main verb is imperfective and the denoted location is a prototypical one given the verb's semantics. In sentences with an imperfective, such as "The diver was snorkeling in the ocean/pond," a larger N400 was evoked by *pond* than by *ocean*. This N400 effect was reduced if the aspect was perfective, as in "The diver had snorkeled in the ocean/pond." Describing an event as ongoing using the imperfective aspect leads readers

to construct a situation model in which locations and other dimensions of the action become relevant, while such dimensions are ignored if the action is viewed perfectly.

The imperfective leads also to expectations concerning the outcome of the event described. Baggio, van Lambalgen, and Hagoort (2008) investigated whether, in sentences like "The girl was writing a letter when her friend spilled coffee on the tablecloth/paper," the goal state (a complete letter)

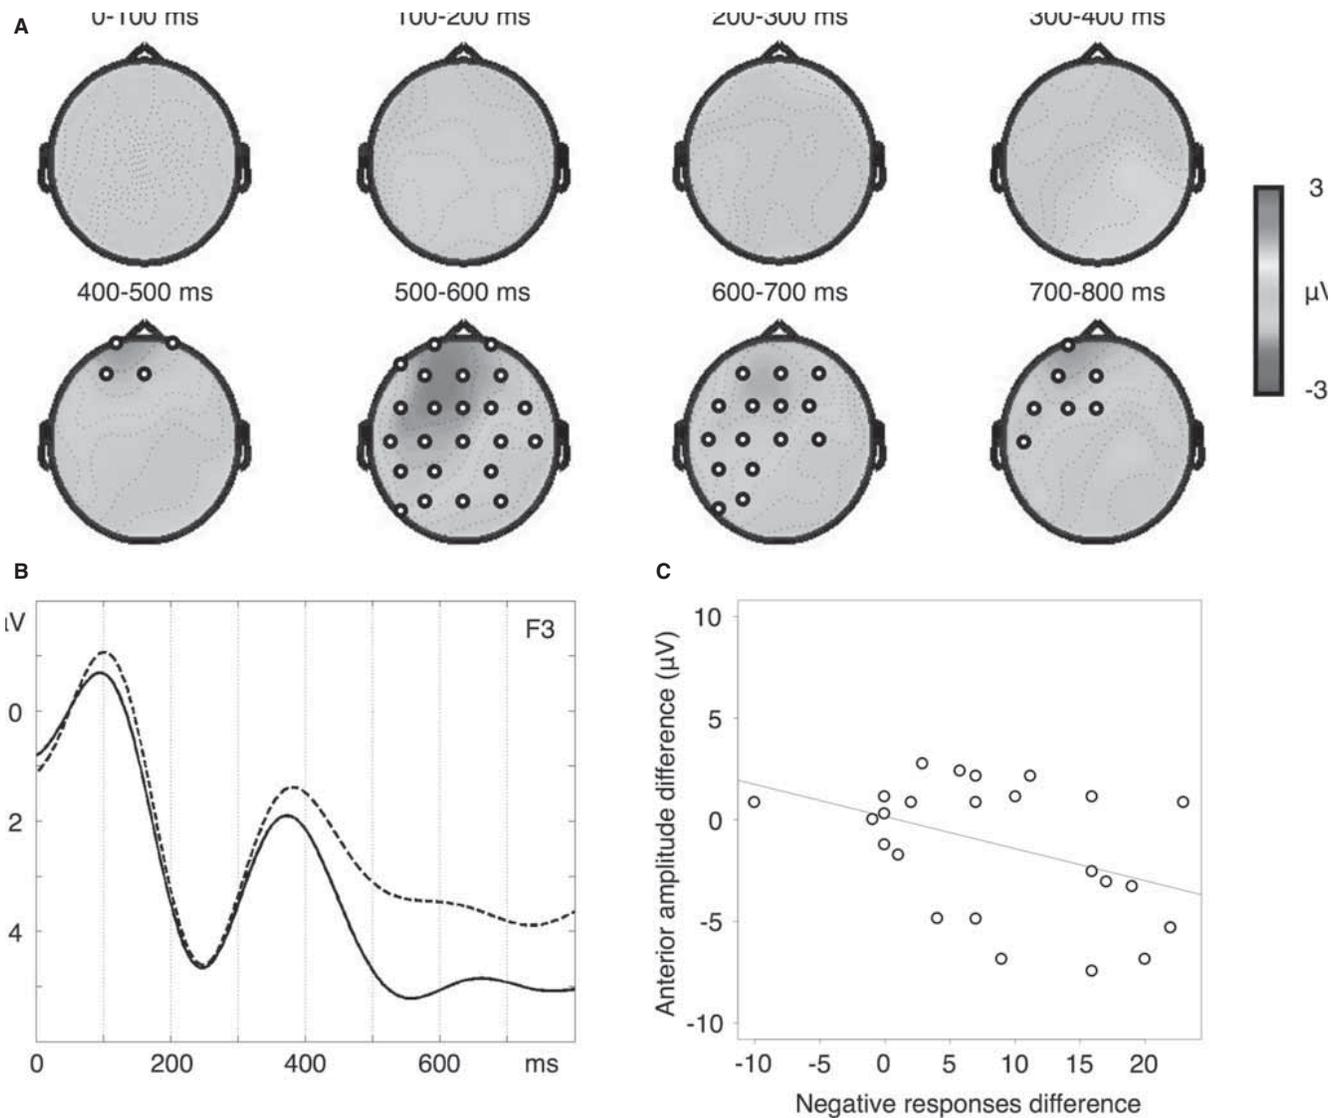

was represented online during the unification process. If the goal is predicted to occur whenever the imperfective is used, a difference should be observed at the word *paper* compared to *tablecloth*. Spilling coffee on the paper implies that the goal state was not attained, and forces the system to revise the earlier commitment to the event's completion (Baggio & van Lambalgen, 2007). Spilling coffee on the tablecloth, however, does not have this implication. *Paper* did indeed result in a larger sustained anterior negativity (SAN) compared to *tablecloth*, and the effect was correlated with the frequency with which participants concluded that the event was not completed (see figure 56.3). These results again suggest that semantic processing is not bound to asserted content, but can include inferences anticipating the outcome of actions and events, as well as other inferences invalidating previously drawn conclusions. In this sense, unification can be described as a defeasible process: discourse models built up incrementally at any one stage may have to be revised when additional information becomes available, as when the word *paper* is encountered in this example (cf. Carreiras, Garnham, Oakhill, & Cain, 1996; Sturt, 2007).

FICTIONAL DISCOURSE AND SILENT MEANING Simple composition implies that unification preserves the semantic identity of the constituent expressions. However, experimental research suggests that discourse may override even such core features of word semantics as animacy. Nieuwland and van Berkum (2006) showed that sentences that make sense on their own, like "The peanut was salted," appear anomalous if they are embedded in a context in which the inanimate subject (the peanut) is attributed animate features. In a narrative in which the peanut danced and sang, because it fell in love with an almond it had met, the final word in "The peanut was salted" resulted in a larger N400 compared to "The peanut was in love" (see figure 56.4). This result is taken to show that discourse can override seemingly context-invariant semantic features of words.

Another interesting phenomenon is that of silent meaning—that is, meaning not expressed in the syntax and phonology of an expression. A number of linguistic devices are available to speakers and hearers that allow efficient communication of meaning beyond what is explicitly asserted. Among these are coercing expressions, functioning as a shorthand for lengthier definite descriptions, as in the classic examples "The ham sandwich in the corner wants some more coffee," where *ham sandwich* in fact refers to the person who ordered one, and "Plato is on the top shelf next to Russell," where *Plato* and *Russell* refer to copies of the works of the two philosophers. More extreme forms of coercion are possible, as in "Fishing the edges dry," where *dry* is a condensed expression for the phrase *using a dry fly*, or in resultative constructions like "Hammering the metal flat," where *flat* denotes the final state of the metal after hammer-

ing. What all these widely used expression types have in common is a silent semantic element, which has to be recovered (sometimes obligatorily) to make full sense of the sentence. Semantic processing might be taxed during such recovery process, and that is indeed what was found experimentally. Complement-coercing sentences like "The journalist began the article," which presumably means that she began writing or typing the article, are more difficult to process than sentences in which the activity is part of the asserted content like "The journalist wrote the article." The processing costs of complement coercion have been established using reading times (McElree, Traxler, Pickering, Seely, & Jackendoff, 2001), eye tracking (Traxler, Pickering, & McElree, 2002; Traxler, McElree, Williams, & Pickering, 2005), and MEG (Pykkänen & McElree, 2007). Pykkänen and McElree found a magnetoencephalography (MEG) response that was located in ventromedial prefrontal cortex to coerced sentences, which was different from the M350, the magnetic correlate of the N400. Semantic processing beyond the single-word level is therefore not restricted to processing asserted content as delivered by the input, but is crucially engaged in recovering silent meaning in presuppositions, implicatures, coercions, and so on. Crucially, recovered meanings are triggered by expressions that are given as input but are themselves phonologically and syntactically silent, an effect that shows that semantics is relatively independent from the two other components of the language system. This "autonomy of semantics" is at odds with the syntax-semantics homomorphism postulated by formal semanticists (Montague, 1970; Partee, Ter Meulen, & Wall, 1990), as well as with the "interface uniformity" upon which generative grammar is built (Culicover & Jackendoff, 2005).

UNIFICATION AND THE SYNTAX-SEMANTICS INTERFACE A language-relevant ERP effect that has been related to syntactic processing is a positivity, nowadays referred to as P600 or as P600/SPS (Coulson, King, & Kutas, 1998; Hagoort, Brown, & Osterhout, 1999; Osterhout, McLaughlin, & Bersick, 1997). The P600 is the syntactic equivalent of the N400 effect. One of the antecedent conditions of P600 effects is a violation of a syntactic constraint. The relation between N400 and the P600 effects might provide insights into the interplay between semantic and syntactic unification. Modulations of the P600 have been observed not only to syntactic violations, syntactic ambiguities, and syntactic complexity, but also to breakdowns of normal operations at the syntax-semantics interface (for a review, see Kuperberg, 2007). For example, Kim and Osterhout (2005) reported larger P600s evoked by *devouring* in "The hearty meal was devouring . . .," compared to either "The hearty meal was devoured . . ." or "The hungry boys were devouring . . ."; this despite the fact that the sentence is syntactically well

Het meisje was een brief aan het schrijven toen haar vriendin koffie op het tafelkleed morste.

'The girl was writing a letter when her friend spilled coffee on the tablecloth.'

Het meisje was een brief aan het schrijven toen haar vriendin koffie op het papier morste.

'The girl was writing a letter when her friend spilled coffee on the paper.'

FIGURE 56.3 (A) Grand-average topographies displaying the mean amplitude difference between the ERPs evoked by the sentence-final verb when it terminated versus when it did not terminate the accomplishments in the progressive. Circles represent electrodes in a significant ($P < 0.05$) cluster. (B) Grand-average ERP waveforms from a representative site (F3) time-locked to the onset (0 ms) of the verb in terminated versus nonterminated accomplishments. Negative values are plotted upward. (C) Scatter plot displaying the correlation between the amplitude of the sustained anterior negativity elicited by terminated accomplishments and the fre-

quency of negative responses in a button-press, probe-selection task ($r = -0.415$, $T(22) = -2.140$, $P = 0.043$). The mean difference of negative responses between terminated and nonterminated accomplishments is plotted on the abscissa. The mean amplitude difference at frontopolar and frontal electrodes between terminated and nonterminated accomplishments in the 500–700-ms interval following the onset of the sentence-final verb is plotted on the ordinate. (After Baggio, van Lambalgen, & Hagoort, 2008.) (See color plate 72.)

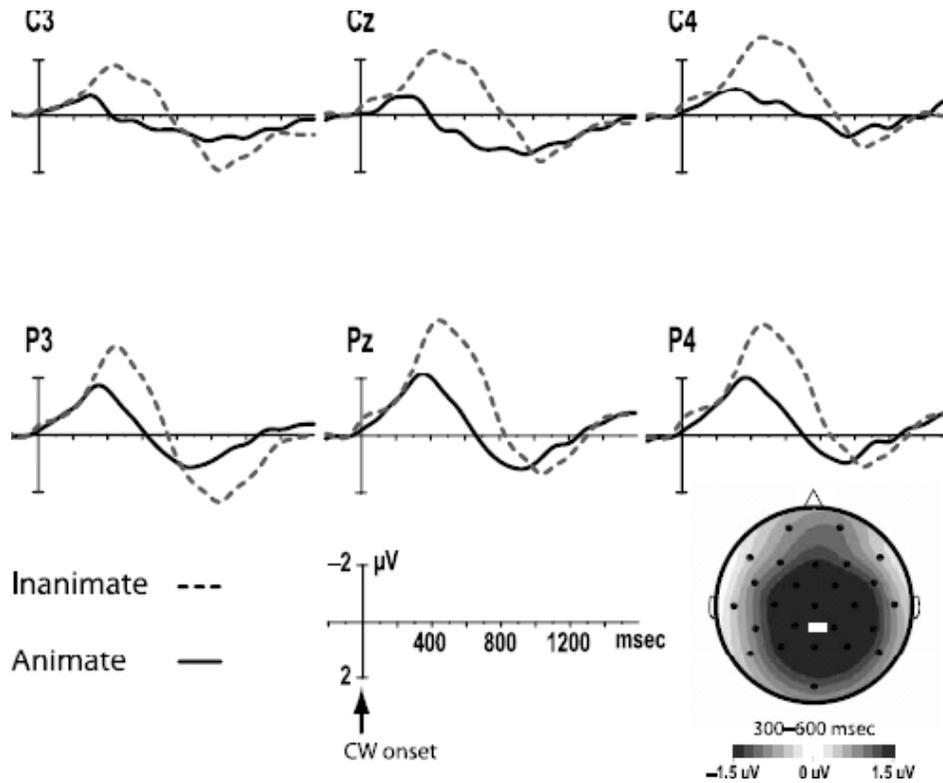

FIGURE 56.4 N400 effects triggered by a correct predicate (*salted*) that is, however, contextually disfavored in comparison to an incorrect predicate (*in love*). Waveforms are presented for representative

electrode sites, time-locked to the onset of the critical inanimate/animate predicate in the fifth sentence. (After Nieuwland & van Berkum, 2006.)

formed (see figure 56.5). The semantics of *meal* and *devour* suggest a plausible thematic role assignment to *meal*: a *theme* instead of an *agent* as the syntax implies. In this case, semantic plausibility overrides syntactic constraints, and the verb *devouring* is presumably perceived as a morphosyntactic violation indexed by the P600. Conflicts between syntactic and semantic constraints might result in N400 or P600 effects depending on whether, respectively, the semantic or the syntactic constraints are the weakest. In cases where the input is anomalous because of a conflict between semantic and syntactic cues, the modus operandi of the system seems to obey a “loser takes all” principle. That is, if the semantic cues are stronger than the syntactic cues, the effect will appear at the level of syntactic unification (P600). Kuperberg (2007) argues that there are at least two neural routes subserving language comprehension: (1) a semantic, memory-based stream that provides elementary meanings as well as conceptual, categorical, and thematic relations between them; (2) a combinatorial stream that provides analyses based on morphosyntactic constraints and thematic roles as given in the input. The P600 reported by Kim and Osterhout (2005), for example, might be taken to suggest that semantic associations between words are the strongest constraints—for instance, because in this case they are taken into account earlier than the syntactic cues.

CONCLUSION In general, ERP research on semantic processing has found that word meaning is very rapidly assembled into compound meaning. This statement holds for individual word meanings in the context of single words, sentences, or discourse. But it also holds for meaning that is extracted from pictures, co-speech gestures, or stereotypes inferred from speaker characteristics (Willems, Özyürek, & Hagoort, 2007, 2008; van Berkum et al., 2008). The effects of semantic processing are most often observed as modulations of the N400 amplitude. The topographic distribution of the N400 differs slightly for different stimulus types. It is more evenly distributed for auditory than for the visual N400. Pictures and co-speech gestures elicit a more frontal N400 than sentences without concomitant nonlinguistic information. This finding suggests that the set of neural generators contributing to the scalp-recorded N400 is not fully overlapping for the different types of meaningful stimuli. This result is consistent with the results from fMRI studies, showing both overlapping and distinct activations in connection to the various types of meaningful input (see the next section). Intracranial recordings and MEG studies indicate that the scalp-recorded N400 is caused by coordinated activity in a number of different brain areas, including the anterior inferotemporal cortex (McCarthy, Nobre, Bentin, & Spencer, 1995), the superior temporal cortex

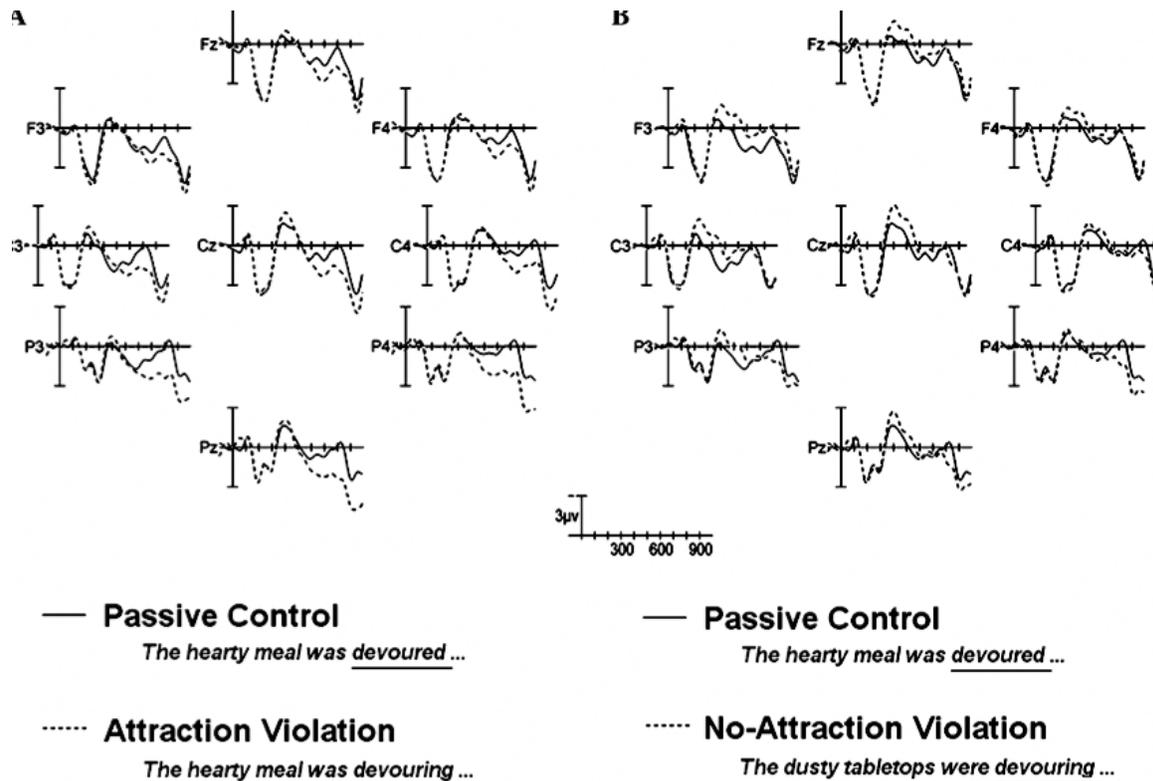

FIGURE 56.5 At the interface between syntax and semantics. Grand-average ERPs recorded at three midline sites and six medial-lateral sites. All sentences are syntactically correct. (A) ERPs to passive control verbs (solid line) and thematic violation verbs (dashed line). (B) ERPs to active control verbs (solid line) and thematic viola-

tion verbs (dashed line). In both cases the inconsistency between grammatical roles and thematic role biases resulted in robust P600 effects. Onset of the critical verbs is indicated by the vertical bar. Each hash mark represents 100 ms. Positive voltage is plotted down. (Kim & Osterhout, 2005; reprinted with permission.)

(Dale et al., 2000; Helenius, Salmelin, Service, & Connolly, 1998; Halgren et al., 2002), and the left inferior frontal cortex (Halgren et al., 1994, 2002; Guillem, Rougier, & Claverie, 1999). Other ERP effects (e.g., anterior negativities) have also been observed to aspects of postlexical semantic processing. How they differ from the N400 effects in their functional characterization is an issue for further research.

The semantic unification network

In recent years a series of fMRI studies were aimed at identifying the semantic unification network. These studies either compared sentences containing semantic/pragmatic anomalies with their correct counterparts (Hagoort et al., 2004; Newman, Pancheva, Ozawa, Neville, & Ullman, 2001; Kuperberg et al., 2000, 2003; Kuperberg, Sitnikova, & Lakshmanan, 2008; Ni et al., 2000; Baumgaertner, Weiller, & Buchel, 2002; Kiehl, Laurens, & Liddle, 2002; Friederici, Ruschemeyer, Hahne, & Fiebach, 2003; Ruschemeyer, Zysset, & Friederici, 2006) or compared sentences with and without semantic ambiguities (Hoenig & Scheef, 2005; Rodd, Davis, & Johnsrude, 2005; Zemleni, Renken, Hoeks, Hoogduin, & Stowe, 2007; Davis et al., 2007). The most

consistent finding across all these studies is the activation of the left inferior frontal cortex (LIFC), more particularly BA 47 and BA 45. In addition, the left superior and middle temporal cortex is often found to be activated (see figure 56.6 for an overview), as well as left inferior parietal cortex. For instance, Rodd and colleagues had subjects listen to English sentences such as “There were dates and pears in the fruit bowl” and compared to the BOLD response of these sentences to the BOLD response of sentences such as “There was beer and cider on the kitchen shelf.” The crucial difference between these sentences is that the former contains two homophones—“dates” and “pears”—which, when presented auditorily, have more than one meaning. This is not the case for the words in the second sentence. The sentences with the lexical ambiguities led to increased activations in LIFC and in the left posterior middle/inferior temporal gyrus. In this experiment all materials were well-formed English sentences in which the ambiguity usually goes unnoticed. Nevertheless, the results were very similar to those obtained in experiments that used semantic anomalies. Areas involved in semantic unification were found to be sensitive to the increase in semantic unification load that resulted from the ambiguous words.

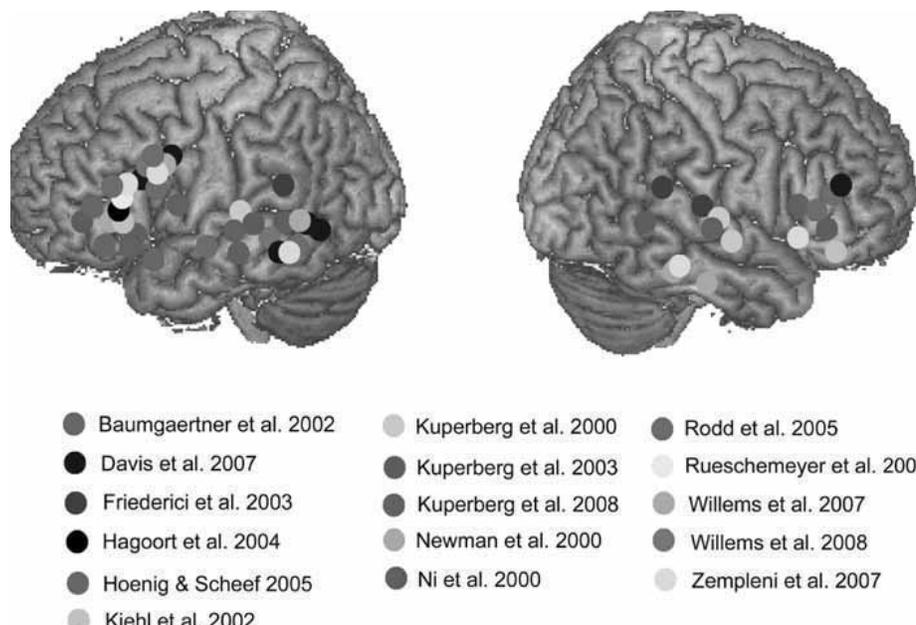

FIGURE 56.6 Overview of local maxima in inferior frontal cortex and in temporal cortex in neuroimaging studies employing sentences with semantic anomalies or semantic ambiguities. The local maxima (in MNI space) of each study were overlaid on a rendering of a brain in MNI space. For local maxima see tables 56.1 and 56.2; for a summary of the results see table 56.3. Rendering was

In short, the semantic unification network seems to include at least LIFC, left superior/middle temporal cortex, and the (left) inferior parietal cortex. To some degree, the right hemisphere homologues of these areas are also found to be activated (see figure 56.6). In the following subsections we will discuss the possible contributions of these regions to semantic unification.

THE MULTIMODAL NATURE OF SEMANTIC UNIFICATION

An indication for the respective functional roles of the left frontal and temporal cortices in semantic unification comes from a few studies investigating semantic unification of multimodal information with language. Using fMRI, Willems and colleagues assessed the neural integration of semantic information from spoken words and from co-speech gestures into a preceding sentence context (Willems et al., 2007). Spoken sentences were presented in which a critical word was accompanied by a co-speech gesture. Either the word or the gesture could be semantically incongruous with respect to the previous sentence context. Both an incongruous word and an incongruous gesture led to increased activation in LIFC as compared to congruous words and gestures (see Willems et al., 2008, for a similar finding with pictures of objects). Interestingly, the activation of the left posterior STS was increased by an incongruous spoken word but not by an incongruous hand gesture. The latter resulted in a specific increase in dorsal premotor cortex

made using MRICroN. Please note that the local maxima of the Ni and colleagues (2000) and the Kuperberg and colleagues (2003) studies are displayed, but that these are not based on coordinates, since no coordinates were provided. The local maxima are drawn by hand based upon the figures in the respective papers. (See color plate 73.)

(Willems et al., 2007). This finding suggests that activation increases in left posterior temporal cortex are triggered most strongly by processes involving the retrieval of lexical-semantic information. LIFC, however, is a key node in the semantic unification network, unifying semantic information from different modalities.

From these findings it seems that semantic unification is realized in a dynamic interplay between LIFC as a multimodal unification site on the one hand, and modality-specific areas on the other hand.

SEMANTIC UNIFICATION BEYOND THE SENTENCE LEVEL

Recently a few studies have set out to investigate the neural networks involved in semantic processing at the level of multisentence utterances, such as short stories. Besides the network that is also activated to semantic unification at the sentence level, story comprehension involves activation of dorsomedial prefrontal cortex and, presumably, right inferior frontal cortex. In a recent meta-analysis, Ferstl and colleagues report the consistent involvement of medial prefrontal cortex, left STS/MTG, and LIFC when participants process coherent text as compared to sentences that do not form a coherent story or as compared to word lists (Ferstl, Neumann, Bogler, & von Cramon, 2008). In a variant of this line of research, Kuperberg, Lakshmanan, Caplan, and Holcomb (2006) presented participants with sentence quartets in which the relation of the last

TABLE 56.1

Involvement of the inferior frontal cortex in fMRI studies of sentence comprehension employing semantic anomalies or semantic ambiguities.

The table shows the studies that were used for the overview in figure 56.6, a brief description of the contrast that was employed in each of the studies, the reported coordinates of the local maxima in inferior frontal cortex in MNI space, and a verbal description of the location of the local maxima. When necessary, Talairach coordinates were converted to MNI space using the transformation suggested by Brett (<http://imaging.mrc-cbu.cam.ac.uk/imaging/MniTalairach>). Note that in computing the mean coordinates the findings from Kuperberg and colleagues (2003) and Ni and colleagues (2000) were not taken into consideration, since no coordinates were reported in these studies.

TABLE 56.3

Summary of the activations in the studies used for the overview in figure 56.6.

The coordinates from tables 56.1 and 56.2 were used. Table 56.3 specifies the mean coordinates for left and right inferior frontal and temporal cortices, the standard deviation in the x , y , and z directions in millimeters, the mean Euclidian distance of the local maxima to the mean coordinates, the number of maxima that were reported, and the number of studies that report maxima in that region. Note that the number of maxima is higher than the number of studies, since several studies report more than one maximum. Note that the findings from Kuperberg and colleagues (2003) and Ni and colleagues (2000) were not used in computing the mean coordinates, since no coordinates were reported in these studies.

	Mean ($x y z$) (MNI)	SD ($x y z$) (mm)	Mean Distance to Mean (mm)	Number of Studies (out of total)

Right	57 -26 0	8.8 10.9 13.7	17.2	6/16

sentence to the previous story context was manipulated. The less related sentences required an extra causal inference in order to make sense of the story. It was found that less related sentences (which evoked more inferencing) led to stronger activations in left and right IFC, left MTG, left middle frontal gyrus, and bilateral medial prefrontal cortex (Kuperberg et al.; see Hasson, Nusbaum, & Small, 2007, for a related result). These and other studies (e.g., St George, Kutas, Martinez, & Sereno, 1999; Xu, Kemeny, Park, Frattali, & Braun, 2005; Sieborger, Ferstl, & von Cramon, 2007) suggest that LIFC and left superior/middle temporal cortex are also important for unification of information beyond the sentence level. It is interesting to note that the medial prefrontal cortex, which is found activated for discourse but not for sentence-level processing, has been implicated in so-called mentalizing tasks, requiring the observer to take the perspective of someone else (Buckner, Andrews-Hanna, & Schacter, 2008; Frith & Frith, 2006). According to Mason and Just, this domain-general area is recruited in discourse processing for the sake of interpreting a protagonist's or agent's perspective (Mason & Just, 2006). In addition, right-hemisphere regions are sometimes but not consistently reported in the context of discourse processing (Maguire, Frith, & Morris, 1999; St George et al., 1999; Ferstl et al., 2008) (see Ferstl et al., 2008; Mason & Just, 2006, for extensive reviews). Some studies find that the temporal poles may be related to successful integration during story comprehension (Fletcher et al., 1995; Maguire et al.). The studies that report these activations are mostly done using PET. It is hard to assess the consistency of temporal pole activation during story/text comprehension because of the susceptibility to artifacts that these regions often suffer from in fMRI studies (but see Xu et al.; Ferstl et al.).

CONTROLLED PROCESSING AND SELECTION ACCOUNTS FOR LIFC Although LIFC (including Broca's area) has traditionally been construed as a language area, there is a wealth of recent neuroimaging data suggesting that its role extends beyond the language domain. Several authors have therefore argued that LIFC function is best characterized as "controlled retrieval" or "(semantic) selection" (Thompson-Schill, D'Esposito, Aguirre, & Farah, 1997; Wagner, Pare-Blagoev, Clark, & Poldrack, 2001; Badre, Poldrack, Pare-Blagoev, Insler, & Wagner, 2005; Gold, Balota, Kirchoff, & Buckner, 2005; Moss et al., 2005; Thompson-Schill, Bedny, & Goldberg, 2005). For instance, Thompson-Schill and colleagues showed that LIFC was more strongly activated in a verb-generation task when the noun that served as the cue allowed for many different verb responses, as opposed to nouns that are reliably related to only one or a few verbs (Thompson-Schill et al., 1997). In response to the noun cue "scissors," for example, most participants generate the verb "to cut," whereas the noun "wheel" triggers a more diverse set of responses. On the basis of these and other findings, it was argued that LIFC guides semantic selection among competing alternatives, with higher activation when there are more competitors.

How does the selection account of LIFC function relate to the unification account? As is discussed in more detail elsewhere, unification often implies selection (Hagoort, 2005). For instance, in the study by Rodd and colleagues described earlier, increased activation in LIFC is most likely due to increased selection demands in reaction to sentences with ambiguous words. Selection is often, but not always, a prerequisite for unification. Unification with or without selection is a core feature of language processing. During natural language comprehension, information has to be kept in working memory for a certain period of time, and incoming

information has to be integrated and combined with previous information. The combinatorial nature of language necessitates that a representation be constructed online, without the availability of an existing representation of the utterance in long-term memory. In addition, some information sources that are integrated with language do not have a stable representation in long-term memory such that they can be selected. For instance, there is no stable representation of the meaning of co-speech gestures, which are highly ambiguous outside of a language context. Still, in all these cases increased activation is observed in LIFC, such as when the integration load of information from co-speech gestures is high (Willems et al., 2007). Similarly, it is unlikely that integration of information about characteristics of the speaker as indicated by the acoustics of the voice (e.g., whether the speaker is male or female, child or adult) relies on selection. Nevertheless, increased activation levels are observed in LIFC when integrating speaker characteristics with the content of the message gets more difficult (Tesink et al., in press). Therefore, unification is a more general account of LIFC function. It implies selection, but it covers additional integration processes as well.

INTEGRATION VERSUS UNIFICATION We have so far used the term “unification” to refer to the assembly of complex meaning. Although the term “integration” is often used as a synonym for unification, including by ourselves, we suggest that it is useful to make a functional distinction between the two. Semantic integration is at stake if different sources of information converge on a common memory representation. An example is the sound and the sight of an animal (e.g., a barking dog). The sight of a dog, the barking sound, and their combined occurrence most likely all activate a memory representation of “dog” that has multimodal characteristics. Semantic unification, however, is always a constructive process in which a semantic representation is constructed that is not already available in memory. This distinction makes opposite predictions for the BOLD response. Semantic unification is always harder for semantic incongruities. These should result in a stronger BOLD response than semantically congruent items. In contrast, congruent input results in converging support for a prestored representation, which might thus be more strongly activated compared to a situation with incongruent input. Hence, in the case of integration, the congruent condition will elicit a stronger BOLD response than the incongruent condition. A few studies on multimodal integration have indeed reported activation increases to matching stimulus combinations. For instance, Van Atteveldt, Formisano, Goebel, and Blomert (2004) observed a higher activation level in left superior temporal cortex in response to a matching phoneme and letter combination (e.g., letter “p” with phoneme [p]) as compared to a mismatching combination (e.g., letter “k”

with phoneme [p]) (see also Calvert, Campbell, & Brammer, 2000, for the integration of lip movements and speech sounds). The same is true in the study by Beauchamp, Lee, Argall, and Martin (2004), who found higher activation in left posterior temporal cortex to the matching combination of a picture of an object and its sound versus an incongruent combination. In a recent paper Hein and colleagues (2007) reported an interesting difference between inferior frontal cortex (IFC) and posterior temporal cortex. The IFC showed a stronger response to incongruent familiar animal sounds and images (e.g., a meowing dog) than to the familiar combination (a barking dog). This was, however, not observed in STG and pSTS. This region was found to be more strongly activated to highly familiar combinations of objects and sounds as compared to combinations of artificial objects and sounds. This result suggests a possible division of labor between inferior frontal and superior temporal areas, with a stronger contribution to integration for temporal cortex and a stronger role for the IFC in unification—that is, in constructing a common representation that is not already available in long-term memory.

However, as we have seen, many studies on sentence processing have found increased activation, especially in left superior/middle temporal cortex when the (semantic) unification load of a word increases given the preceding sentence context (e.g., Bookheimer, 2002; Friederici et al., 2003; Kuperberg et al., 2003; Hagoort et al., 2004; Rodd et al., 2005; Ruschemeyer, Fiebach, Kempe, & Friederici, 2005; Davis et al., 2007; Willems et al., 2007, 2008). We propose that this results from signals from LIFC, indicating that in the service of unification, lexical-semantic information needs to be maintained active longer or needs to be reaccessed when unification load increases (cf. Humphries, Binder, Medler, & Liebenthal, 2007). In this way, it is the dynamic interplay between LIFC and left superior/middle temporal cortex that is necessary for successful semantic unification.

Conclusion

Over and above the retrieval of individual word meanings, sentence and discourse processing requires combinatorial operations that result in a coherent interpretation of multiword utterances. These operations do not adhere to a simple principle of compositionality. World knowledge, information about the speaker, co-occurring visual input, and discourse information all trigger electrophysiological responses similar to those triggered by sentence-internal semantic information. A network of brain areas, including the left inferior frontal gyrus, the left superior/middle temporal cortex, the left inferior parietal cortex, and, to a lesser extent, their right-hemisphere homologues are recruited to perform semantic unification. In line with the MUC framework,

semantic unification operations are under top-down control of left, and in the case of discourse, also right inferior frontal cortex. This contribution modulates activations of lexical information in memory as represented by the left superior and middle temporal cortex, presumably with additional support for unification operations in left inferior parietal areas (e.g., angular gyrus). A more precise account of the individual contributions of these core nodes in the unification network awaits further research.

ACKNOWLEDGMENTS We thank Jos van Berkum, Karl-Magnus Petersson, and the Neurocognition of Language Ph.D.s for their comments on an earlier version of this chapter.

57 Early Language Acquisition: Neural Substrates and Theoretical Models

PATRICIA K. KUHL

ABSTRACT Infants learn language(s) with apparent ease, and the tools of modern neuroscience are providing valuable information about the mechanisms that underlie this capacity. Noninvasive, safe brain technologies have now been proven feasible for use with children starting at birth, and studies in the past decade at the phonetic, word, and sentence levels have produced an explosion in neuroscience research examining young children's language processing. At all levels of language, the neural signatures of learning can be documented at remarkably early points in development. Importantly both for theory and for the eventual application of this work to the diagnosis and treatment of developmental disabilities, early brain measures of infants' responses to phonetic differences are reflected in infants' language abilities in the second and third year of life. Developmental neuroscience studies using language are beginning to answer questions about the origins and development of human's language faculty.

Infants begin life with the capacity to detect phonetic distinctions across all languages, and they develop a language-specific phonetic capacity and acquire early words before the end of the first year (Jusczyk, 1997; Kuhl, Conboy, Padden, Rivera-Gaxiola, & Nelson, 2008; Werker & Curtin, 2005). A major question remains, however: Do infants' initial capacities and their ability to learn effortlessly from exposure to language reflect domain-specific mechanisms that operate exclusively on linguistic data or mechanisms that operate on more general learning mechanisms? In a classic debate, a nativist and a learning theorist took very different positions regarding the innate state and the nature of learning regarding language. Noam Chomsky (1959) argued that infants' innate capacities and the manner in which language was acquired were unique to language and to humans, while B. F. Skinner (1957) asserted that neither the initial state nor the manner in which language was learned was unique.

The tools of modern developmental neuroscience are bringing us closer to addressing these issues and may one

day help resolve the classic debate about the interaction between biology and culture that produces the human capacity for language. Neuroscientific studies will also provide valuable information that may allow us to diagnose developmental disabilities at a stage in development when interventions are more likely to improve children's lives.

Remarkable progress has been made in the last decade in scientists' abilities to examine the young infant brain while its owner processes language, reacts to social stimuli such as faces, listens to music, or hears the voice of the child's mother. This review focuses on the new techniques and what they are teaching us about the earliest phases of language acquisition.

Neuroscientific studies on infants and young children now extend from phonemes to words to sentences. These studies fuel the hope that an understanding of development in typically developing children and in children with developmental disabilities will be achieved. Studies show that exposure to language in the first year of life begins to set the neural architecture in a way that vaults the infant forward in the acquisition of language. The goal in this chapter is to explore what we have learned about the neural mechanisms that underlie language in typically developing children, and how they differ in children with developmental disabilities that involve language such as autism.

Neuroscience techniques measure language processing in the young brain

Rapid advances have been made in the development of noninvasive techniques to examine language processing in infants and young children (figure 57.1). These methods include electroencephalography (EEG)/event-related potentials (ERPs), magnetoencephalography (MEG), functional magnetic resonance imaging (fMRI), and near-infrared spectroscopy (NIRS). ERPs have been widely used to study speech and language processing in infants and young children (for reviews see Conboy, Rivera-Gaxiola, Silva-Pereyra, & Kuhl, 2008; Friederici, 2005; Kuhl, 2004; Kuhl

Neuroscience techniques used with infants

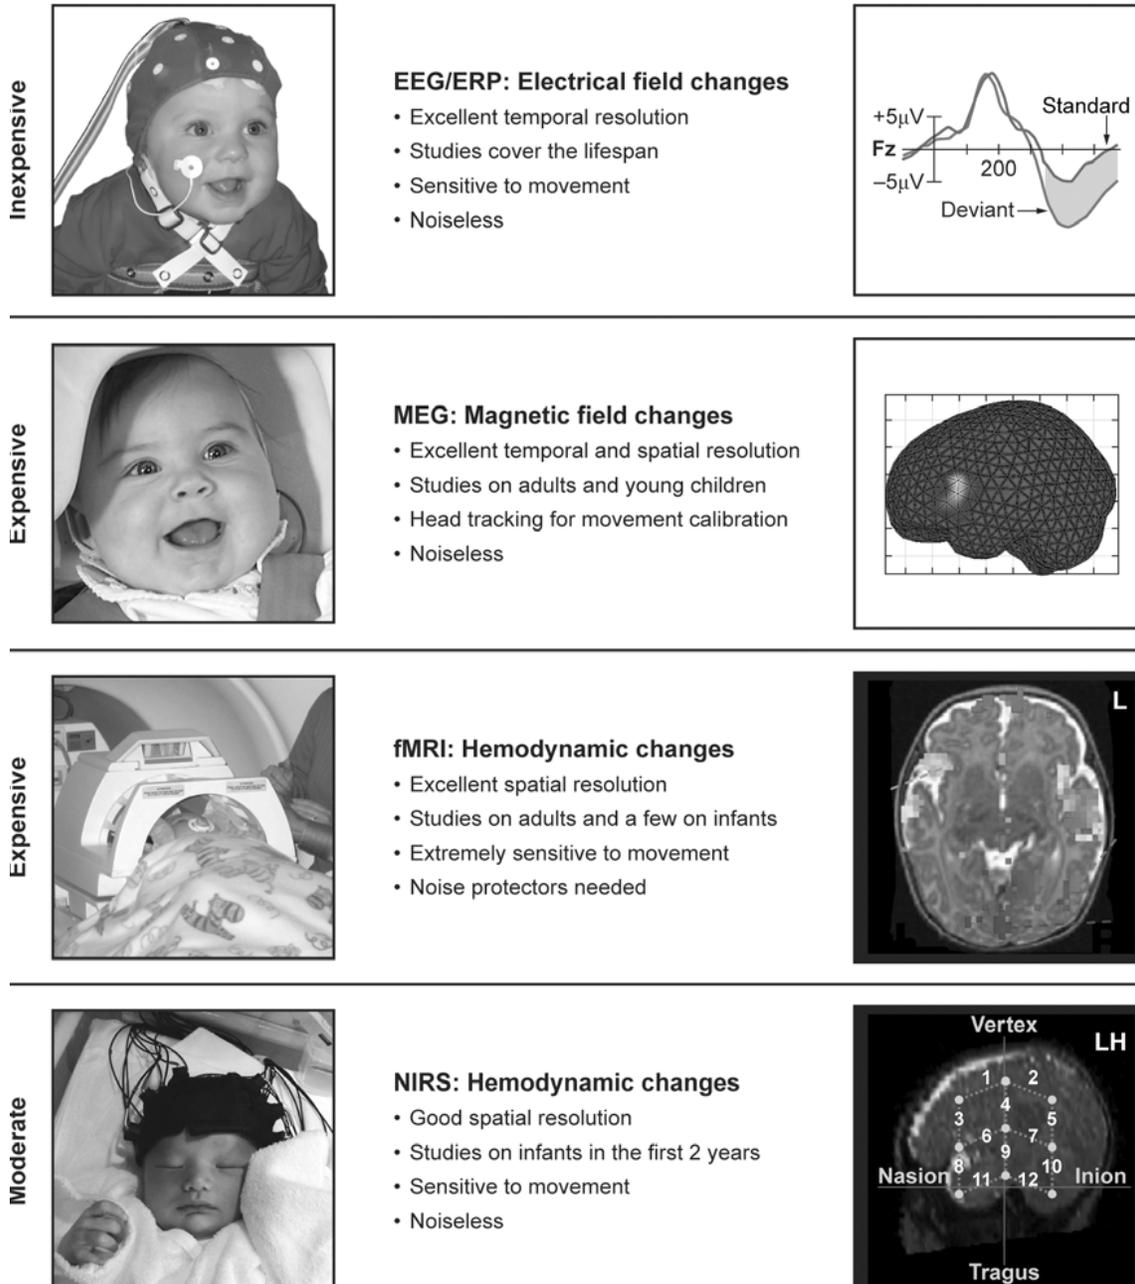

FIGURE 57.1 Four neuroscience techniques now used with infants and young children to examine the brain’s responses to linguistic signals. (From Kuhl & Rivera-Gaxiola, 2008.)

& Rivera-Gaxiola, 2008). Event-related potentials (ERPs), a part of the EEG, reflect electrical activity that is time-locked to the presentation of a specific sensory stimulus (e.g., syllables, words) or a cognitive process (recognition of a semantic violation within a sentence or phrase). By placing sensors on a child’s scalp, the activity of neural networks firing in a coordinated and synchronous fashion in open field configurations can be measured, and voltage changes occurring as a function of cortical neural activity can be detected.

ERPs provide precise time resolution (milliseconds), making them well suited for studying the high-speed and temporally ordered structure of human speech. ERP experiments can also be carried out in populations who, because of age or cognitive impairment, cannot provide overt responses. Spatial resolution of the source of brain activation is, however, limited.

Magnetoencephalography (MEG) is another brain-imaging technique that tracks activity in the brain with

exquisite temporal resolution. MEG (as well as EEG) techniques are safe and noiseless, allowing data collection while infants listen to language in a quiet environment. The SQUID (superconducting quantum interference device) sensors located within the MEG helmet measure the minute magnetic fields associated with electrical currents that are produced by the brain when it is performing sensory, motor, or cognitive tasks. MEG allows precise localization of the neural currents responsible for the sources of the magnetic fields, and it has been used to test phonetic discrimination in adults (Kujala, Alho, Service, Ilmoniemi, & Connolly, 2004).

Recently a genuine advance was documented by the first MEG studies testing awake infants in the first year of life (Bosseler et al., 2008; Cheour et al., 2004; Imada et al., 2006, 2008). In these studies, the use of sophisticated head-tracking software and hardware allows correction for infants' head movements, so infants are free to move comfortably during the tests. MEG studies allow whole-brain imaging during speech discrimination, which is now providing data on the location and timing of brain activation in critical regions (Broca's and Wernicke's) involved in language acquisition (see Bosseler et al.; Imada et al., 2006, 2008).

MEG and/or EEG can be combined with magnetic resonance imaging (MRI), a technique that provides static structural/anatomical pictures of the brain. Using mathematical modeling methods, the specific brain regions that produce the magnetic or electrical signals can be identified in the human brain with high spatial resolution (millimeter). Structural MRIs allow measurement of anatomical changes in white and gray matter in specific brain regions across the life span. MRIs can be superimposed on the physiological activity detected by MEG or EEG to refine the spatial localization of brain activities for individual participants.

Functional magnetic resonance imaging (fMRI) is now considered a standard method of neuroimaging in adults because it provides high-spatial-resolution maps of neural activity across the entire brain (e.g., Gernsbacher & Kachak, 2003). However, unlike EEG and MEG, fMRI does not directly detect neural activity, but rather the changes in blood oxygenation that occur in response to neural activation/firing. Neural events happen in milliseconds, while the blood-oxygenation changes that they induce are spread out over several seconds, thereby severely limiting fMRI's temporal resolution. Adult studies are employing new fMRI data-analysis methods for speech stimuli and correlating the fMRI data to behavioral data. For example, Raizada, Tsao, Liu, and Kuhl (2009), using a multivariate pattern classifier, showed that English—but not Japanese—speakers exhibited distinct neural activity patterns for /ra/ and /la/ in primary auditory cortex. Subjects who behaviorally distinguished the sounds most accurately also had the most distinct neural activity patterns.

Functional MRI techniques would be very valuable with infants, but few studies have attempted fMRI with infants (Dehaene-Lambertz, Dehaene, & Hertz-Pannier, 2002; Dehaene-Lambertz, Hertz-Pannier, Dubois, Meriaux, & Roche, 2006). The technique requires subjects to be perfectly still, and the MRI device produces loud sounds making it necessary to shield infants' ears while delivering language stimuli.

Near-infrared spectroscopy (NIRS) also measures cerebral hemodynamic responses in relation to neural activity, but employs the absorption of light, which is sensitive to the concentration of hemoglobin, to measure activation (Aslin & Mehler, 2005). NIRS utilizes near-infrared light to measure changes in blood oxy- and deoxyhemoglobin concentrations in the brain as well as total blood volume changes in various regions of the cerebral cortex. The NIRS system can determine where and how active the specific regions of the brain are by continuously monitoring blood hemoglobin levels, and reports have begun to appear on infants in the first two years of life (Bortfeld, Wruck, & Boas, 2007; Homae, Watanabe, Nakano, Asakawa, & Taga, 2006; Pena et al., 2003; Taga & Asakawa, 2007). Homae and colleagues, for example, provided data using NIRS that suggest that sleeping 3-month-old infants process the prosodic information in sentences in the right temporoparietal region. As with other techniques relying on hemodynamic changes such as fMRI, NIRS does not provide good temporal resolution. One of the most important uses of this technique is that coregistration with other testing techniques such as EEG and MEG may be possible.

The use of these techniques with infants and young children has produced an explosion of neuroscience studies using stimuli that tap all levels of language—phoneme, word, and sentence. In the next sections, examples of recent findings will be described to give a sense of the promise of neuroscience for the study of language acquisition in children.

Neural signatures of phonetic learning in typically developing children

Perception of the basic units of speech—the vowels and consonants that make up words—is one of the most widely studied behaviors in infancy and adulthood, and studies using ERPs have advanced our knowledge of development and learning.

Behavioral studies demonstrated that at birth young infants exhibit a universal capacity to detect differences between phonetic contrasts used in the world's languages (Eimas, Siqueland, Jusczyk, & Vigorito, 1971). We have referred to this as Phase 1 in development (Kuhl et al., 2008). This universal capacity is dramatically altered by language experience starting as early as 6 months for vowels and by 10 months for consonants: over time, native language

phonetic abilities significantly increase (Cheour et al., 1998; Kuhl et al., 2006; Kuhl, Williams, Lacerda, Stevens, & Lindblom, 1992; Rivera-Gaxiola, Silva-Pereyra, & Kuhl, 2005; Sundara, Polka, & Genesee, 2006) while the ability to discriminate phonetic contrasts that are not relevant to the language of the culture declines (Best & McRoberts, 2003; Cheour et al., 1998; Kuhl et al., 2006; Rivera-Gaxiola, Silva-Pereyra, et al., 2005; Werker & Tees, 1984).

By the end of the first year, the infant brain is no longer universally prepared for all languages, but primed to acquire the specific one(s) to which they have been exposed. We refer to this as Phase 2 in infant phonetic development (Kuhl et al., 2008). The explanation of this transition from Phase 1 to Phase 2 has become the focus of intense study because it illustrates the interaction between biology and culture—between infants' initial state and infants' abilities to learn. Speech offers the opportunity to study the brain's ability to be shaped implicitly by experience.

Kuhl and colleagues (2008) examined whether the transition in phonetic perception from a language-general ability to a language-specific one—from Phase 1 to Phase 2—can be linked to the growth of language. The work provided a critical test stemming from the native language neural commitment (NLNC) hypothesis (Kuhl, 2004). According to NLNC, initial native language learning involves *neural commitment* to the patterned regularities contained in ambient speech, with bidirectional effects: neural coding facilitates the detection of more complex language units (words) that build on initial learning, while simultaneously reducing attention to alternate patterns, such as those of a foreign language.

This formulation suggests that infants with excellent phonetic learning skills should advance more quickly toward language. In contrast, foreign-language phonetic perception reflects the degree to which the infant brain remains uncommitted to native-language patterns—still in Phase 1 as it were—at a more universal and immature phase of development. Infants in Phase 1 remain “open” to nonnative-speech patterns. As an open system reflects uncommitted circuitry, infants who remain highly skilled at discriminating foreign-language phonetic units would be expected to show a slower progression toward language.

New ERP studies of infants support the NLNC assertion. Kuhl and colleagues (2008) measured infants' ERPs at 7.5 months of age in response to changes in native (/p-t/) and nonnative (Mandarin /ç-tç^h/ and Spanish /t-d/) phonemes. The mismatch negativity (MMN), which has been shown in adults to be a neural correlate of phonetic discrimination (Näätänen et al., 1997), was calculated for both the native and nonnative phonemes for each infant. Individual variation was observed for both native and nonnative discrimination, representing either “noise” or meaningful differences among infants.

The results supported the idea that the differences among infants were meaningful. MMN measurements taken at 7.5 months—for both the native and the nonnative phonetic contrasts—predicted later language. However, and in accord with the NLNC hypothesis, the native and nonnative contrasts predicted language growth in opposing directions (Kuhl et al., 2008).

The MMN component was elicited in individual infants (figure 57.2A). Native and nonnative contrasts were measured in counterbalanced order, and the MMN was observed between 250 and 400 ms (figure 57.2B). For the infant shown in figure 57.2A, greater negativity of the MMN, indicating better neural discrimination, was shown for the native when compared to the nonnative phonetic contrast; other infants showed equal discrimination for the two contrasts or better discrimination of the nonnative contrast. Infants' language abilities were measured at four later points in time: 14, 18, 24, and 30 months of age using the MacArthur-Bates Communicative Development Inventories (CDI), a reliable and valid measure assessing language and communication development from 8 to 30 months of age (Fenson et al., 1993).

The MMN measures taken at 7.5 months of age were related to the language measures taken between 14 and 30 months of age. For the native contrast, the strength of the MMN (better discrimination) predicted accelerated word production at 24 months, greater sentence complexity at 24 months, and longer mean length of utterance at 30 months of age. In contrast, for the nonnative stimulus pair, the strength of the MMN at the same age in the same infants predicted slower language development at the same future points in time. Behavioral (Kuhl, Conboy, Padden, Nelson, & Pruitt, 2005) and brain measures (Kuhl et al., 2008), collected on the same infants, were significantly correlated.

This pattern, showing differential effects of good discrimination for the native and nonnative contrasts, can be readily seen in the growth of vocabulary from 14 to 30 months (figure 57.2C). Hierarchical Linear Growth Curve modeling (Raudenbush, Bryk, Cheong, & Congdon, 2005) shows that both native and nonnative discrimination at 7.5 months significantly predicts vocabulary growth, but the effects of good phonetic discrimination are reversed for the native and nonnative predictors. Better native phonetic discrimination predicts accelerated vocabulary growth, whereas better nonnative phonetic discrimination predicts slower vocabulary growth (Kuhl et al., 2008). These results support the NLNC hypothesis.

Rivera-Gaxiola and colleagues (Rivera-Gaxiola, Klarman, Garcia-Sierra, & Kuhl, 2005; Rivera-Gaxiola, Silva-Pereyra, et al., 2005) demonstrated a similar pattern of prediction using a different nonnative contrast. They recorded auditory ERP complexes in 7- and 11-month-old American infants in response to both Spanish and English voicing contrasts.

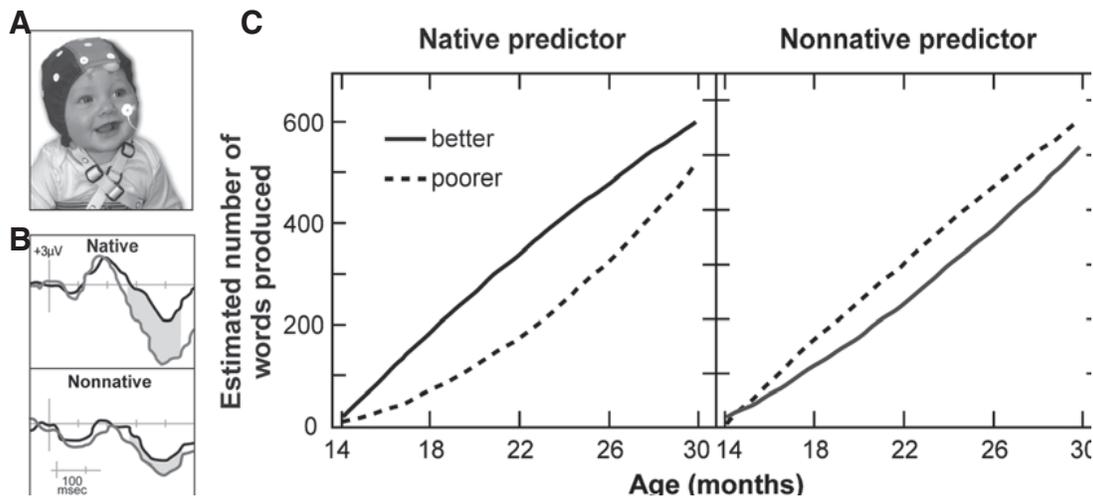

FIGURE 57.2 (A) A 7.5-month-old infant wearing an ERP electrode cap. (B) Infant ERP waveforms at one sensor location (CZ) for one infant are shown in response to native (English) and nonnative (Mandarin) phonetic contrast at 7.5 months. The mismatch negativity (MMN) is obtained by subtracting the standard waveform (black) from the deviant waveform (gray). This infant's response suggests that native-language learning has begun because the MMN negativity in response to the native English contrast is considerably stronger (more negative) than that to the nonnative contrast. (C) Hierarchical linear growth modeling of vocabulary growth between 14 and 30 months is shown for two groups of

children, those whose MMN values at 7.5 months indicated better discrimination (-1 SD) and those MMN values indicated poorer discrimination ($+1$ SD). Vocabulary growth was significantly faster for infants with better MMN phonetic discrimination for the native contrast at 7.5 months of age (C, left). In contrast, infants with better discrimination for the nonnative contrasts (-1 SD) as indicated by MMN at 7.5 months showed slower vocabulary growth (C, right). Both contrasts predict vocabulary growth, but the effects of better discrimination are reversed for the native and nonnative contrasts. (From Kuhl & Rivera-Gaxiola, 2008.)

Two patterns of ERP response were observed—an early positive-going wave (P150–250) and a later negative-going wave (N250–550) (Rivera-Gaxiola, Silva-Pereyra, et al., 2005). Further work examined the patterns of the same auditory ERP positive-negative complexes in a larger sample of 11-month-old monolingual American infants using the same contrasts used in the developmental study, and found that infants' response to the nonnative contrast predicted the number of words produced at 18, 22, 25, 27, and 30 months of age (Rivera-Gaxiola, Klarman, et al., 2005). Infants showing an N250–550 to the foreign contrast at 11 months of age (indexing better neural discrimination) produced significantly fewer words at all ages when compared to infants showing a less negative response. Scalp distribution analyses on 7-, 11-, 15-, and 20-month-old infants revealed that the P150–250 and the N250–550 components differ in distribution (Rivera-Gaxiola et al., 2007). Thus in both Kuhl and colleagues (2008) and Rivera-Gaxiola, Klarman, and colleagues (2005), an enhanced negativity in response to the nonnative contrast is associated with slower language development.

The continuity in language development documented in these studies using infants' early phonetic skills to predict later language (Kuhl, Conboy, et al., 2005; Kuhl et al., 2008; Rivera-Gaxiola, Klarman, et al., 2005; Tsao, Liu, & Kuhl, 2004) is also seen in studies that use infants' early pattern detection skills for speech to predict later language

(Newman, Ratner, Jusczyk, Jusczyk, & Dow, 2006), as well as in studies that use infants' early processing efficiency for words to predict later language (Fernald, Perfors, & Marchman, 2006). Taken as a whole, these studies form bridges between the early precursors to language in infancy and measures of language competencies in early childhood, bridges that are important to theory building as well as to clinical populations with developmental disabilities that involve language.

ERP studies at the phonetic level suggest that the young brain's response to the elementary building blocks of language matters and that initial native language phonetic learning is a pathway to language (Kuhl, 2008). The data also suggest that discriminating nonnative phonetic contrasts for a longer period of time in early development—reflecting infants' initial, more immature state—can be linked to slower language development. In infants exposed to a single language, the ability to attend to changes in the phonetic contrasts that are relevant to the culture's language, while at the same time reducing attention to phonetic contrasts from other languages that are discriminable but irrelevant to the language of their culture, appears to be an important first step toward the acquisition of language. What neuroscience tools may allow us to do in the future is to understand this process and its relation to the “critical period” for language development (see Kuhl, Conboy, et al., 2005, for discussion).

Brain measures of learning from exposure to a second language

Recent studies have shown that young infants are capable of phonetic learning at 9 months of age from exposure to a new language but only when exposure occurs during live human presentation; television or audio-only exposure did not produce learning (Kuhl, Tsao, & Liu, 2003). Social interaction appears to be a critical component for language learning, a finding that ties early communicative learning in speech to examples of communicative learning in neurobiology more generally, as shown by the importance of social factors in song learning in birds (e.g., Brainard & Knudsen, 1998). I have used these second-language exposure studies to argue that the social brain may “gate” the computational mechanisms underlying language learning during the earliest stages of human language acquisition (Kuhl, 2007).

The social “gating” hypothesis was tested in studies using ERP measures of second-language learning (Conboy, Brooks, Taylor, Meltzoff, & Kuhl, 2008; Conboy & Kuhl, 2007). In the study, American monolingual infants were exposed to Spanish at 9 months of age by native Spanish speakers, and their ability to learn both phonemes and words from this foreign-language exposure was tested. The study tested the social hypothesis by examining whether the infants’ tendency to interact in socially sophisticated ways during the exposure sessions would predict the degree to which individual infants learned both phonemes and words from the new language.

Infants’ ERPs in response to English and Spanish phonemes, as well as their ERP responses to Spanish words, were measured before and after exposure to Spanish. As in the Mandarin study, exposure consisted of live interaction with foreign-language “tutors” during 12 sessions, each of which lasted 25 minutes. All sessions were videotaped using a four-camera system, and detailed measures of shared visual attention between the infants and their tutors were taken by an independent observer.

The ERP results demonstrated that the MMN response to the Spanish contrast was not present before exposure, but that following exposure to Spanish, the MMN was robust (Conboy & Kuhl, 2007), replicating the behavioral findings in the Mandarin study (Kuhl et al., 2003). This result confirms infants’ ability to learn phonetically from exposure to a foreign language at 9 months of age. Extending these previous findings beyond phoneme learning, Conboy and Kuhl also showed that infants learned Spanish words that were presented during the exposure sessions. When compared to Spanish words that had not been presented, infants’ ERPs to the Spanish words revealed the classic components related to known words (Conboy & Kuhl, 2007).

The social gating hypothesis was also strongly supported. Infants’ degree of social engagement—for example, the

degree to which infants alternated their visual attention between a newly presented toy and the tutor’s eyes, as opposed to simply focusing on the toy or on the tutor—predicted the degree of learning both for phonemes and for words (Conboy, Brooks, et al., 2008). In other words, the degree to which an individual infant interacted socially during the 12 language sessions predicted the degree of learning measured well after the four-week exposure was complete (Conboy, Brooks, et al., 2008). Gaze following has previously been shown to predict word learning in infants (Brooks & Meltzoff, 2008). These results show that the relationship between social interaction and language learning can be demonstrated experimentally for new learning of language material at 9 months of age. Finally, the results of the study suggest the possibility that exposure to a new language provides a cognitive enhancement. Pre- and post-exposure measures of “cognitive control”—the ability to attend selectively and inhibit prepotent responses, which has previously been shown to be enhanced in bilingual adults (Bialystok, 1999) and children (Carlson & Meltzoff, 2008)—were also obtained from the children involved in the language exposure experiments. These measures indicated that cognitive control skills are enhanced after, but not prior to, Spanish exposure, linking bilingual learning to the enhancement of particular cognitive skills (Conboy, Sommerville, & Kuhl, 2008).

In sum, ERPs provide a highly sensitive measure of learning for both phonemes and words. ERP responses to speech not only predict the growth of language over the first 30 months (Kuhl et al., 2008; Rivera-Gaxiola, Klarman, et al., 2005), but are also sufficiently sensitive to reflect the subtle abilities that contribute to infant learning, such as infants’ social eye-gaze following (Conboy, Brooks, et al., 2008). Complex natural language learning may demand social interaction, because language evolved in a social setting. The neurobiological mechanisms underlying language likely utilized interactional cues made available only in a social setting. In the future, whole-brain measures, such as those provided by MEG, will allow us to observe brain activation during live presentations of language versus those that are merely televised to explore hypotheses about why human interaction is essential to language learning (Kuhl et al., 2003). Moreover, using “social” robots, we are now conducting studies that will define what constitutes a social agent for a young child (Virnes, Cardillo, Kuhl, & Movellan, 2008).

Neural signatures of word learning

A sudden increase in vocabulary typically occurs between 18 and 24 months of age—a “vocabulary explosion” (Fernald et al., 2006; Ganger & Brent, 2004)—but word learning starts much earlier. Infants show recognition of their own

name at 4.5 months (Mandel, Jusczyk, & Pisoni, 1995). At 6 months, infants use their own names or the word *Mommy* in an utterance to identify word boundaries (Bortfeld, Morgan, Golinkoff, & Rathbun, 2005) and look appropriately to pictures of their mother or father when hearing *Mommy* or *Daddy* (Tincoff & Jusczyk, 1999). By 7 months, infants listen longer to passages containing words they previously heard rather than passages containing words they have not heard (Jusczyk & Hohne, 1997), and by 11 months infants prefer to listen to words that are highly frequent in language input over infrequent words (Halle & de Boysson-Bardies, 1994).

Behavioral studies indicate that infants learn words using both “statistical learning” strategies in which the transitional probabilities between syllables are exploited to identify likely words (Newport & Aslin, 2004; Saffran, 2003; Saffran, Aslin, & Newport, 1996) and pattern detection strategies in which infants use the typical pattern of metric stress that characterizes ambient language to segment running speech into likely words (Cutler & Norris, 1988; Höhle, Bijeljac-Babic, Herold, Weissenborn, & Nazzi, 2009; Johnson & Jusczyk, 2001; Nazzi, Iakimova, Bertoncini, Frédonie, & Alcantara, 2006).

How is word recognition evidenced in the brain? ERPs in response to words index word familiarity as early as 9 months of age and word meaning by 13–17 months of age. ERP studies have shown differences in amplitude and scalp distributions for components that are related to words that are known versus unknown to the child (Mills, Coffey-Corina, & Neville, 1993, 1997; Mills, Plunkett, Prat, & Schafer, 2005; Molfese, 1990; Molfese, Morse, & Peters, 1990; Molfese, Wetzel, & Gill, 1993; Thierry, Vihman, & Roberts, 2003).

As early as 9 months of age, ERPs indicate word familiarity, and by 13–17 months of age, studies show ERP components that reliably signal the brain’s coding of words that are known versus unknown by the child (Mills et al., 1993, 1997, 2005; Molfese et al., 1990, 1993; Thierry et al., 2003). Toddlers with larger vocabularies tend to have a more focalized and larger N200 for known words—they show an enhanced negativity to known versus unknown words only at left temporal and parietal electrode sites—whereas children with smaller vocabularies show more broadly distributed effects (Mills et al., 1993), features that also distinguish typically developing preschool children from preschool children with autism (Coffey-Corina, Padden, Kuhl, & Dawson, 2007).

Processing efficiency for phonemes and words can be seen as well in the relative focalization and duration of brain activation in adult MEG studies (Zhang, Kuhl, Imada, Kotani, & Tohkura, 2005), indicating that these features index language experience and proficiency not only in children (Conboy, Rivera-Gaxiola, et al., 2008; Friederici,

2005), but also over the life span. Individual differences in the response latency to a familiar word at the age of 2 are related to both lexical and grammatical measures collected between 15 and 25 months, providing more evidence that processing speed is associated with greater language facility (Fernald et al., 2006).

Mills and colleagues (2005) used ERPs in 20-month-old toddlers to examine new word learning. The children listened to known and unknown words, and to nonwords that were phonotactically legal in English. ERPs were recorded as the children were presented with novel objects paired with the nonwords. After the learning period, ERPs to the nonwords that had been paired with novel objects were shown to be similar to those of previously known words, suggesting that that new words may be encoded in the same neural regions as previously learned words.

ERP studies on German infants reveal the development of word-segmentation strategies based on the typical stress patterns of German words. When presented with bisyllabic strings with either a trochaic (typical in German) or iambic pattern, infants who heard a trochaic pattern embedded in an iambic string showed the N200 ERP component, similar to that elicited in response to a known word, whereas infants presented with the iambic bisyllable embedded in the trochaic pattern showed no response (Weber, Hahne, Friedrich, & Friederici, 2004). The data suggest that German infants at this age are applying a metric segmentation strategy, consistent with the behavioral data of Höhle and colleagues (2009).

Infants’ early lexicons

There is evidence suggesting that young children’s word representations are phonetically underspecified. Children’s growing lexicons must code words in a way that distinguishes words from one another, and, given that by the end of the first year infants’ phonetic skills are language specific (Best & McRoberts, 2003; Kuhl et al., 2006; Werker & Tees, 1984), it was assumed that children’s early word representations were phonetically detailed. However, studies suggest that learning new words taxes young children’s capacities, and that as a result, new word representations are not phonetically complete.

Reactions to mispronunciations—the age at which children no longer accept *tup* for *cup* or *bog* for *dog*—provides information about phonological specificity. Studies across languages suggest that by one year of age mispronunciations of common words (Fennel & Werker, 2003; Jusczyk & Aslin, 1995), words in stressed syllables (Vihman, Nakai, DePaolis, & Halle, 2004), or monosyllabic words (Swingley, 2005) are not accepted as target words, indicating well-specified representations. Other studies using visual fixation of two targets (e.g., apple and ball) while one is named (*Where’s the ball?*)

show that between 14 and 25 months children's tendencies to fixate the target item when it is mispronounced diminish over time (Bailey & Plunkett, 2002; Ballem & Plunkett 2005; Swingley & Aslin, 2000, 2002).

However, behavioral and neural evidence suggests that learning new words can tax children's phonological skills. Stager and Werker (1997) demonstrated that 14-month-old infants fail to learn new words when similar-sounding phonetic units are used to distinguish those words ("bih" and "dih"), but do learn if the two new words are distinct phonologically ("leef" and "neem"). By 17 months of age, infants can learn to associate similar-sounding nonsense words to novel objects (Bailey & Plunkett, 2002; Werker, Fennell, Corcoran, & Stager, 2002). Infants with larger vocabularies succeeded on this task even at the younger age, suggesting the possibility that infants with greater phonetic learning skills acquire new words more rapidly, consistent with studies showing that better native phonetic learning skills are associated with advanced word-learning skills (Kuhl, Conboy, et al., 2005; Kuhl et al., 2008; Rivera-Gaxiola, Klarman et al., 2005; Tsao et al., 2004).

Mills and colleagues (2004) used ERPs to corroborate these results. They compared ERP responses to familiar words that were either correctly pronounced or mispronounced, as well as nonwords. At the earliest age tested, 14 months, a negative ERP component (N200–400) distinguished known versus dissimilar nonsense words (*bear* versus *kobe*) but not known versus phonetically similar nonsense words (*bear* versus *gare*). By 20 months, this same ERP component distinguished correct pronunciations, mispronunciations, and nonwords, supporting the idea that between 14 and 20 months children's phonological representations of early words become increasingly detailed. Other evidence of early processing limitations stems from infants' failure to learn a novel word when its auditory label closely resembles a word they already know (*gall* which closely resembles *ball*), suggesting lexical competition effects (Swingley & Aslin, 2007).

How phonetic and word learning interact—and whether the progression is from phonemes to words, words to phonemes, or bidirectional—is a topic of strong interest that will be aided by the use of neuroscientific methods. Recent theoretical models of early language acquisition such as NLM-e (Kuhl et al., 2008) and PRIMER (Werker & Curtin, 2005) suggest that phonological and word learning may bidirectionally influence one another. On the one hand, infants with better phonetic learning skills advance more quickly toward language because phonetic skills assist the detection of phonotactic patterns, the detection of transitional probabilities in adjacent syllables, and the ability to phonologically distinguish minimally contrastive words (Kuhl, Conboy, et al., 2005). On the other hand, the more words children

learn, the more crowded lexical space becomes, putting pressure on children to attend to the phonetic units that distinguish them (see Swingley & Aslin, 2007, for discussion). Further studies examining both phoneme and word learning in the same children, as in the studies using exposure to a foreign language and ERP measures as assessments of learning, will help address this issue (Conboy & Kuhl, 2007).

ERP research shows that the young brain has difficulty representing phonetic detail when focused on the task of assigning a new auditory label to a novel object. ERP results also show that brain signatures distinguish words that are known from ones that are unfamiliar to toddlers. ERPs recorded to words in the first two years suggest that experience with words results in the formation of neural representations of those words that are increasingly well specified toward the end of the second year of life.

Neural signatures of early sentence processing

To understand sentences, the child must have exquisite phonological abilities that allow segmentation of the speech signal into words, and the ability to extract word meaning. In addition, the relationship among words composing the sentence—between a subject, its verb, and its accompanying object—must be deciphered to arrive at a full understanding of the sentence. Human language is based on the ability to process hierarchically structured sequences (Friederici, Fiebach, Schlesewsky, Bornkessel, & von Cramon, 2006).

Electrophysiological components have been recorded in children and contribute to our knowledge of when and how the young brain decodes syntactic and semantic information in sentences. In adults, specific neural systems process semantic versus syntactic information within sentences, and the ERP components elicited in response to syntactic and semantic anomalies are well established (figure 57.3). For example, a negative ERP wave occurring between 250 and 500 ms that peaks around 400 ms, referred to as the N400, is elicited to semantically anomalous words in sentences (Kutas, 1997). A late positive wave peaking at about 600 ms and largest at parietal sites, known as the P600, is elicited in response to syntactically anomalous words in sentences (Friederici, 2002). And a negative wave over frontal sites between 300 and 500 ms, known as the "late anterior negativity" (LAN), is elicited in response to syntactic and morphological violations (Friederici, 2002).

Beginning in the second year of life, ERP data on sentence processing in children suggest that adultlike components in response to semantic and syntactic violations can be elicited, but also that there are differences in the latencies and scalp distributions of these components in children and adults (Harris, 2001; Friederich & Friederici, 2005, 2006; Oberecker & Friederici, 2006; Oberecker, Friedrich,

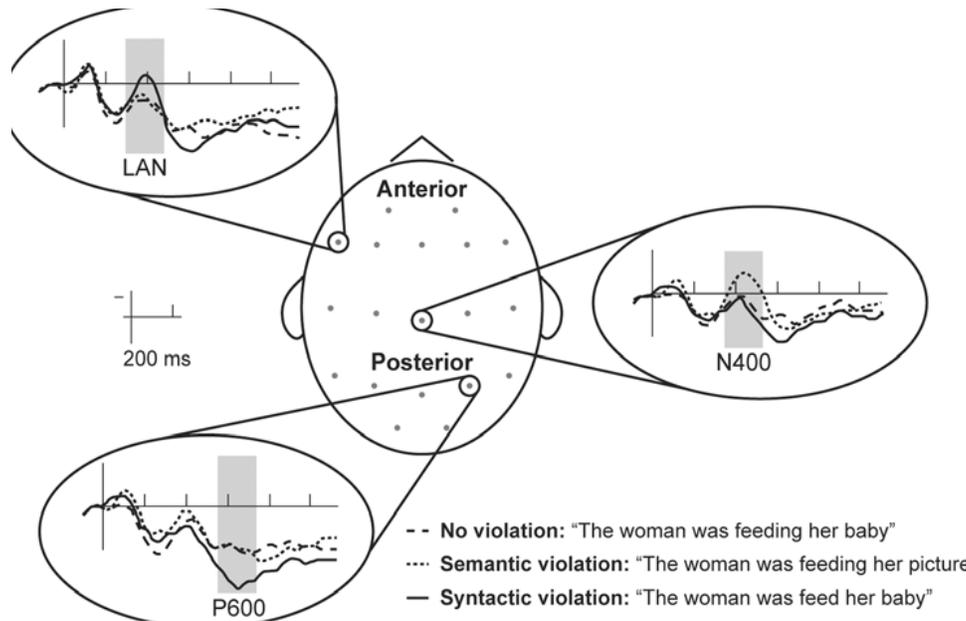

FIGURE 57.3 ERP responses to normal sentences and sentences with either semantic or syntactic anomalies show distinct distribution and polarity differences in adults. (From Kuhl & Rivera-Gaxiola, 2008.)

& Friederici, 2005; Silva-Pereyra, Conboy, Klarman, & Kuhl, 2007; Silva-Pereyra, Klarman, Lin, & Kuhl, 2005; Silva-Pereyra, Rivera-Gaxiola, & Kuhl, 2005). Holcomb, Coffey, and Neville (1992) reported the N400 in response to semantic anomaly in children from 5 years of age to adolescence; the latency of the effect was shown to decline systematically with age (see also Hahne, Eckstein, & Friederici, 2004; Neville, Coffey, Holcomb, & Tallal, 1993). Studies also show that syntactically anomalous sentences elicit the P600 in children between 7 and 13 years of age (Hahne et al.).

Recent studies have examined these ERP components in preschool children. Harris (2001) reported an N400-like effect in 36–38-month-old children, which was largest over posterior regions of both hemispheres, unlike the adult scalp distribution. Friederich and Friederici (2005) observed an N400-like wave to semantic anomalies in 19- and 24-month-old German-speaking children.

Silva-Pereyra, Rivera-Gaxiola, and Kuhl (2005) recorded ERPs in children between 36 and 48 months of age in response to semantic and syntactic anomalies. In both cases the ERP effects in children were more broadly distributed and elicited at later latencies than in adults. In work with even younger infants (30 month olds), Silva-Pereyra, Klarman, and colleagues (2005) used the same stimuli and observed late positivities distributed broadly posteriorly in response to syntactic anomalies and anterior negativities in response to semantically anomalous sentences, though in each case with longer latencies than seen in the older children and in adults (figure 57.4), a pattern seen repeatedly

and attributed to the immaturities and inefficiencies of the developing processing mechanisms.

Syntactic processing of sentences with semantic content information removed—“jabberwocky sentences”—has also been tested using ERP measures with children. Silva-Pereyra and colleagues (2007) recorded ERPs to phrase structure violations in 36-month-old children using sentences in which the content words were replaced with pseudowords while leaving grammatical function words intact. The ERP components elicited to the jabberwocky phrase-structure violations differed from the same violations in real sentences. Two negative components, one from 750 to 900 ms and the other from 950 to 1050 ms, rather than the positivities seen in response to phrase structure violations in real sentences in the same children, were observed. Jabberwocky studies with adults (Canseco-Gonzalez, 2000; Hahne & Jeschenick, 2001; Munte, Matzke, & Johannes, 1997) have also reported negative-going waves for jabberwocky sentences, though at much shorter latencies.

ERP measures of early language processing in children with autism spectrum disorder (ASD)

Scientific discoveries on the progression toward language by typically developing children are now providing new insights into the language deficit shown by children with autism spectrum disorder (ASD). Neural measures of language processing in children with autism, involving both phonemes and words, when coupled with measures of ASD children’s social interest in speech, are revealing a tight coupling

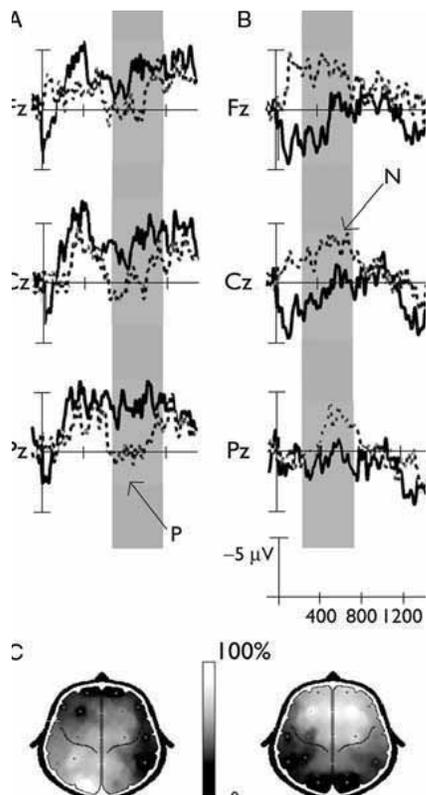

FIGURE 57.4 ERP waveforms elicited from 30-month-old children in response to sentences with (A) syntactic or (B) semantic violations. (C) Children's ERP responses resemble those of adults (see figure 57.3) but have longer latencies and are more broadly distributed. (From Silva-Pereyra, Klarman, Lin, & Kuhl, 2005.)

between social interaction skills and language acquisition. These measures hold promise as potential diagnostic markers of risk for autism in very young children, and therefore there is a great deal of excitement surrounding the application of these basic measures of speech processing in very young children with autism.

In typically developing children, ERP responses to simple speech syllables such as “pa” and “ta” predict the growth of language to the age of 30 months (Kuhl et al., 2008). It is therefore interesting to test whether ERP measures of autism at the phonetic level are sensitive to the degree of severity of autism, and also the degree to which the brain's responses to syllables can be predicted by other factors, such as a social interest in speech.

The first study of preschool-aged children with ASD using ERP methods examined phonetic perception (Kuhl, Coffey-Corina, Padden, & Dawson, 2005). ERPs to a simple change in two speech syllables, as well as a measure of social interest in speech, were taken. In these experiments, a listening choice test allowed young toddlers with autism to select between listening to motherese or nonspeech signals in which the formant frequencies of speech were matched by pure tones—the resulting signal was a computer warble

that exactly followed the frequencies and amplitudes of the 5-s speech samples over time. Slight head turns in one direction or the other allowed the toddlers to choose their preferred signal on each trial. The goal was to compare performance at the group level between typically developing children and children with ASD, as well as to examine the relationship between brain measures of speech perception and measures of social processing of speech in children with ASD.

Considering first the ERP measures of phonetic perception, the results showed that, as a group, children with ASD exhibited no MMN to the simple change in syllables. However, when children with ASD were subgrouped on the basis of their preference for infant-directed (ID) speech (often called motherese), very different results were obtained.

The results showed that while typically developing children listen to both signals, children with autism strongly preferred the nonspeech-analogue signals. Moreover, the degree to which they did so was significantly correlated with both the severity of autism symptoms, and individual children's MMN responses to speech syllables. Toddlers with ASD who preferred motherese produced MMN responses that resembled those of typically developing children, whereas those who preferred the nonspeech analogue did not show an MMN response to the change in a speech syllable.

These results underscore the importance of a social interest in speech early in development, especially an interest in motherese. Research has shown that the phonetic units in motherese are acoustically exaggerated, making them more distinct from one another (Burnham, Kitamura, & Vollmer-Conna, 2002; Englund, 2005; Kuhl et al., 1997; Liu, Kuhl, & Tsao, 2003; Liu, Tsao, & Kuhl, 2007). Infants whose mothers use the exaggerated phonetic patterns to a greater extent when talking to them show significantly better performance in phonetic discrimination tasks (Liu et al., 2003). In the absence of a listening preference for motherese, children with autism would miss the benefit these exaggerated phonetic cues provide.

Infant-directed speech also produces unique brain responses in typically developing infants. Brain measures of typical infants' response to infant-directed speech, used by Pena and colleagues (2003) in the first study using NIRS, showed more activation in left temporal areas when infants were presented with infant-directed speech as opposed to backward speech or silence. Bortfeld and colleagues (2007) obtained analogous results using NIRS in a sample of 6–9-month-old infants presented with infant-directed speech and visual stimulation. It will be of interest to examine brain activation while children with autism listen to motherese as opposed to acoustically matched nonspeech signals. In children with ASD, brain activation to carefully controlled

speech versus nonspeech signals may provide clues to their aversion to the highly intonated speech signals typical of motherese.

Recent studies extend the findings on children with autism to word processing using ERP measures (Coffey-Corina, Padden, Kuhl, & Dawson, 2008). In this study, 24 toddlers with autism spectrum disorders between 18 and 31 months of age were separated into high-functioning and low-functioning subgroups defined by the severity of their social symptoms. ERP measures were recorded in response to known words, unknown words, and words played backward. They were compared to ERPs elicited from a group of 20 typically developing toddlers between the ages of 20 and 31 months of age.

The results for typically developing toddlers showed a highly localized response to the difference between known and unknown words at a left temporal electrode site (T3) in the 200–500-ms and 500–700-ms windows (figure 57.5A). These data replicate previous data on typically developing children published by Mills and colleagues (1993) and indicate that highly focalized responses are a marker of increasing developmental sophistication in the processing of words in typically developing children. It was therefore of interest to observe that toddlers with ASD showed a very diffuse response to known and unknown words. Known words showed a greater negativity than unknown words across all electrode sites, and at a later latency than age-matched typically developing children (figure 57.5B). Both the more diffuse pattern of brain activation and responses with longer latencies are patterns observed in younger typically developing children (Mills et al., 1997).

Replicating the pattern seen in the studies of phonetic perception in children with autism, the word-processing results for children with ASD differed markedly depending on the children's social skills. High-functioning toddlers with ASD produced ERP responses that were similar to those of typically developing children—they exhibited a localized left-hemisphere response to known and unknown words. Significant word-type effects were observed only at the left parietal electrode site (P3) in the 200–500-ms time window (figure 57.5C). In contrast, ERP waveforms of low-functioning toddlers with ASD exhibited a diffuse response to words. Known words were significantly more negative than unknown words at multiple electrode sites and in all measurement windows (figure 57.5D).

The idea that ERP measures in response to syllables and words may allow us to predict future language outcomes in young children with ASD is exciting. Toward that end, we note that children with ASD exhibited highly significant correlations between their ERP components at the initial test time and their verbal IQ scores measured one year after ERP data collection (figure 57.6).

In new studies with the siblings of children with autism spectrum disorder, we are now exploring whether these early brain and behavioral responses to syllables, and listening preferences for speech, are diagnostic markers for autism. The interest in these measures is that they can be used reliably in infants as early as 6 months of age, an age at which intervention measures might be more effective in changing the course of development for children at risk for autism.

Mirror neurons and shared brain systems

Neuroscience studies that focus on shared neural systems for perception and action have a long tradition in speech research (Fowler, 2006; Liberman & Mattingly, 1985). The discovery of *mirror neurons* for social cognition (Gallese 2003; Meltzoff & Decety, 2003; Pulvermuller, 2005; Rizzolatti, 2005; Rizzolatti & Craighero, 2004) has reinvigorated this tradition. Neuroscience studies using speech and whole-brain imaging techniques have the capacity to examine the origins of shared brain systems in infants from birth (Bosseler et al., 2008; Imada et al., 2006).

In speech, the theoretical linkage between perception and action came in the form of the original *motor theory* (Liberman, Cooper, Shankweiler, & Studdert-Kennedy, 1967) and in a different formulation of the direct perception of gestures, named *direct realism* (Fowler, 1986). Both posited close interaction between perception and speech production. The perception-action link for speech was viewed as innate by the original motor theorists (Liberman & Mattingly, 1985). Alternatively, it was viewed as forged early in development through experience with speech motor movements and their auditory consequences (Kuhl & Meltzoff, 1982, 1996). Two new infant studies have shed some light on the developmental issue.

Imada and colleagues (2006) used magnetoencephalography (MEG), studying newborns, 6-month-old infants, and 12-month-old infants while they listened to nonspeech signals, harmonics, and syllables (figure 57.7). Dehaene-Lambertz and colleagues (2006) used fMRI to scan 3-month-old infants while they listened to sentences. Both studies show activation in brain areas responsible for speech production (the inferior frontal, Broca's area) in response to auditorally presented speech. Imada and colleagues reported synchronized activation in response to speech in auditory and motor areas at 6 and 12 months, and Dehaene-Lambertz and colleagues reported activation in motor speech areas in response to sentences in 3-month-olds.

Is activation of Broca's area to the pure perception of speech present at birth? Newborns tested by Imada and colleagues showed no activation in motor speech areas for any signals, whereas auditory areas responded robustly to all signals, suggesting the possibility that perception-action

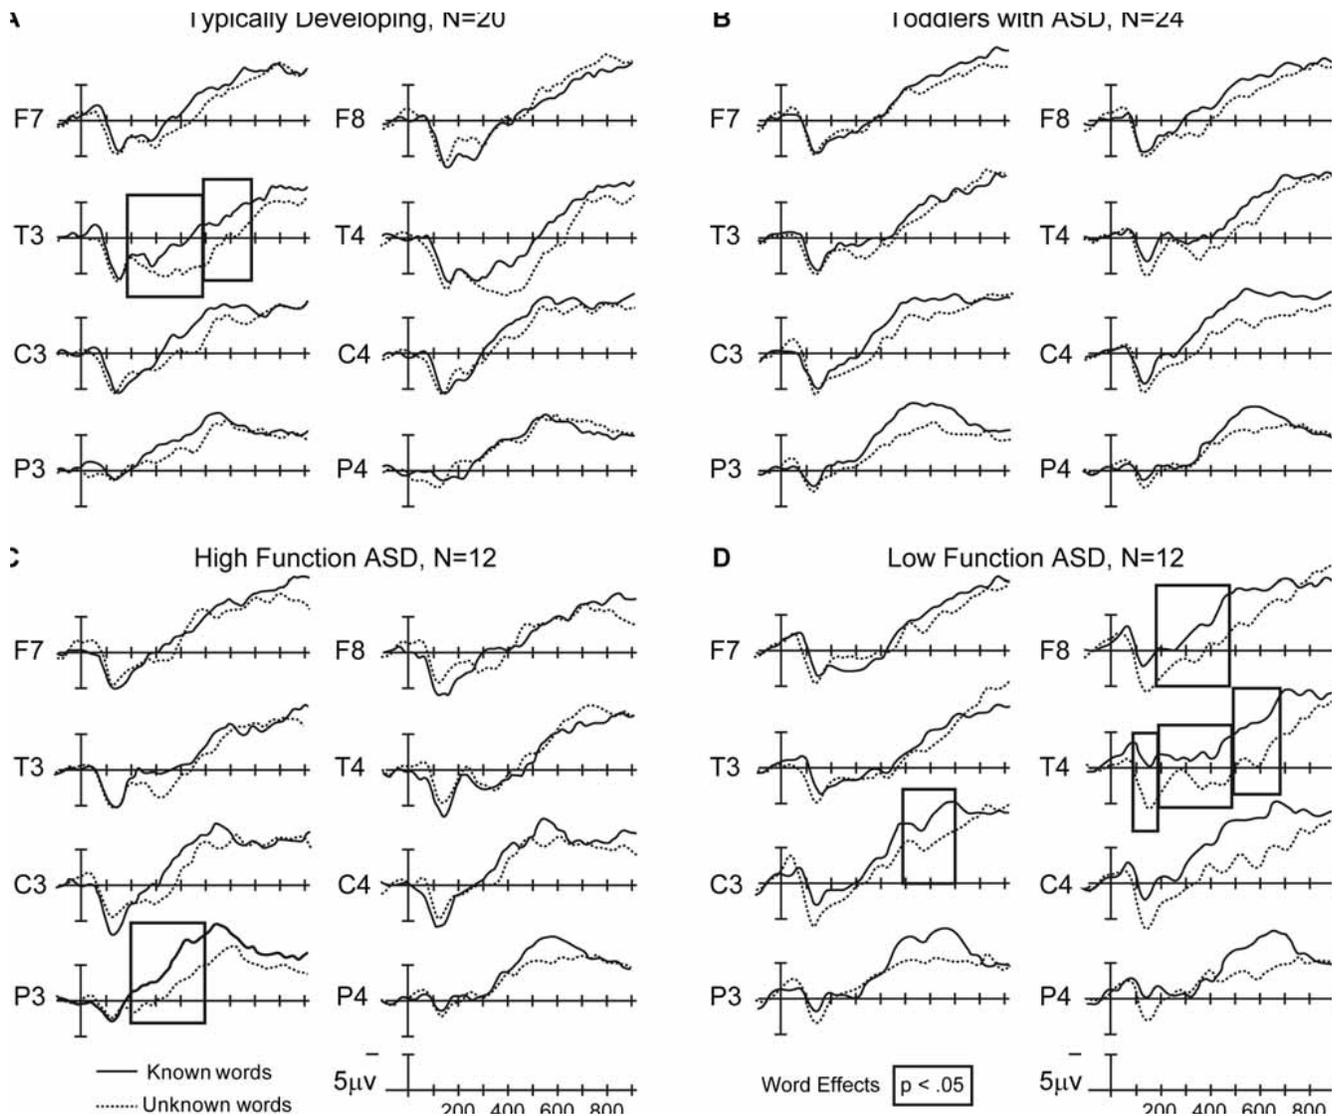

FIGURE 57.5 Group data showing ERP waveforms for (A) typically developing toddlers and (B) toddlers with autism spectrum disorder. TD toddlers exhibit a localized response with significant differences between known and unknown words at the left temporal electrode site (T3). Toddlers with ASD exhibit a diffuse response to known and unknown words, but the differences are significant across all electrode sites in the 500–700-ms measurement window. (C) Subgroup analysis shows that ERP waveforms for high-functioning toddlers with ASD exhibit a localized response

with significant differences between known and unknown words at a parietal electrode site in the left hemisphere (P3), similar to typically developing children. (D) Low-functioning toddlers with ASD exhibit a diffuse response to known and unknown words with significant differences in multiple time windows and electrode sites, and a significant effect when collapsed across all electrode sites in the 500–700-ms measurement window. (From Coffey-Corina, Padden, Kuhl, & Dawson, 2008.)

linkages for speech develop by 3 months of age as infants produce vowel-like sounds. But further work must be done to answer the question. How the binding of perception and action takes place, and whether it requires experience, is one of the exciting questions that can now be addressed with infants from birth using the tools of modern neuroscience.

We now know a great deal about the linkages and the circuitry underlying language processing in adults (Kuhl & Damasio, in press). What is unknown, but waiting to be discovered, is the state of this circuitry at birth and how refined

connections are forged in early infancy as perception and action are jointly experienced.

Bilingual infants: two languages, one brain

One of the most interesting questions is how infants map two distinct languages in the brain. From phonemes to words, and then to sentences, how do infants simultaneously bathed in two languages develop the neural networks necessary to respond in a nativelike manner to two different codes?

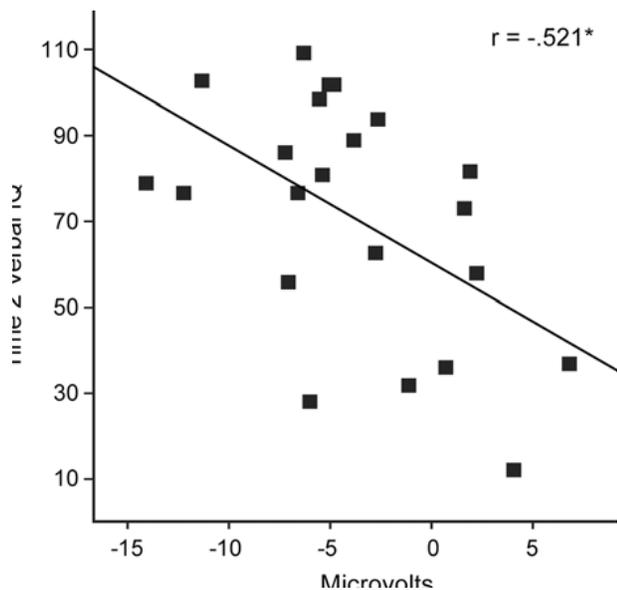

FIGURE 57.6 Predictive correlations for children with ASD between the mean amplitude of ERPs to known words at the left parietal electrode site (P3) and verbal IQ measured one year later. A more negative response predicted significantly higher verbal IQ ($r = -.521$, $p = .013$). (From Coffey-Corina, Padden, Kuhl, & Dawson, 2008.)

Bilingual language experience could potentially have an impact on development—because the learning process requires the development of two codes and because it could take a longer period of time for sufficient data from both languages to be experienced than in the monolingual case. Infants learning two first languages simultaneously might reach the developmental change in perception at a later point in development than infants learning either language monolingually. This difference could depend on such factors as the number of people in the infants’ environment producing the two languages in speech directed toward the child and the amount of input they provide. These factors could change the rate of development in bilingual infants.

There are very few studies that address this question thus far, and the data that do exist provide somewhat mixed results. Some studies suggest that infants exposed to two languages show later acquisition of phonetic skills in the two languages when compared to monolingual infants (Bosch & Sebastian-Galles, 2003a, 2003b). This is especially the case when infants are tested on contrasts that are phonemic in only one of the two languages; this has been shown both for vowels (Bosch & Sebastian-Galles, 2003b) and consonants (Bosch & Sebastian-Galles, 2003a). However, other studies report no change in the timing of the developmental transition in phonetic skills in the two languages of bilingual infants (Burns, Yoshida, Hill, & Werker, 2007; Sundara, Polka, & Molnar, 2008). For example, Sundara and colleagues, testing monolingual English and monolingual French as well as

bilingual French-English infants, examined discrimination of dental (French) and alveolar (English) consonants. They demonstrated that at 6–8 months, infants in all three language groups succeeded; at 10–12 months, monolingual English infants and French-English bilingual infants, but not monolingual French infants, distinguished the English contrast. Thus bilingual infants performed on par with their English monolingual peers and better than their French monolingual peers. Moreover, data from an ERP study of Spanish-English bilingual infants show that, at both 6–9 and 9–12 months of age, bilingual infants show MMN responses to both Spanish and English phonetic contrasts (Rivera-Gaxiola & Romo, 2006), distinguishing them from English-learning monolingual infants who fail to respond to the Spanish contrast at the later age (Rivera-Gaxiola, Silva-Pereyra, et al., 2005).

ERP studies on word development in bilingual children have just begun to appear. Conboy and Mills (2006) recorded ERPs to known and unknown English and Spanish words in bilingual children at 19–22 months. Expressive vocabulary sizes were obtained in both English and Spanish, and were used to determine language dominance for each child. A conceptual vocabulary score was calculated by summing the total number of words in both languages and then subtracting the number of times a pair of conceptually equivalent words (e.g., “*water*” and “*agua*”) occurred in the two languages.

ERP differences to known and unknown words in the dominant language occurred as early as 200–400 and 400–600 ms in these 19–22-month-old infants, and were broadly distributed over the left and right hemispheres, resembling patterns observed in younger (13–17-month-old) monolingual children (Mills et al., 1997). In the nondominant language of the same children, these differences were not apparent until late in the waveform, from 600 to 900 ms. Moreover, children with high versus low conceptual vocabulary scores produced greater responses to known words in the left hemisphere, particularly for the dominant language (Conboy & Mills, 2006).

Research has just begun to explore the nature of the bilingual brain, and it is one of the areas in which neuroscience techniques will be of strong interest. Using whole-brain imaging, we may be able to understand whether learning a second language at different ages—in infancy as opposed to adulthood—recruits different brain structures. These kinds of data may play a role in our eventual understanding of the “critical period” for language learning.

Conclusions

Knowledge of infant language acquisition is now beginning to reap benefits from information obtained by experiments that directly examine the human brain’s response to

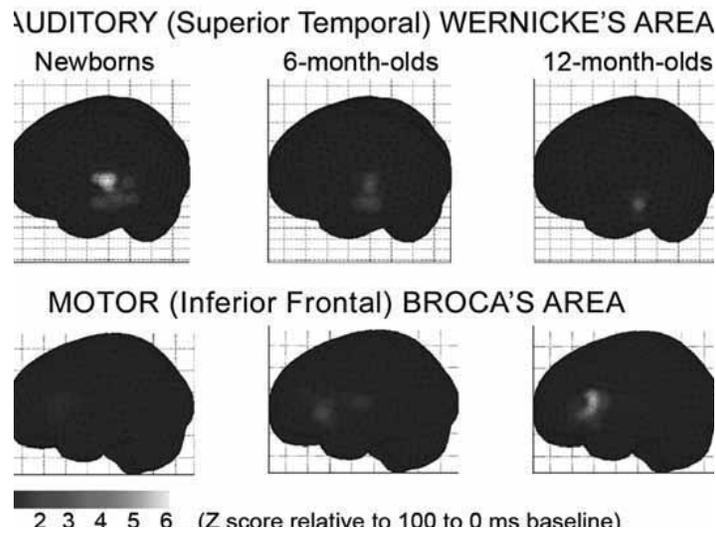

FIGURE 57.7 Neuromagnetic signals were recorded using MEG in newborns, 6-month-old infants, and 12-month-old infants while listening to speech (shown) and nonspeech auditory signals. Brain activation recorded in auditory (*top row*) and motor (*bottom row*) brain regions revealed no activation in the motor speech areas in the

newborn in response to auditory syllables. However, activation increased in the motor areas in response to speech (but not nonspeech) in 6- and 12-month-old infants that was temporally synchronized between the auditory and motor brain regions. (From Imada et al., 2006.) (See color plate 74.)

linguistic material as a function of experience. EEG, MEG, fMRI, and NIRS technologies—all safe, noninvasive, and proven feasible—are now being used in studies with very young infants, including newborns, as they listen to the phonetic units, words, and sentences of a specific language. Brain measures now document the neural signatures of learning as early as 7 months for native-language phonemes, 9 months for familiar words, and 30 months for semantic and syntactic anomalies in sentences. Studies show continuity from the earliest phases of language learning in infancy to the complex processing evidenced at the age of three when all typically developing children show the ability to carry on a sophisticated conversation. Individual variation in language-specific processing at the phonetic level—at the cusp of the transition from Phase 1, in which all phonetic contrasts are discriminated, to Phase 2, in which infants focus on the distinctions relevant to their native language—is strongly linked to infants’ abilities to process words and sentences two years later. This finding is important theoretically but is also vital to the eventual use of these early speech

precursors to diagnose children with developmental disabilities that involve language. In fact, new studies suggest the possibility that early measures of the brain’s responses to speech may provide a diagnostic marker for autism spectrum disorder. The fact that language experience affects brain processing of both the signals being learned (native patterns) and the signals to which the infant is not exposed (nonnative patterns) may play a role in our understanding of the brain mechanisms underlying the critical period. At the phonetic level, the data suggest that learning itself, not merely time, may contribute to the critical-period phenomenon. Whole-brain imaging now allows us to examine multiple brain areas during speech processing, including both auditory and motor brain regions, revealing the possible existence of a shared brain system (a “mirror” system) for speech. Research has also begun to use these measures to understand how the bilingual brain maps two distinct languages. Answers to the classic questions about the unique human capacity to acquire language will be enriched by studies that utilize the tools of modern neuroscience to peer into the infant brain.

58 Genetics of Language

FRANCK RAMUS AND SIMON E. FISHER

ABSTRACT It has long been hypothesized that the human faculty to acquire a language is in some way encoded in our genetic program. However, only recently has genetic evidence been available to begin to substantiate the presumed genetic basis of language. Here we review the first data from molecular genetic studies showing association between gene variants and language disorders (specific language impairment, speech sound disorder, developmental dyslexia), we discuss the biological function of these genes, and we further speculate on the more general question of how the human genome builds a brain that can learn a language.

Since the beginning of the cognitive revolution, it has been hypothesized that the human faculty to acquire a language is “innate,” that is, part of our species’ biological makeup and, therefore, encoded in some way in our genetic program (Chomsky, 1959). Over the years, a wide variety of arguments have been advanced in support of this view: the universality of some properties of human languages (Chomsky, 1957), the “poverty of the stimulus” available for language acquisition (Chomsky, 1965), the spontaneous emergence of languages (Bickerton, 1984; Goldin-Meadow & Mylander, 1998), biological adaptations such as that of the vocal tract (Lenneberg, 1967), the existence of inherited disorders that may specifically affect language (Gopnik & Crago, 1991), the heritability of language abilities and disorders (Stromswold, 2001), the adaptiveness of language as a communication system (Pinker & Bloom, 1990), and the plausibility of a gradual evolution of the language faculty (Jackendoff, 1999) (on the special topic of language evolution, see chapter 59 in this volume by W. Tecumseh Fitch).

Although the evidence gathered in the last decades in favor of a biological basis of language looks convincing to many scientists, until recently genetic evidence has remained relatively indirect, in the sense that it has not addressed the fundamental questions: If there is a genetic basis for language, then what exactly is there in the human genome that is different from other species and that gives us language? How does it build a brain that can learn a human language?

There is no easy way to obtain a direct answer to these fascinating questions. Genetic differences between species

are only beginning to be systematically searched, and the many differences that are found are not straightforwardly identifiable as associated with language (Fisher & Marcus, 2006). However, part of the answer will likely come from addressing a related but different question: What human genetic variations are associated with variations in the ability to learn a language? Indeed, most genetic methods rely on detecting correlations between variations in the genotype and variations in the phenotype. The capacity to acquire spoken language is usually treated as a universal characteristic of our species. Nevertheless, like many other traits, the language abilities that are observed in the human population vary along a normal distribution. Cases in the lower end of the distribution (“disorders”) are typically the most informative, as they may highlight causal relationships between genes, brain, and cognition that are often not readily apparent in normal development. Indeed, disorders of language acquisition have so far provided almost all the available data on language genetics. Furthermore, developmental language disorders are diverse, affecting different aspects of language, therefore promising to illuminate putative genetic influences on particular components of language (phonology, morphology, syntax, articulation . . .). Accordingly, this chapter reviews the genetic data gathered on the various types of language-related disorders (specific language impairment, speech sound disorder, developmental dyslexia . . .) and reflects on what they teach us about the genetic basis of language.

Evidence for genetic influences on language

Historically, the first hint at a genetic influence on language abilities came from the observation that language-related disorders tend to run in families (Hallgren, 1950; Morley, 1967; Stephenson, 1907; Tallal et al., 2001): when one person has language problems, the risk in first-degree relatives is around 50%, far above the normal population prevalence. Although the inheritance pattern in many families may appear consistent with autosomal dominant transmission (e.g., the transmission of a dominant gene variant carried by a nonsexual chromosome), this observation is not sufficient to prove genetic involvement, as members of a family share not only genes but also a linguistic environment. It is conceivable that parents with a language disorder would constitute a less favorable environment for the acquisition of

language by their children, so studies of familial clustering inevitably confound genetic and nongenetic (shared environmental) factors.

Twin and adoption studies are the usual method to try and disentangle genetic and environmental factors. In the most classic twin studies, one compares the concordance of a given disorder (i.e., the probability that the disorder, when present in one twin, is present in the other one) between monozygotic (MZ) and dizygotic (DZ) twins.¹ For instance, in a meta-analysis of twin studies by Stromswold (2001), the concordance of spoken language disorders was found to be around 84% for MZ twins and 48% for DZ twins. Both figures are far above the typical prevalence of spoken language disorders (1–3%), and the substantial difference between MZ and DZ twins can largely be attributed to differences in their genetic similarity. Such concordance measures thus allow estimation of heritability, that is, the proportion of phenotypic variance that can be attributed to genetic variance. Although diagnostic criteria and precise definition of disorder have varied from one twin study to the next, Stromswold's review of the published research estimated heritabilities of 70% for spoken language disorders and 64% for written language disorders (dyslexia). These estimates have not been significantly challenged, either by more recent studies or by adoption studies that rely on slightly different assumptions (Felsenfeld & Plomin, 1997).

Beyond the categorical classification of individuals as having a disorder or not, the same approach can be generalized to any quantitative measure of language abilities (e.g., vocabulary, syntactic or morphological abilities . . .). Then the correlation of quantitative scores (rather than the concordance of disorders) between twins can be compared between MZ and DZ twins, revealing again higher correlations for the former than for the latter, hence a significant heritability of these scores. One advantage of this approach is that, since it does not require twins to have a disorder, it opens the possibility of assessing genetic influences on variations in normal language abilities as well as on more pathological variations. It turns out that the heritability of normal language abilities is typically lower than that of disorders, yet it remains significantly above zero (Colledge et al., 2002; Stromswold, 2001).

Furthermore, quantitative genetic analyses also lend themselves to investigations of specific components of language. As an example, in a recent study including twin pairs with or without language disorders, the heritability of deficits in various language tests varied depending on whether they tapped primarily phonological short-term memory (61%), morphology (74%), syntax (82%), or vocabulary (1%) (Bishop, Adams, & Norbury, 2006). It is also possible to analyze to what extent the covariance between two phenotypic variables is itself due to genetic and to nongenetic variance. It is generally found that most cognitive abilities are correlated

and share genetic variance (Oliver & Plomin, 2007). Nevertheless, it is not the case that all cognitive variables share a single genetic source of variance. For instance, in the study by Bishop and colleagues, morphological and syntactic abilities shared a substantial amount of genetic variance (around 40%), but these abilities in turn did not seem to share much genetic variance with phonological abilities. This finding raises the possibility that certain genetic factors might influence differentially the components of language.

There have been huge debates around twin studies and their implications (Gould & Lewontin, 1979; Joseph, 2002). Their assumptions have been questioned, and their heritability estimates have been argued to be inflated. The fact is that there is no “true” value for heritability; this depends on the particular population considered and on the range of genetic and environmental variance that it presents. Nevertheless, absolute heritability estimates do not matter much. Twin and adoption studies have established beyond reasonable doubt that there are significant genetic influences on cognitive performance and on language disorders in particular. The more important matter now is to identify those genetic factors and understand how they exert their effects. The fact that this approach is now bearing fruit provides a post hoc confirmation of heritability.

A series of progressive advances in molecular biology, culminating with the sequencing of the human genome, now make it possible to carry out the appropriate empirical investigations. Several types of approaches can provide relevant data on language genetics, such as the following:

- Linkage studies, carried out on families, typically analyze which chromosomal regions have genetic markers that are inherited more frequently in family members with a language disorder than in those without. The “linked” chromosomal regions may still contain hundreds of genes, many with unknown function, but they help restrict the search space for association studies.

- Association studies look for gene variants that occur more often in affected than in control individuals, usually at the population level. They can lead to identification of an allele of a gene that increases significantly the risk of developing the disorder. In the case of disorders that are common in the population (like specific language impairment, or SLI, and dyslexia), such alleles may be relatively frequent, also appearing in unaffected individuals. These common alleles may have only subtle effects on gene function, such as reducing the amount of a particular protein that is made.

- Occasionally, sequencing of candidate genes in some families can identify rare mutations that co-occur with the disorder and that severely interfere with the function of the gene in question.

- Comparative studies look for a homologous form of a candidate gene in other species. They typically find one

(at least in mammals). They can then analyze the similarity between the sequences in the various species and attempt to reconstitute the evolutionary history of the specific gene variants that have appeared in the human lineage. Moreover, prior knowledge of the gene's function in other species can give the first clues to its role in humans.

- Expression studies investigate the expression pattern of the candidate gene (where and when the protein is synthesized) as another important clue to its function.

- Many other approaches may be used to further investigate the function of a candidate gene: detection of familiar parts in the sequence and comparison with other, similar genes, algorithmic predictions of the shape of the protein, in vitro experiments to study the mechanisms of action of the target protein and its interactions with other molecules, in vivo experiments to study the effects of disrupting its expression, particularly on brain development and function, and so on.

We now turn to the specific results obtained on the different forms of language disorders.

Developmental dyslexia

Developmental dyslexia is by definition a disorder of reading and spelling acquisition, despite adequate intelligence and opportunity, and in the absence of obvious sensory, neurological, or psychiatric disorder. Nevertheless, it has been well established over the last three decades that most cases of dyslexia can be attributed to a subtle disorder of oral language (the "phonological deficit"),² whose symptoms happen to surface most prominently in reading acquisition (Lyon, Shaywitz, & Shaywitz, 2003; Ramus, 2003; Snowling, 2000). Therefore dyslexia is expected to ultimately reveal something about genetic factors implicated in language, in particular in phonology. However, both the exact nature of the phonological deficit and its underlying cognitive/neural causes remain unclear.

Indeed, the main symptoms of the "phonological deficit in dyslexia" are poor phonological awareness (the ability to pay attention to and explicitly manipulate speech sounds), poor verbal short-term memory, and slow lexical retrieval (evidenced in rapid naming tasks where subjects must name series of objects, colors, or digits in quick succession). This diversity of impairments has led many researchers to hypothesize that dyslexics' phonological representations are somewhat degraded, fuzzy, or noisy, lacking either in temporal or spectral resolution, or insufficiently attuned to the categories of the native language. This degradation is assumed either to be specific to the speech-processing system (Adlard & Hazan, 1998; Serniclaes, Van Heghe, Mousty, Carré, & Sprenger-Charolles, 2004; Snowling, 2000) or to follow from a lower-level auditory deficit (Goswami et al., 2002; Tallal,

1980). The latter view has been much challenged in recent years (Ramus, 2003; S. Rosen, 2003; S. White, Frith, et al., 2006; S. White, Milne, et al., 2006). As will become apparent later, the neurobiological and genetic data are consistent with the view that an auditory disorder is not necessary to engender a phonological deficit in people with dyslexia (Ramus, 2004). An alternative view is that phonological representations in dyslexia are intrinsically normal and that the observed difficulties in certain (but not all) phonological tasks arise from a deficit in the access to these representations that is particularly recruited for short-term memory and conscious manipulations (Marshall, Harcourt-Brown, Ramus, & van der Lely, submitted; Ramus & Szenkovits, 2008; Szenkovits, Darma, Darcy, & Ramus, submitted). The elucidation of the precise nature of the phonological deficit will therefore determine whether dyslexia can inform us on the links between genes and phonology per se, or rather between genes and some cognitive processes operating on phonological representations.

In the 1970s, Galaburda and colleagues began to dissect human brains whose medical records indicated a diagnosis of developmental dyslexia (Galaburda & Kemper, 1979). After dissecting four consecutive brains and finding evidence for abnormalities of neuronal migration in all four, they hypothesized that this was unlikely to occur by chance and that such brain development aberrations might provide an explanation of dyslexia (Galaburda, Sherman, Rosen, Aboitiz, & Geschwind, 1985). Most interestingly, neuronal migration disruptions were found predominantly in left perisylvian areas traditionally associated with language. More specifically, these areas are the left inferior frontal, posterior superior temporal, and supramarginal and angular gyri. Galaburda and colleagues subsequently confirmed these findings in three more brains (Humphreys, Kaufmann, & Galaburda, 1990), as well as the rarity of such abnormalities in control brains (Kaufmann & Galaburda, 1989). Unfortunately, no attempt at an independent replication was ever published, so the dyslexia research community came to consider these findings as intriguing but inconclusive. Nevertheless, brain-imaging studies have largely confirmed structural and functional abnormalities in dyslexics' left perisylvian areas, although at a different level of description. Findings from MRI studies typically consist of reduced gray matter density, reduced anisotropy of the underlying white matter, and hypo- or hyperactivations (Démonet, Taylor, & Chaix, 2004; Eckert, 2004; Temple, 2002). At the moment it is impossible to establish their relationship with putative perturbations of neuronal migration, which are not visible in MRI scans. Quite strikingly, new results emerging from genetic studies suggest a reappraisal of the old neuronal migration hypothesis.

Until recently, linkage studies had provided at least six reliable chromosomal loci suspected to harbor genes

associated with dyslexia, on chromosomes 1, 2, 3, 6, 15, and 18 (Fisher & DeFries, 2002; Grigorenko, 2003). Now six genes showing association with dyslexia have been identified in some of these loci: *DYX1C1* on 15q21 (Taipale et al., 2003), *KIAA0319* on 6p22 (Cope et al., 2005; Paracchini et al., 2006), *DCDC2* a nearby gene also on 6p22 (Meng et al., 2005), *ROBO1* on 3p12 (Hannula-Jouppi et al., 2005), and *MRPL19* and *C2ORF3* on 2p12 (Anthoni et al., 2007). The association of variants in *KIAA0319* and *DCDC2* with dyslexia has been replicated in at least some independent studies (Harold et al., 2006; Schumacher et al., 2005).

For two of these genes (*DYX1C1* and *ROBO1*), mutations, chromosomal rearrangements, or at least rare patterns of alleles (haplotypes) have been found in the dyslexic members of some isolated families, but these changes are too rare to play a significant role in explaining dyslexia in general. As yet, there is little evidence that more common variants of these genes modulate the susceptibility to dyslexia in the general population (Bellini et al., 2005; Brkanac et al., 2007; Marino et al., 2005; Meng et al., 2005; Scerri et al., 2004; Wigg et al., 2004). As far as the other genes are concerned, the associated variants are alleles that are relatively frequent in the population. Thus the mere possession of such a susceptibility allele is not a necessary and sufficient condition to cause dyslexia. Rather, it increases the probability of developing the disorder. Therefore, as predicted by earlier research (Fisher & DeFries, 2002), it seems that the most common cases of dyslexia belong to the family of “complex genetic diseases” (like diabetes, heart disease, and certain cancers), where multiple genetic factors intervene, interact with each other, and interact with environmental factors, thereby modulating the susceptibility to the disorder. Rather than altering the amino-acid sequence of the protein, such susceptibility alleles typically produce more subtle effects, altering quantitatively the expression of the protein (Hannula-Jouppi et al., 2005; Meng et al., 2005) or the way that this is regulated. Follow-up investigations are necessary to pin down the precise functional role of putative risk alleles by studying more directly the structure of the encoded protein and its subdomains (Tapia-Paez, Tammimies, Massinen, Roy, & Kere, 2008; Velayos-Baeza, Toma, da Roza, Paracchini, & Monaco, 2007; Velayos-Baeza, Toma, Paracchini, & Monaco, 2008), as well as its expression patterns across the cortex and at different stages of brain development. It turns out that genes associated with dyslexia are highly (although not exclusively) expressed in the brain, in the cerebral cortex, and particularly so during fetal development (Fisher & Francks, 2006; Meng et al., 2005; Paracchini, Scerri, & Monaco, 2007).

On top of these relatively classic functional studies, LoTurco and colleagues have used a particularly innovative technique to study the role of three of these genes in brain development (Bai et al., 2003). They have produced

“functional knockout” rats using *in vivo* RNA interference. This technique allowed them to specifically block the translation of the gene of interest, *in vivo*, locally, and at a chosen stage of development (indeed, *in utero* during neuronal migration). Using this technique, they showed that *DYX1C1* is involved in radial neuronal migration and that the part of the protein that is truncated in a Finnish dyslexic family (Taipale et al., 2003) is necessary and sufficient for normal neuronal migration (Wang et al., 2006). They have further shown that cortical ectopias (like the ones observed in dyslexic brains) sometimes occur as a result of the *DYX1C1*-induced disruption of neuronal migration, and that more generally the laminar organization is locally disrupted, with a distribution of neurons skewed in favor of layers I and II as well as toward the white matter (G. Rosen et al., 2007). The same team has been able to conduct similar studies on both *DCDC2* (Burbridge et al., 2008; Meng et al., 2005) and *KIAA0319* (Paracchini et al., 2006), again concluding that these genes are likely to be crucial for neuronal migration and the laminar organization of the cortex. Finally, *ROBO1* is a homologue of a well-known *Drosophila* gene that is involved in interhemispheric axon guidance and in the migration of cortical interneurons (Andrews et al., 2008; Lopez-Bendito et al., 2007).

A gene will often play multiple roles depending on cellular/developmental context and can be involved in many different processes, but it is striking that functional links to neuronal migration have been uncovered for each of the candidate genes we have described. It would seem a priori highly unlikely that the first four genes associated with developmental dyslexia should all be implicated in this particular aspect of neurodevelopment. The fact that they are suggests that there is indeed a real link between disturbances of neuronal migration and dyslexia, at least in a significant proportion of cases. Thus, 20 years after the first postmortem studies, the emerging genetic findings are remarkably consistent with the original hypothesis of Galaburda and colleagues (Ramus, 2006a), suggesting a relatively coherent account of the etiology of dyslexia, which can be summarized as follows. Certain variants (alleles or mutations) of particular genes increase the susceptibility to disruptions of neuronal migration, sometimes engendering ectopias or microgyri but, most importantly, locally disrupting the laminar organization of the cortex. Through mechanisms that are not yet understood, these disruptions may, in certain individuals, accumulate in left perisylvian areas that are involved in speech processing and phonology, and that are later recruited for reading acquisition. The disruption of these areas also surfaces more macroscopically in the MRI in the form of reduced gray matter density and reduced anisotropy of the underlying white matter. It engenders subtle deficits of phonological abilities that may have little consequence on the acquisition of oral language, but mani-

fest most remarkably during the acquisition of written language, which recruits those abilities particularly intensively (Galaburda, LoTurco, Ramus, Fitch, & Rosen, 2006; Ramus, 2004). There may be alternative neurogenetic pathways that lead to dyslexia and that remain to be uncovered. However, the convergence of data from multiple lines of investigation makes this neuronal migration model particularly compelling as at least one highly testable account of dyslexia etiology.

Specific language impairment

Specific language impairment (SLI) is a disorder of language acquisition that can be attributed neither to mental retardation, nor to other known pathologies (autism, brain lesion, epilepsy, deafness . . .), nor to environmental deprivation or disadvantage. Children with SLI show heterogeneous profiles, but typically have their language development delayed, with reduced vocabulary, reduced expression and/or comprehension abilities, reduced verbal short-term memory, and persistent production of ungrammatical patterns affecting both syntax (sentence structure) and morphology (e.g., verb inflections, gender, plural or case marking) (Leonard, 1998).

At a cognitive level, the most straightforward hypothesis is that children with SLI have deficits in one or several components of language, including syntax, morphology, phonology, the lexicon, and their interfaces (van der Lely, 2005). The precise combination of deficits in a given child, plus the interaction between different language abilities throughout development, would produce the particular cognitive profile presented by the child. An alternative view is that linguistic deficits arise either from a perceptual (auditory) deficit (Tallal & Gaab, 2006; Tallal & Piercy, 1973) or from a more general cognitive deficit (Leonard, 1998; Tomblin & Pandich, 1999). Again, this debate is quite controversial and goes well beyond the present chapter, so we refer the reader to the appropriate literature (Bishop, Adams, Nation, & Rosen, 2005; Ramus, 2004; S. Rosen, 2003; Tallal, 2004; Tallal & Gaab, 2006; van der Lely, 2005; van der Lely, Rosen, & Adlard, 2004; van der Lely, Rosen, & McClelland, 1998). For the purpose of the present discussion, while leaving the precise nature of impairments open, we assume that deficits can have differential impacts on aspects of language. As we will see, this view is at least consistent with the available neurobiological and genetic data.

The overall picture provided by neurobiological data, although far from being clear and consistent, is that loosely defined language-related brain areas are disrupted or differently organized in children with SLI. The most frequent MRI findings have concerned asymmetries between left and right perisylvian areas. The inferior frontal gyrus (IFG; Broca's area) and the planum temporale, generally found to

be larger on the left than on the right, show a reduced or reversed asymmetry in people with SLI (De Fossé et al., 2004; Gauger, Lombardino, & Leonard, 1997; Plante, Swisher, Vance, & Rapcsak, 1991). An extra sulcus in the left IFG has also been reported in some individuals with SLI (Clark & Plante, 1998). In addition, it has been suggested that children with SLI present a broader pattern of deviant asymmetries, again in favor of the right hemisphere on average (Herbert et al., 2005). Affected children have also been shown to have a larger total brain volume, as a result of a substantial increase in white matter volume, while the cerebral cortex and the caudate nucleus are relatively smaller (Herbert et al., 2003). Finally, it should be noted that in Galaburda's dissection studies, three to four of the seven patients showed, on top of dyslexia, some form of language delay or disorder (Galaburda et al., 1985; Humphreys et al., 1990). Therefore it is not impossible that the same set of neuronal migration disruptions, perhaps located slightly differently, might lie at the heart of SLI as well as of dyslexia (Ramus, 2004, 2006b). However, there is no direct evidence for that in the case of SLI.

At the genetic level, thus far the search for genes associated with SLI has been less successful than for dyslexia. Nevertheless, there are quite a few interesting results to mention. Familial transmission of language disorders is widely reported, and one study has also reported that atypical perisylvian asymmetry patterns can be found in the relatives of children with SLI (Plante, 1991), suggesting that the transmission of neuroanatomical phenotypes underlies that of behavioral phenotypes. Twin studies also have applications beyond simple heritability estimations. Analyzing correlations between the performance of one twin in a given test and the other twin in a different test allows one to estimate whether the same sources of genetic variance underlie both capacities. One study thus found that syntactic and morphological abilities (typically measured, in English, by the ability to form the past tense of verbs) share some of their genetic variance, but phonological short-term memory and morphological abilities do not (Bishop et al., 2006). This finding suggests that some genetic factors may have differential effects on distinct aspects of language. In a similar vein, another study of children with SLI found that deficits in phonological tests (nonword repetition) are highly heritable, while impairments on a popular auditory processing test do not show significant evidence of genetic influence (Bishop et al., 1999). This finding casts further doubt on the idea that language and phonological deficits necessarily originate from low-level perception.

Finally, genomewide linkage studies of SLI have converged on three main linkage sites: one named SLI1 on chromosome 16, another named SLI2 on chromosome 19 (SLI Consortium, 2002, 2004), and a third one on chromosome 13 (Bartlett et al., 2003, 2002). So far no candidate gene
