CONTENTS

Preface xv

I DEVELOPMENT AND EVOLUTION

- Introduction PASKO RAKIC AND LEO M. CHALUPA 3
- 1 Development of the Primate Cerebral Cortex PASKO RAKIC,
JON I. ARELLANO, AND JOSHUA BREUNIG 7
- 2 Early Development of Neuronal Circuitry of the Human Prefrontal Cortex
IVICA KOSTOVIĆ AND MILOŠ JUDAŠ 29
- 3 The Cognitive Neuroscience of Human Uniqueness
TODD M. PREUSS 49
- 4 Unraveling the Role of Neuronal Activity in the Formation of Eye-Specific
Connections LEO M. CHALUPA AND ANDREW D. HUBERMAN 67
- 5 Brain Changes Underlying the Development of Cognitive Control and Reasoning
SILVIA A. BUNGE, ALLYSON P. MACKEY, AND KIRSTIE J. WHITAKER 73

II PLASTICITY

- Introduction HELEN NEVILLE AND MRIGANKA SUR 89
- 6 Patterning and Plasticity of Maps in the Mammalian Visual Pathway
SAM HORNG AND MRIGANKA SUR 91

7	Synaptic Plasticity and Spatial Representations in the Hippocampus JONATHAN R. WHITLOCK AND EDVARD I. MOSER	109
8	Visual Cortical Plasticity and Perceptual Learning CHARLES D. GILBERT	WU LI AND 129
9	Characterizing and Modulating Neuroplasticity of the Adult Human Brain ALVARO PASCUAL-LEONE	141
10	Exercising Your Brain: Training-Related Brain Plasticity C. SHAWN GREEN, AND MATTHEW W. G. DYE	DAPHNE BAVELIER, 153
11	Profiles of Development and Plasticity in Human Neurocognition COURTNEY STEVENS AND HELEN NEVILLE	165
 III ATTENTION		
	Introduction	STEVEN J. LUCK AND GEORGE R. MANGUN 185
12	Attention: Theoretical and Psychological Perspectives	ANNE TREISMAN 189
13	Mechanisms of Selective Attention in the Human Visual System: Evidence from Neuroimaging AND DIANE M. BECK	SABINE KASTNER, STEPHANIE A. McMAINS, 205
14	The Frontoparietal Attention Network CHAD M. SYLVESTER, AND GORDON L. SHULMAN	MAURIZIO CORBETTA, 219
15	Spatiotemporal Analysis of Visual Attention HANS-JOCHEN HEINZE, MIRCEA A. SCHOENFELD, AND STEVEN A. HILLYARD	JENS-MAX HOPF, 235
16	Integration of Conflict Detection and Attentional Control Mechanisms: Combined ERP and fMRI Studies AND BONG J. WALSH	GEORGE R. MANGUN, CLIFFORD D. SARON, 251
17	A Right Perisylvian Neural Network for Human Spatial Orienting HANS-OTTO KARNATH	259
18	Spatial Deficits and Selective Attention	LYNN C. ROBERTSON 269
19	The Effect of Attention on the Responses of Individual Visual Neurons JOHN H. R. MAUNSELL	281
20	Selective Attention Through Selective Neuronal Synchronization THILO WOMELSDORF AND PASCAL FRIES	289

IV SENSATION AND PERCEPTION

- Introduction J. ANTHONY MOVSHON AND BRIAN A. WANDELL 305
- 21 Grandmother Cells, Symmetry, and Invariance: How the Term Arose and What the Facts Suggest HORACE BARLOW 309
- 22 Olfaction: From Percept to Molecule YAARA YESHURUN, HADAS LAPID, RAFI HADDAD, SHANI GELSTIEN, ANAT ARZI, LEE SELA, AHARON WEISBROD, REHAN KHAN, AND NOAM SOBEL 321
- 23 Auditory Masking with Complex Stimuli VIRGINIA M. RICHARDS AND GERALD KIDD, JR. 343
- 24 Insights into Human Auditory Processing Gained from Perceptual Learning BEVERLY A. WRIGHT AND YUXUAN ZHANG 353
- 25 Auditory Object Analysis TIMOTHY D. GRIFFITHS, SUKHBINDER KUMAR, KATHARINA VON KRIEGSTEIN, TOBIAS OVERATH, KLAAS E. STEPHAN, AND KARL J. FRISTON 367
- 26 The Cone Photoreceptor Mosaic in Normal and Defective Color Vision JOSEPH CARROLL, GEUNYOUNG YOON, AND DAVID R. WILLIAMS 383
- 27 Bayesian Approaches to Color Vision DAVID H. BRAINARD 395
- 28 Wiring of Receptive Fields and Functional Maps in Primary Visual Cortex DARIO L. RINGACH 409
- 29 Encoding and Decoding with Neural Populations in the Primate Cortex EYAL SEIDEMANN, YUZHONG CHEN, AND WILSON S. GEISLER 419
- 30 Perceptual Filling-in: From Experimental Data to Neural Network Modeling RAINER GOEBEL AND PETER DE WEERD 435
- 31 Neural Transformation of Object Information by Ventral Pathway Visual Cortex CHARLES E. CONNOR, ANITHA PASUPATHY, SCOTT BRINGAT, AND YUKAKO YAMANE 455
- 32 The Cognitive and Neural Development of Face Recognition in Humans ELINOR MCKONE, KATE CROOKES, AND NANCY KANWISHER 467
- 33 Roles of Visual Area MT in Depth Perception GREGORY C. DEANGELIS 483
- 34 Multisensory Integration for Heading Perception in Macaque Visual Cortex DORA E. ANGELAKI, YONG GU, AND GREGORY C. DEANGELIS 499
- 35 Visual Stability during Saccadic Eye Movements CONCETTA MORRONE AND DAVID BURR 511
- 36 Optimal Estimation in Sensory Systems EERO P. SIMONCELLI 525

V MOTOR SYSTEMS

- Introduction SCOTT T. GRAFTON AND EMILIO BIZZI 539
- 37 Neurobiology of Coordinate Transformations EMILIO BIZZI AND
FERDINANDO A. MUSSA-IVALDI 541
- 38 Basal Ganglia and Cerebellar Circuits with the Cerebral Cortex
RICHARD P. DUM AND PETER L. STRICK 553
- 39 The Basal Ganglia and Cognition ANN M. GRAYBIEL AND
JONATHAN W. MINK 565
- 40 Computational Neuroanatomy of Voluntary Motor Control
REZA SHADMEHR AND JOHN W. KRAKAUER 587
- 41 Forward Models and State Estimation in Posterior Parietal Cortex
GRANT H. MULLIKEN AND RICHARD A. ANDERSEN 599
- 42 Parallels between Sensory and Motor Information Processing
EMANUEL TODOROV 613
- 43 The Mirror Neuron System: A Motor-Based Mechanism for Action and
Intention Understanding GIACOMO RIZZOLATTI, LEONARDO FOGASSI, AND
VITTORIO GALLESE 625
- 44 Relative Hierarchies and the Representation of Action SCOTT T. GRAFTON,
L. AZIZ-ZADEH, AND R. B. IVRY 641

VI MEMORY

- Introduction DANIEL L. SCHACTER 655
- 45 Comparative Analysis of the Cortical Afferents, Intrinsic Projections, and
Interconnections of the Parahippocampal Region in Monkeys and Rats
WENDY A. SUZUKI 659
- 46 Medial Temporal Lobe Function and Human Memory YAEL SHRAGER AND
LARRY R. SQUIRE 675
- 47 Reconsolidation: A Possible Bridge between Cognitive and Neuroscientific Views
of Memory KARIM NADER 691
- 48 The Dynamic Interplay between Cognitive Control and Memory
ELIZABETH A. RACE, BRICE A. KUHL, DAVID BADRE, AND
ANTHONY D. WAGNER 705
- 49 Phases of Influence: How Emotion Modulates the Formation and Retrieval of
Declarative Memories ELIZABETH A. KENSINGER 725

- 50 Individual Differences in the Engagement of the Cortex during an Episodic Memory Task MICHAEL B. MILLER 739
- 51 Constructive Memory and the Simulation of Future Events
DANIEL L. SCHACTER, DONNA ROSE ADDIS, AND RANDY L. BUCKNER 751

VII LANGUAGE

- Introduction ALFONSO CARAMAZZA 765
- 52 The Cortical Organization of Phonological Processing
GREGORY HICKOK 767
- 53 Morphological Processes in Language Production KEVIN A. SHAPIRO AND ALFONSO CARAMAZZA 777
- 54 Ventral and Dorsal Contributions to Word Reading LAURENT COHEN AND STANISLAS DEHAENE 789
- 55 The Neural Basis of Syntactic Processing DAVID CAPLAN 805
- 56 Semantic Unification PETER HAGOORT, GIOSUÈ BAGGIO, AND ROEL M. WILLEMS 819
- 57 Early Language Acquisition: Neural Substrates and Theoretical Models
PATRICIA K. KUHL 837
- 58 Genetics of Language FRANCK RAMUS AND SIMON E. FISHER 855
- 59 The Biology and Evolution of Language: “Deep Homology” and the Evolution of Innovation W. TECUMSEH FITCH 873

VIII THE EMOTIONAL AND SOCIAL BRAIN

- Introduction TODD F. HEATHERTON AND JOSEPH E. LEDOUX 887
- 60 Ontogeny of Infant Fear Learning and the Amygdala REGINA M. SULLIVAN, STEPHANIE MORICEAU, CHARLIS RAINEKI, AND TANIA L. ROTH 889
- 61 Emotional Reaction and Action: From Threat Processing to Goal-Directed Behavior JOSEPH E. LEDOUX, DANIELA SCHILLER, AND CHRISTOPHER CAIN 905
- 62 Interactions of Emotion and Attention in Perception PATRIK VUILLEUMIER AND TOBIAS BROSCHE 925
- 63 Context Effects and the Amygdala PAUL J. WHALEN AND F. CAROLINE DAVIS 935

- 64 Neurogenetic Studies of Variability in Human Emotion
AHMAD R. HARIRI 945
- 65 Components of a Social Brain JASON P. MITCHELL AND
TODD F. HEATHERTON 953
- 66 The Neural Basis of Emotion Regulation: Making Emotion Work for You and
Not Against You JENNIFER S. BEER 961
- 67 Sharing the Emotions of Others: The Neural Bases of Empathy
TANIA SINGER AND SUSANNE LEIBERG 973
- 68 The Cognitive Neuroscience of Moral Judgment JOSHUA D. GREENE 987

IX HIGHER COGNITIVE FUNCTIONS

- Introduction ELIZABETH A. PHELPS 1003
- 69 Prefrontal Substrate of Human Relational Reasoning
BARBARA J. KNOWLTON AND KEITH J. HOLYOAK 1005
- 70 Decision Making and Prefrontal Executive Function
CHRISTOPHER SUMMERFIELD AND ETIENNE KOEHLIN 1019
- 71 Circuits in Mind: The Neural Foundations for Object Concepts
ALEX MARTIN 1031
- 72 Semantic Cognition: Its Nature, Its Development, and Its Neural Basis
JAMES L. MCCLELLAND, TIMOTHY T. ROGERS, KARALYN PATTERSON,
KATIA DILKINA, AND MATTHEW LAMBON RALPH 1047
- 73 Two Views of Brain Function MARCUS E. RAICHEL 1067
- 74 The Neuroeconomics of Simple Goal-Directed Choice (Circa 2008)
ANTONIO RANGEL 1075
- 75 Neuroeconomics and the Study of Valuation PAUL W. GLIMCHER 1085
- 76 Emotion and Decision Making ELIZABETH A. PHELPS AND
MAURICIO R. DELGADO 1093

X CONSCIOUSNESS

- Introduction CHRISTOF KOCH 1107
- 77 Comparing the Major Theories of Consciousness NED BLOCK 1111
- 78 Recovery of Consciousness after Brain Injury: An Integrative Research Paradigm
for the Cognitive Neuroscience of Consciousness
NICHOLAS D. SCHIFF 1123

PREFACE

It has been 20 years since we first met in Squaw Valley to assess the state of cognitive neuroscience. We have held this meeting three times before and each meeting had its own signature. When the first meeting concluded, we knew we had a vibrant, young field on our hands. As the years passed, our knowledge deepened and slowly and gradually new ideas emerged. With the fourth meeting cognitive neuroscience is busting out all over. Fundamental stances are changing and new ideas are emerging. Everything from the view that individual neurons change their functional role through time to claims that our moral decisions can be tracked in the brain are indicants of the range and excitement of cognitive neuroscience. Fresh air sweeps in and reinvigorates us on the view that we will some day figure out how the brain works its magic and produces the human mind.

It is always in the first two sessions that one finds the contrast in approaches to studying the brain so markedly different. The development and evolution section talks about a dynamic growth pattern that becomes specific and fixed. At the same time those interested in plasticity see the neuronal systems always changing and the dynamics seen in development as continuing for the life of the brain. In our most recent meeting the reports on brain plasticity were more bold than ever before.

The attention session featured a new emphasis on the interactions between reafferent top-down and feed-forward, bottom-up attentional processes. Benefiting from ever-impressive technological advances, the elucidation of attentional mechanisms is proceeding at a dizzying pace. It is refreshing to note that in addition to providing a more comprehensive picture of attentional processes, this exciting new empirical evidence has also verified many central tenets of some of the most longstanding and influential theories in the cognitive neuroscience of attention.

In the motor session, the boundaries of the motor system continued to be pushed further into the realm of cognition. Some have demonstrated the existence of motor-related areas in the parietal lobe that are involved in representing goals of oneself and of others, providing a link for how we may intuitively translate the actions of others into a model of their mental processes. Separate research indicates that areas once thought to have only motor roles actually contain circuits related to executive and limbic function, further complicating the distinction between cognition and motor processes. Perhaps above all else, the work of the motor section suggests that we might be wise to relieve ourselves of the need to make stark distinctions between these two phenomena, at least in higher primates.

Memory research is, paradoxically, providing great insight into how humans imagine future events. Moreover, new models of reconsolidation and retrieval are emerging, and exciting evidence of individual differences in cortical activation patterns during episodic retrieval are forcing a careful reevaluation of central tenets of functional imaging analysis.

The perception session demonstrated the vast potential of Bayesian modeling to provide beneficial descriptions of how the brain performs various functions. But Bayesian modeling

does not hold a monopoly; other theoretical and methodological pioneers are dramatically enhancing our understanding of vision, quite literally from the level of the retina to large-scale networks that connect distributed regions of the cortex. Keeping pace with advances in vision science are exciting findings across the modalities of audition, olfaction, and vestibular function.

Next, we turned our attention to language (and secretly hoped that a few lectures would pass without mention of the word “Bayesian”). The understanding of specific components of language processing is expanding, while exciting parallel studies are examining the genes that may wire our brain in a way that enables language acquisition. But even as we move toward an understanding of how genes and experience sculpt the human brain into a speaking device, the question of who exactly is doing the speaking arises. Fittingly, we transitioned into the session on executive function, where we came across a surprising answer to this question. There does not appear to be a need for a “top” in top-down control; instead, various regions for self-regulation and cognitive control have been identified and their interactions have been modeled in ways that leave the mythical homunculus homeless. As if this were not profound enough, we also learned about an exciting new characterization of resting brain activity, a remarkable advance that has too many implications to list.

Over a week removed from our introduction to theory of mind in the motor session, the emotion and social neuroscience section further demystified the rapidly expanding science of the social brain. New ideas on how our emotions and sense of self inform the ways in which we think about and reflexively understand others continue to evolve, while evidence for the genetic basis of individual variation in affect and, astoundingly, for differences in BOLD activity related to this genetic variation has further shaped the current models of how the emotional brain develops and operates.

As it always does, the conference ended with a bang, featuring two days’ worth of lively discussion on the topic of consciousness. An exciting novel mechanism for how the brain generates the baseline activity necessary to sustain conscious experience was complemented by a bold theoretical attempt to make the problem of qualia a bit more tractable. Between these extremes, others reported suggestive new evidence about the neural basis of visual conscious experience. This session also served as a reminder of how far we had come during those three weeks in Squaw Valley, as topics such as action, emotion, language, and executive function reemerged in the context of examining how such varied processing contributes to the content of conscious experience.

After three weeks of such intense stimulation, it is a testament to the amazing progress unveiled that one somehow leaves Tahoe reinvigorated and enthusiastic to get back into the lab. The past 20 years have seen advances that we could never have anticipated, and, incredibly, the next five or ten hold the potential to continue this exponential progress. The Summer Institute at Tahoe reveals simultaneously the exciting new ideas in the field and the bright minds that are vigorously attacking the persisting mysteries of cognitive neuroscience. It also exposes a talented group of graduate and postdoctoral students to the wonderful breadth and depth of the field. Scanning the room of eager young minds hanging onto the words of the various leaders of the field is truly a sight to behold. It is exhilarating to witness the handing of the baton from one generation to the next. One can only pause, take it all in, smile, and then get back to paying attention to the lecture because the next big idea presented might knock you right out of your seat!

Needless to say, complex events and publications like this work well only if there are dedicated people involved. First, the MIT Press continues to be exceptionally supportive in carrying out high-quality production in a timely manner. Once again my daughter, Marin Gazzaniga, managed the ebb and flow of the manuscripts, playing both good cop and bad cop as the manuscripts moved between authors, section editors, and ultimately the publisher. Marin is a brilliant playwright, actress, and writer in her own right, and all of those skills are required in herding academics to a common goal.

The actual event at Lake Tahoe was managed from the beginning by my assistant, Jayne Rosenblatt. She is always good humored and incredibly dedicated and runs complex events seemingly effortlessly. Finally, these books don't just happen. Peggy Gordon brings it all together into print with a steady hand and professionalism.

Warm thanks and congratulations to all. We will see you all again in five years.

Introduction

PASKO RAKIC AND LEO M. CHALUPA

IN THE 15 YEARS since the first edition of *The Cognitive Neurosciences* we have witnessed immense advances in the understanding of the intricacies of human cognitive abilities. As evident from the many articles in this as well as previous editions of this popular reference book, the progress that has been made can to a large extent be linked with studies of the cerebral cortex using very sophisticated noninvasive imaging methods in human subjects. These methods allow examination of human-specific cognitive functions directly in living people as they develop, as they are perturbed, and as they decline (e.g., Gazzaniga, 2008). It is thus somewhat paradoxical that during this very same time period the major advances in our understanding of the cellular and molecular mechanisms of cortical development and the models of evolutionary elaborations have derived almost entirely from studies of rodent brains.

Although basic principles of cortical development are probably similar in all species, the modifications of developmental events during evolution produce not only quantitative changes (e.g., the number of neurons; expansion in surface, timing, and sequence of cellular events; increase in number of synapses, etc.), but also many qualitative changes (e.g., the elaboration of new types of neurons and glia, and most importantly additions of novel specialized cytoarchitectonic areas associated with corresponding new pathways and patterns of connectivity). It has become evident that even essential genes that are responsible for survival of the species give different phenotypes in the mouse and human (Liao & Zhang, 2008). Furthermore, the timing and duration of cell genesis, the composition of the ventricular zone, and the ratios of cell proliferation, versus programmed cell death occurring in the enlarged subventricular and marginal zones of the embryonic cerebral cortex, suggest not only a slower development, but also

expanded, diversified, and novel roles of these transitional layers in primates including human (Bystron, Blakemore, & Rakic, 2008). It is for this reason that the first three chapters in this volume are dedicated to the development and evolution of the cerebral cortex with a particular emphasis on humans and nonhuman primates.

The first chapter, by Rakic, Arellano, and Breunig, is dedicated to the prenatal development of the primate neocortex. It emphasizes the developmental features that are prominent and essential for the formation of the large and convoluted cerebral cortex. For example, there are marked species-specific differences in the timing and sequence of divergence of neural stem and radial glial cell lines as well as in the levels of their differentiation and longevity. There are also subclasses of neural stem cells that produce interneurons for the neocortex as well as for the association thalamic nuclei not detectable in rodents (Letinic & Rakic, 2001; Letinic, Zonku, & Rakic, 2002). These neurons may be involved in human-specific language and cognitive functions that do not exist in non-primate species.

The second chapter, by Kostović and Judaš, describes the early development of neuronal circuitry of the human prefrontal cortex, which is most elaborated and enlarged in humans, and arguably does not exist in nonprimate species. These studies are helped by the increase in resolution of the MRI to the degree that one can visualize normal and possible abnormal columns in the human fetal neocortex (e.g., McKinstry et al., 2002).

The third chapter, by Preuss, which deals with evolutionary aspects of cortical development in the hominoids, provides a compelling account of recent evidence documenting unique features in the organization of the human brain. These new insights have been derived by using new technologies, in combination with more established techniques, to assess different aspects of the relation between structure and function in the brain, ranging from neuronal morphology to connectional pathways.

The fourth chapter, by Chalupa and Huberman, is concerned with unraveling the role of neuronal activity in the formation of eye-specific connections in nonhuman primates. It deals with the development, competition, and plasticity of the projections of the two eyes to the lateral geniculate nucleus and the formation of the ocular dominance columns in the primary visual cortex. Their work challenges the widely held notion that neuronal activity, in particular the retinal waves of activity, plays an instructional role in the formation of eye-specific retinogeniculate projections.

The fifth chapter, by Bunge, Mackey, and Whitaker, deals with human brain changes underlying improved cognitive abilities during childhood and adolescence, with a particular emphasis on fluid reasoning. Focusing primarily on pre-

frontal and parietal cortices and using the most advanced neuroimaging methods and conceptual approaches, this chapter aptly demonstrates the power of the developmental approach in linking brain mechanisms with higher cognitive functions.

Collectively, these studies may help in understanding the biological bases of the high level of cognitive ability that is achieved during primate evolution culminating in humans. However, from a practical perspective, the findings obtained from studies on human and nonhuman primates may be essential for the design of psychiatric drug therapies, since, for example, the capacity for regeneration has diminished during vertebrate evolution, and the absence of neurogenesis in the primate cerebral cortex (Bhardwaj et al., 2006) indicates that overcoming the brain's resistance to the acquisition of functionally competent new neurons will require an understanding of why neurogenesis ceases at the end of specific developmental time windows and why there are regional variations in this phenomenon (Rakic, 2002, 2006). Another difference is the existence of distinct types of interneurons in the human brain that are not detectable in rodent species (e.g., DeFelipe, Alonso-Nanclares, & Arellano, 2002). In addition, a subclass of interneurons of the thalamic association nuclei that originate in the ganglionic eminence are not detectable in rodents (Letinic & Rakic, 2001). Likewise, unlike in rodents, in which interneurons arise from the ganglionic eminences, in primates these originate in large numbers in the enlarged subventricular zone (Letinic et al., 2002; Petanjek, Dujmovic, Kostovic, & Esclapez, 2008). These neurons may be involved in human-specific disorders such as schizophrenia that do not occur spontaneously in nonprimate species. Thus modifications in the expression pattern of transcription factors in the human forebrain may underlie species-specific programs for the generation of specific classes of cortical neurons that may be differentially affected in genetic and acquired neurological disorders (Lewis, 2000). These novel evolutionary traits may be more vulnerable to genetic mutations and environmental insults, and could be implicated in disorders of higher brain functions, such as autism, developmental dyslexia, Alzheimer's disease, and schizophrenia. Designs of new drugs and replacement therapies need to take into consideration these species-specific distinctions.

1 Development of the Primate Cerebral Cortex

PASKO RAKIC, JON I. ARELLANO, AND JOSHUA BREUNIG

ABSTRACT The cerebral cortex is the crowning achievement of evolution and the biological substrate of human cognitive abilities. Although the basic principles of cortical development in all mammals are similar, the modifications of developmental events during evolution produce not only quantitative but also qualitative changes. Human cerebral cortex, as in the other species, is organized as a map in which specific cell classes are positioned into a radial, laminar, and areal array that depends on the sequential production and phenotypic specification of those cells and the directed migration from their place of origin to their distant final destination. The long and curvilinear migration pathways in the fetal human cerebrum depend critically on the stable radial glial scaffolding. After neurons assume their proper areal and laminar position, they attach locally and develop numerous proximal and long-distance connections that involve specific adhesion molecules, neurotransmitters, and receptors. However, the final pattern of synaptic connections is selected through functional validation and selective elimination of the initially overproduced neurons, axons, and synapses. In this review, the development of the cerebral cortex is described in the context of the radial unit hypothesis, the postulate of an embryonic protomap, and the concept of competitive neural interactions that ultimately create a substrate for the highest cognitive functions.

There is probably no disagreement among biologists that the cerebral cortex is the part of the brain that most distinctively sets us apart from any other species and that the principles governing its development may hold the key to explaining our cognitive capacity, intelligence, and creativity (e.g., Gazzaniga, 2008). Perhaps the most prominent feature of the cerebral cortex in all species, and particularly in primates, is its parcellation into distinct laminar, radial, and areal domains (Eccles, 1984; Mountcastle, 1997; Goldman-Rakic, 1987; Rakic, 1988; Szentagothai, 1978). Although the surface of the neocortex has expanded a thousandfold during phylogeny, its thickness and its basic cytoarchitectonic organization appear to be changed comparatively less. However, this morphological similarity of cortical architecture in histological sections in all mammals may be misleading, since it might invite us to think in terms of a canonical cortex that only varies in size in accordance with

the variations of body mass of the different mammalian species. Conversely, our current knowledge indicates that there are significant qualitative and quantitative changes in the structure of the neocortex between species, in the size of cells, in the proportion of neurons to glia, in the ratio of excitatory projection cells to inhibitory interneurons, in the appearance of new types of neurons, in the specific organization of connections, and, most importantly, in the addition of novel highly specialized cortical areas associated with correspondingly new axonal pathways and patterns of synaptic connectivity that can certainly have a profound effect on the functional capacity of the cerebral cortex. In spite of these differences, the small size, high fertility rate, and low cost of maintenance have converted mice into an unexcelled model for experimental research on neuroscience and particularly on basic cortical organization (Rakic, 2000).

The study of the cortical development of mammals suggests that even small differences in the timing and duration of the genesis of neural cells and changes in the composition and the ratios of cell proliferation and programmed cell death in the transient embryonic zones of the developing forebrain can be responsible for the evolutionary expansion of the neocortex and the concomitant appearance of novel functions in cognitive processing of information (Bystron, Blakemore, & Rakic, 2008). Although genetically humans are surprisingly similar to other mammals, the uniqueness of the human cognitive potential, which is an output of cortical function, must have some genetic basis. Since the molecular structure and function of neurotransmitters, receptors, and ion channels do not change substantially over the phylogenetic scale, the secret to the success of *Homo sapiens* is probably mainly due to an increased number of neurons, more elaborated connections, functional specialization, and introduction of new cortical areas. Even the so-called essential genes, which are considered responsible for survival of the individual, give different phenotypes in different species, and about 20% of the mouse orthologs of human-essential genes are nonessential in mice (Liao & Zhang, 2008). It is therefore apparent that neither the genetic, the cellular, nor most importantly, the circuitry basis of human cortical uniqueness can be deciphered by studying exclusively rodents, much as one cannot expect to understand the origin

PASKO RAKIC, JON I. ARELLANO, and JOSHUA BREUNIG Department of Neurobiology, Yale University School of Medicine, New Haven, Connecticut

of the mushroom body of insects by studying the primate association cortex. However, for logistic, ethical, and financial reasons, the easiest approach to understanding general mammalian features is to study the mouse, and the closest we can come to elucidating primate-specific cortical development with the modern molecular and cell biological methods is to analyze its development in the monkey, and specifically in Old World monkeys such as the macaque, which are much more similar to the human species than their relatives the New World monkeys. For the preceding reasons the present review is based on the comparative studies of neocortical development in the mouse, macaque, and human. It is limited to the early developmental events that lead to the formation of cellular constituents and their basic connectivity. The final tuning of synaptic connections and their modifications by experience is described in other communications in this volume.

Onset and span of cortical neurogenesis

The mammalian cerebral cortex is a laminated structure composed of a bewildering diversity of neurons arranged in distinct cytoarchitectonic fields. It is well established, but nevertheless always fascinating, that none of these neurons are generated in the cortex itself. Classical studies of neurogenesis based on the distribution of mitotic figures and deployment of migrating neurons in the cerebral wall in the human fetus suggested that all cortical neurons in the human are likely to be generated mostly before birth (e.g., Poliakov, 1959, 1965; reviewed in Sidman & Rakic, 1973, 1982; Rakic 2002; Bystron et al., 2008). However, the precise data on the onset and termination of corticogenesis could not be established with the classical histological techniques alone (e.g., Conel, 1939), a limitation that was overlooked with the introduction of tritiated thymidine and BrdU incorporation as markers of DNA synthesis to label dividing cells (Breunig, Arellano, Macklis, & Rakic, 2007). These new methods allowed a systematic study of neuronogenesis, and it was established that the neocortex receives the first neurons at ~E10 in mice, and ~E33 in macaque and human (reviewed in Bystron et al., 2008). These studies also showed that there does not exist a pattern between species for the timing of neuronal genesis, and while in mice neurons are generated in the second half of gestation (between E10 and the end of gestation at E18.5), in the macaque monkey and human, neurons are produced much earlier, mostly during the middle of gestation in monkeys and during the first half in humans (between E33 and E100 in monkeys and E33 and E120 in humans, figure 1.5) (Rakic, 1974, 1988, 2002; Rakic & Sidman, 1968; Sidman & Rakic, 1973, 1982). This early neocortical genesis stands in contrast to that of the cerebellum, olfactory bulb, and hippocampus, which in the mouse terminate their development postnatally, and in

primates including human continue to add neurons well after birth (Rakic, 1973; Rakic & Nowakowski, 1981; Kornack & Rakic 1999, 2001b).

In spite of comprehensive search in the adult monkey neocortex, no additional neurons are added during the animal's 30-year life span (Rakic, 1985; Kornack & Rakic 2001a; Koketsu, Mikami, Miyamoto, & Hisatsune, 2003). The claim of new neurons arriving to the prefrontal, parietal, and temporal association cortices in adult macaques could not be confirmed (reviewed in Breunig, Arellano, et al., 2007; Rakic, 2002, 2006), and additional techniques such as the analysis of incorporation of C14 has provided further evidence that all neurons of the human neocortex are generated before birth (Bhardwaj et al., 2006), indicating that for the highest cognitive functions we use and depend on the same set of neurons throughout our entire life span (Rakic, 1985, 2006).

Place of origin

The presence of mitotic figures near the lumen of the cerebral cavity of the embryonic human cerebrum and their paucity and/or absence in the cortical plate itself led to the hypothesis that cortical neurons are produced in the germinal matrix situated at the ventricular surface (His, 1904), an idea that was substantiated by the labeling of dividing cells in mice (Angevine & Sidman, 1961), monkeys (Rakic, 1974), and humans (Rakic & Sidman, 1968; Letinic, Zoncu, & Rakic, 2002). In the last decade, studies in rodents have established two sources of origin of cortical neurons: the germinal regions of the dorsal telencephalon give rise to cortical projection neurons that migrate radially to their final position in the cortex, while the ganglionic eminences in the ventral telencephalon give rise to virtually all GABAergic cortical interneurons (e.g., Lavdas, Grigoriou, Pachnis, & Parnevelas, 1999; Marin & Rubenstein, 2001), which migrate tangentially via the marginal and intermediate zones to the cortex (Ang, Haydar, Gluncic, & Rakic, 2003). This model has been observed in rodents and carnivores (ferrets; Anderson, Kaznowski, Horn, Rubenstein, & McConnell, 2002; Poluch & Juliano, 2007), but also in avians such as chickens (Cobos, Puelles, & Martinez, 2001), and a similar population of tangentially migrating neurons has been observed in the human using classical histological material (Rakic, 1975). However, in what appears to be a significant species-specific difference, neocortical inhibitory interneurons in primates, including human, originate not only in the ganglionic eminences in the ventral telencephalon, but also in the ventricular zone and in the enormously enlarged subventricular zone of the dorsal telencephalon (Letinic et al., 2002; Rakic & Zecevic, 2003; Petanjek, Berger, & Esclapez, 2008; Petanjek, Dujmovic, Kostovic, & Esclapez, 2009) and quantitative data from Letinic and

colleagues (2002) indicated that about two-thirds of the cortical GABAergic interneurons might have a dorsal telencephalic origin in humans.

Proliferative cells in the ventricular zone are organized as a pseudostratified epithelium in which precursor cells divide asynchronously; their nuclei move away from the ventricular surface to replicate their DNA and then move back to the surface to undergo another mitotic cycle (reviewed in Sidman & Rakic, 1973; Rakic, 1988). Early silver impregnation methods revealed a distinct population of elongated, nonneuronal cells in the fetal human brain, which were initially called epithelial cells or fetal glia (Rakic, 2003). Later electron microscopic and immunohistochemical studies using glial acidic fibrillary protein (GFAP) in human and nonhuman primates confirmed their glial nature (Levitt, Cooper, & Rakic, 1981) and justified the use of the term “radial glial cells” (RGC; Rakic, 1988). The distal end-feet of the radial glial cells form the pial surface of the fetal cerebrum (Rakic, 1972). A variety of antigens, such as vimentine, brain-lipid-binding protein (BLBP), the astrocyte specific glutamate transporters (GLAST), and RC1, RC2 have been used to characterize their glial nature (e.g., Bystron et al., 2008).

Radial glia is particularly prominent in the embryonic primate cerebrum, where a subset of GFAP positive cells transiently stops dividing (Schmechel & Rakic, 1979). However, it has become now clear that the RGC can generate both neuronal progenitors and neurons (Cameron & Rakic, 1991; Malatesta, Hartfuss, & Gotz, 2000; Malatesta et al., 2003; Hartfuss, Galli, Heins, & Gotz, 2001; Noctor, Flint, Weissman, Dammerman, & Kriegstein, 2001; Noctor et al., 2002; Tamamaki, Nakamura, Okamoto, & Kaneko, 2001; Fishell & Kriegstein, 2003; Tramontin, Garcia-Verdugo, Lim, & Alvarez-Buylla, 2003; Gal et al., 2006). The dividing RGC generate successive neuronal clones that migrate along the elongated parental process into the cortical plate or populate the subventricular zone (SVZ) where they divide again before entering a postmitotic state and migrate to the overlying cortex. In addition, they generate intermediate progenitors that continue to divide (Levitt et al., 1981; Gal et al., 2006). The SVZ was previously thought to generate mainly glia (Altman & Bayer, 1990). However, it is now well established that this zone is multipotential and also generates projection neurons and interneurons, as well as various types of glial cells in all species studied, although the proportion is different between species (Letinic et al., 2002; reviewed in Bystron et al., 2008). Thus, in rodents and in primates, early divergence of basic cell types has been revealed using the retroviral gene transfer method, which enables the study of cell lineages in the developing mammalian telencephalon (Luskin, Pearlman, & Sanes, 1988; Cameron & Rakic, 1991; Kornack & Rakic, 1995). It appears that in the primate, the radial glial mother cell gives

rise to a daughter cell which either directly or as a dedicated neuronal progenitor goes through several rounds of division to produce bipolar migrating neurons that will migrate up the radial process of the mother cell (Rakic, 2003). Current state-of-the-art methods including in utero electroporation and conditional mouse genetics, which both allow for rapid and powerful gain- and loss-of-function studies, are beginning to unravel the complex molecular interplay between these cell types in the developing cortex. A complete compendium of newly identified signaling pathways is beyond the scope of this chapter, but a few findings deserve mention. For example, it has been demonstrated that the protein Numb is a crucial player in maintaining the adhesiveness of radial glia in the ventricular zone (VZ), preventing premature detachment and subsequent astrogliogenesis (Rasin et al., 2007). In contrast, Notch functions cell-autonomously to maintain the radial glial cell fate while the proneural genes antagonize Notch signaling to promote neuronal differentiation and subsequent migration (Breunig, Silbereis, Vaccarino, Sestan, & Rakic, 2007; Mizutani, Yoon, Dang, Tokunaga, & Gaiano, 2007; Shimojo, Ohtsuka, & Kageyama, 2008; Ge et al., 2006). More precisely, in an example of the exquisite balance of structure and function, it has been shown that the daughter neuronal cell stimulates Notch signaling in the radial glial mother cell to maintain the neurogenic VZ niche and migratory scaffold (Yoon et al., 2008).

Transient embryonic zones

The formation of the adult cortex is the end product of a series of morphogenetic steps that are initiated in the proliferative epithelium at the surface of the lateral cerebral ventricles. Initial cellular events, such as the proliferation, migration, aggregation, and selective death of some of the generated cells, as well as the subsequent outgrowth of axons and dendrites, and the establishment of neuronal connections, proceed in an orderly fashion in each species according to a species-specific timetable that is regulated by differential gene expression. During embryonic and fetal stages, the telencephalic wall consists of several cellular layers that do not exist in the mature brain. These layers, or zones, were recognized by a committee appointed by the American Association of Anatomists (Boulder Committee, 1970) based on the data from the dissertation on human brain development by the senior author of the present chapter (P.R.). The committee recommendations for the names of the transient embryonic cellular compartments, termed zones, have been adopted as a generic description for fundamental developmental events for the entire vertebrate central nervous system. However, in the past four decades, the development of new techniques, particularly genetic tools for fate mapping and gain and loss of function of targeted genes, have contributed largely to elucidate the

genetic regulation of the developmental processes in various species. In particular, the focus has been set on the patterns of expression of transcription factors that seem to exquisitely influence regional differentiation and regulate broad aspects of mitotic activity, fate choice, migration, and differentiation (Gleeson & Walsh, 2000; Ge et al., 2006; Guillemot, 2007; Mizutani et al., 2007; Molyneaux, Arlotta, Menezes, & Macklis, 2007; Rasin et al., 2007). Recent studies have revealed new types of transient neurons and proliferative cells outside the classical *neuroepithelium*, new routes of cellular migration, and additional cellular compartments (Bielle et al., 2005; Bystron, Rakic, Molnar, & Blakemore, 2006; Carney, Bystron, Lopez-Bendito, & Molnar, 2007; Smart, Dehay, Giroud, Berland, & Kennedy, 2002; Zecevic, Chen, & Filipovic, 2005). As a consequence, a revision of the Boulder Committee model that incorporates that new knowledge has recently been proposed (reviewed in Bystron et al., 2008). In figure 1.1 top, the summary diagram from the original Boulder model is reproduced, and at the bottom the new drawing that incorporates new cell types and cellular zones is shown (Bystron et al., 2008).

Although most of the transient embryonic zones defined by the Boulder Committee were described in the classical literature (e.g., His, 1904), the subplate zone (SP) has been recognized as a separate entity only relatively recently (figure 1.2) (Kostovic & Molliver, 1974; reviewed in Kostovic & Rakic, 1990). This zone consists of early generated neurons scattered among numerous axons, dendrites, glial fibers, and migrating neurons. Although it has been suggested that the subplate zone provides an opportunity for interactions between incoming afferent fibers and early generated neurons, the significance of these transient contacts is not fully understood. Another suggestion was that the subplate zone serves as a cellular substrate for competition among the initial contingent of cortical afferents and that this competition serves to regulate their distribution to appropriate regions of the overlying cortical plate (Rakic, 1976b, 1977; Kostovic & Rakic, 1984; McConnell, Ghosh, & Shatz, 1994).

Subsequent autoradiographic, electron microscopic, and histochemical studies revealed that the axons observed in the subplate zone originate sequentially from the brain stem, basal forebrain, thalamus, and the ipsi- and contralateral cerebral hemispheres (figure 1.2) (Kostovic & Rakic, 1990). More recently, the subplate has been shown to be important for the formation of functional architecture in the cortex such as ocular dominance columns in the visual cortex and also for ensuring the proper formation and strengthening of synapses in this area (Kanold, Kara, Reid, & Shatz, 2003). After a variable and partially overlapping period, these diverse fiber systems enter the cortical plate, the subplate zone disappears, and most of these subplate neurons eventually degenerate, leaving only a vestige of cells

scattered throughout the subcortical white matter, which are known as interstitial neurons (Kostovic & Rakic, 1980; Luskin & Shatz, 1985; Chun & Shatz, 1989). A comparison among various species indicates that the size and role of this transient zone increases during mammalian evolution and culminates in parallel with the developing of association areas of the human fetal cortex concomitantly with the enlargement of the cortico-cortical fiber systems (Kostovic & Rakic, 1990; Kostovic & Goldman-Rakic, 1983). The regional differences in the size, pattern, and resolution of the subplate zone correlate also with the pattern and elaboration of cerebral convolutions (Goldman-Rakic & Rakic, 1984). Another transient layer that forms between the neuroepithelium and the pial surface of the dorsal telencephalon that was not mentioned in the Boulder Committee is the preplate that has been widely used and is included in the new schema. Finally, cell divisions outside the classical proliferative zones have been included (Bystron et al., 2008).

Neuronal cell migration

Since all cortical neurons originate near the ventricular surface of the cerebral vesicle, they must all move to their final positions in the cortex, which develops in the outer regions of the cerebral wall, just below the pia. After their last division, postmitotic cells become polarized, extending the leading processes toward the pia and then translocating the nucleus and surrounding cytoplasm within that process (Rakic, 1971, 1972). The extension of the leading process and nuclear translocation are inseparable cellular events. Initially, while the cerebral wall is relatively thin, the tip of the leading process can reach the cortical plate, and the nucleus needs to move only a short distance in both the small rodent cerebrum as well as in the human at comparably early embryonic stages (Sidman & Rakic, 1973; Nadarajah, Alifragis, Wong, & Parnavelas, 2003). However, during the subsequent course of corticogenesis, the cerebral hemispheres enlarge and the length of the migratory pathway increases, particularly in the large primate cerebrum in which, during midgestation, a massive migration of neurons occurs concomitantly with the rapid growth of the cerebral wall. This magnitude of cell movement is perhaps the reason that neuronal cell migration was first observed in human embryos (His, 1874). When this large increase in length occurs, bipolar migrating neurons do not span the entire width of the cerebral wall (reviewed in Sidman & Rakic, 1982; Rakic, 1988, 1990). Subsequent time-lapse imaging studies in the mouse forebrain have shown that this way of migration, termed somal translocation, occurs in all cells irrespective of the length of the migratory pathway (Rakic, 1971, 1972; Nadarajah et al., 2003).

In the early 1970s it was discovered that postmitotic neurons find their way to the cortex by following the

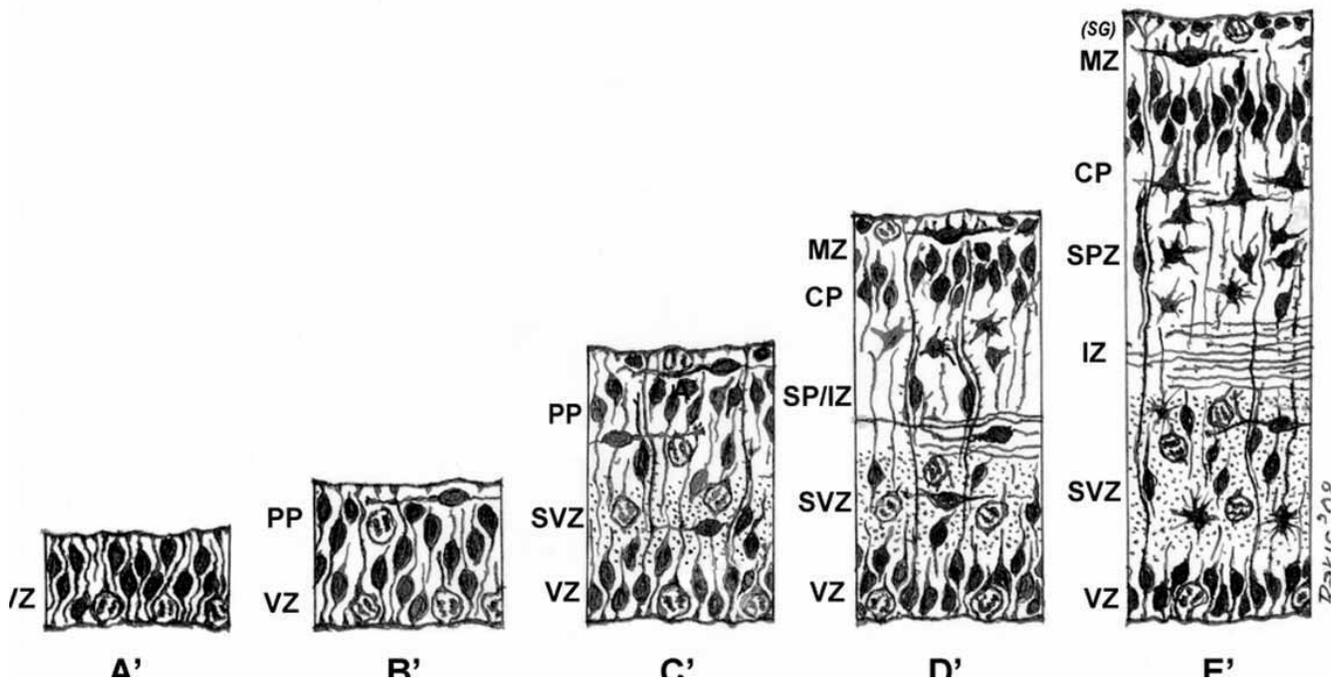

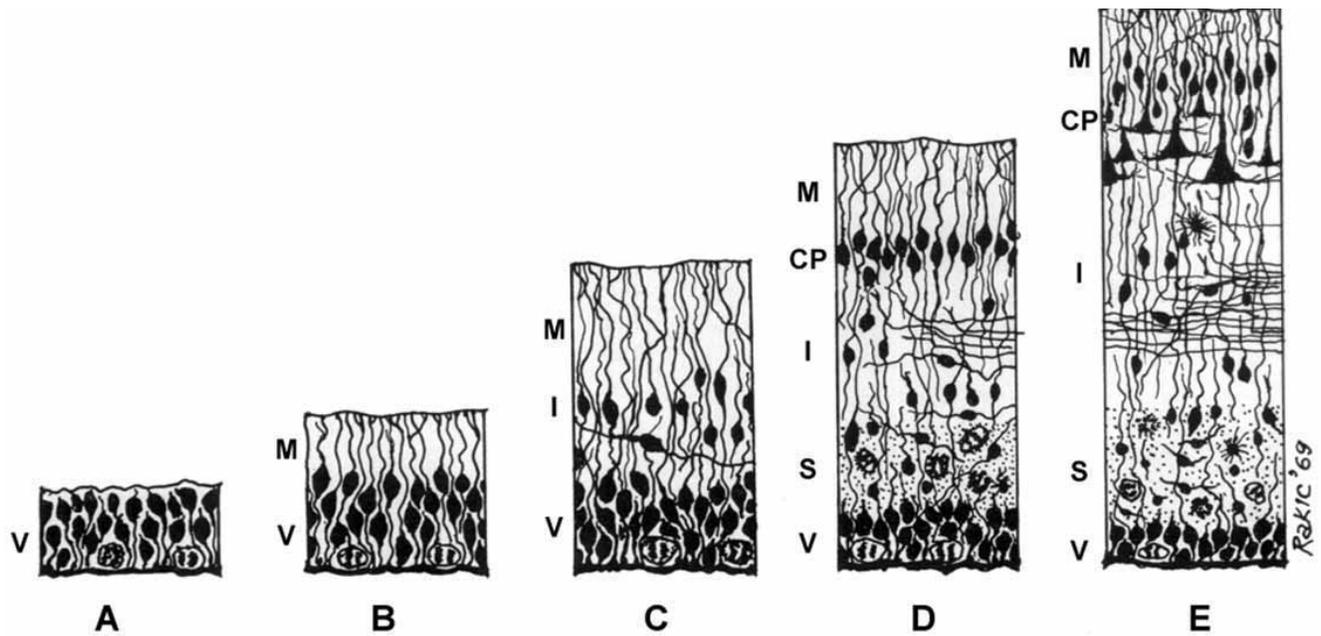

FIGURE 1.1 The original Boulder Committee's (1970) diagram (top) and revised version reprinted from Bystron et al. (2008). Abbreviations in the original diagram (top): V, ventricular zone; M, marginal zone; I, intermediate zone; S, subventricular zone; CP, cortical plate. Abbreviations in the updated diagram (bottom): VZ, ventricular zone; PP, preplate; SP/IZ, subplate/intermediate

zone; SVZ, subventricular zone; MZ, marginal zone; CP, cortical plate; SPZ, subplate; IZ, intermediate zone; (SG), subplial granular layer (part of the MZ). The lower panels correspond to the following approximate ages (for the lateral part of the dorsal telencephalon): A', E30; B', E31-32; C', E45; D', E55; E', 14 GW.

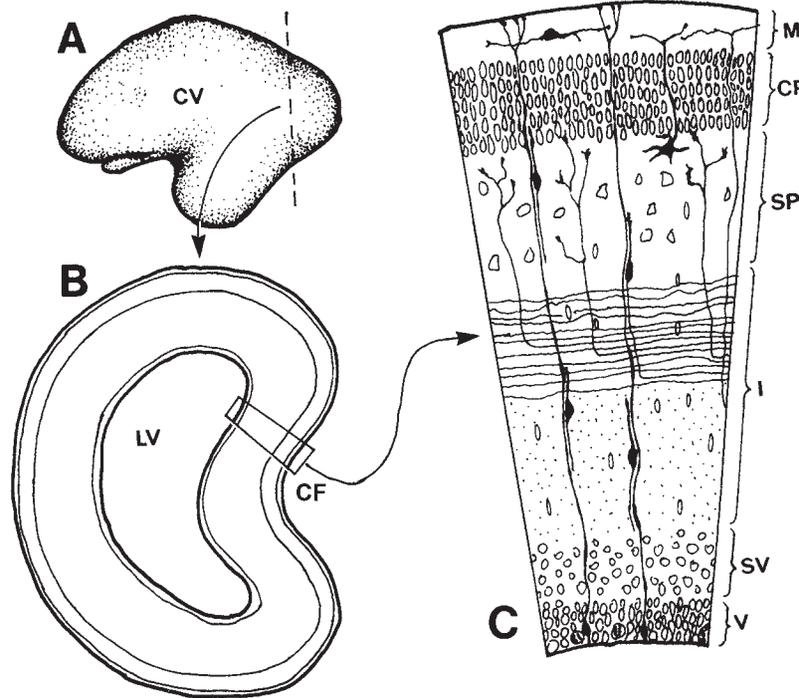

FIGURE 1.2 Cytological organization of the primate cerebral wall during the first half of gestation. (A) The cerebral vesicle of 60–65-day-old monkey fetuses is still smooth and lacks the characteristic convolutions that will emerge in the second half of gestation. (B) Coronal section across the occipital lobe at the level indicated by a vertical dashed line in A. The lateral cerebral ventricle at this age is still relatively large, and only the incipient calcarine fissure (CF) marks the position of the prospective visual cortex. (C) A block of the tissue dissected from the upper bank of the calcarine fissure. At this early stage one can recognize six transient embryonic zones

from the ventricular surface (bottom) to the pial surface (top): ventricular zone (V); subventricular zone (SV); intermediate zone (I); subplate zone (SP); cortical plate (CP); and marginal zone (M). Note the presence of spindle-shaped migrating neurons moving along the elongated radial glial fibers, which span the full thickness of the cerebral wall. The early afferents originating from the brain stem, thalamus, and other cortical areas invade the cerebral wall and accumulate initially in the subplate zone, where they make transient synapses before entering the overlying cortical plate. (From Rakic, 1995b.)

elongated shafts of radial glial cells (figure 1.3 and Rakic, 1972). Radial glial cells are particularly prominent in primates including human, whose fibers span all the length of the convoluted cerebral hemispheres at the late stages of corticogenesis (Rakic, 1976b; deAzevedo 2003). While moving along the glial surface, migrating neurons remain preferentially attached to curvilinear glial fibers, a finding which suggested a “gliophilic” mode of migration (Rakic, 1985, 1990) that may be mediated by heterotypic adhesion molecules (Rakic, Cameron, & Komuro, 1994). As many as 30 migrating GFAP-negative neurons have been observed migrating along a single GFAP-positive radial glial fascicle in the human forebrain during midgestation (Rakic, 2003).

However, some postmitotic cells do not obey glial constraints and move along tangentially oriented axonal fascicles (e.g., black horizontally oriented cells aligned with thalamic radiation (TR in figure 1.3). We suggested the term “neurophilic” to characterize the mode of migration of this cell class (Rakic, 1985, 1990). Although lateral dispersion of postmitotic neurons was initially observed in Golgi-stained preparations (e.g., figure 1A of the report of the Boulder

Committee, 1970), it attracted renewed attention after the characterization of the migration through the rostral migratory stream from the postnatal ventricular zone to the olfactory bulb (Menezes & Luskin, 1994; Lois & Alvarez-Buylla, 1994) and from the ganglionic eminence to the dorsal neocortex (De Carlos, Lopez-Mascaraque, & Valverde, 1996; Tamamaki, Fujimori, & Takauji, 1997). Studies in rodents also suggested a more widespread dispersion of clonally related cortical cells (reviewed in Rakic, 1995a; Tan et al., 1998; Reid, Liang, & Walsh, 1995). Although in rodents most of tangentially migrating cells in the dorsal neocortex are inhibitory GABAergic interneurons (reviewed in Marin & Rubenstein, 2001) there are also a number of migrating oligodendrocytes (He, Ingraham, Rising, Goderie, & Temple, 2001).

It should be underscored, however, that clonal analysis in the convoluted primate cortex revealed that the majority of migrating cells, both projection cells and interneurons, obey the radial constraints imposed by the radial glial scaffolding (Kornack & Rakic, 1995; see also Rakic, 2007, and the following section on the radial unit hypothesis). Also,

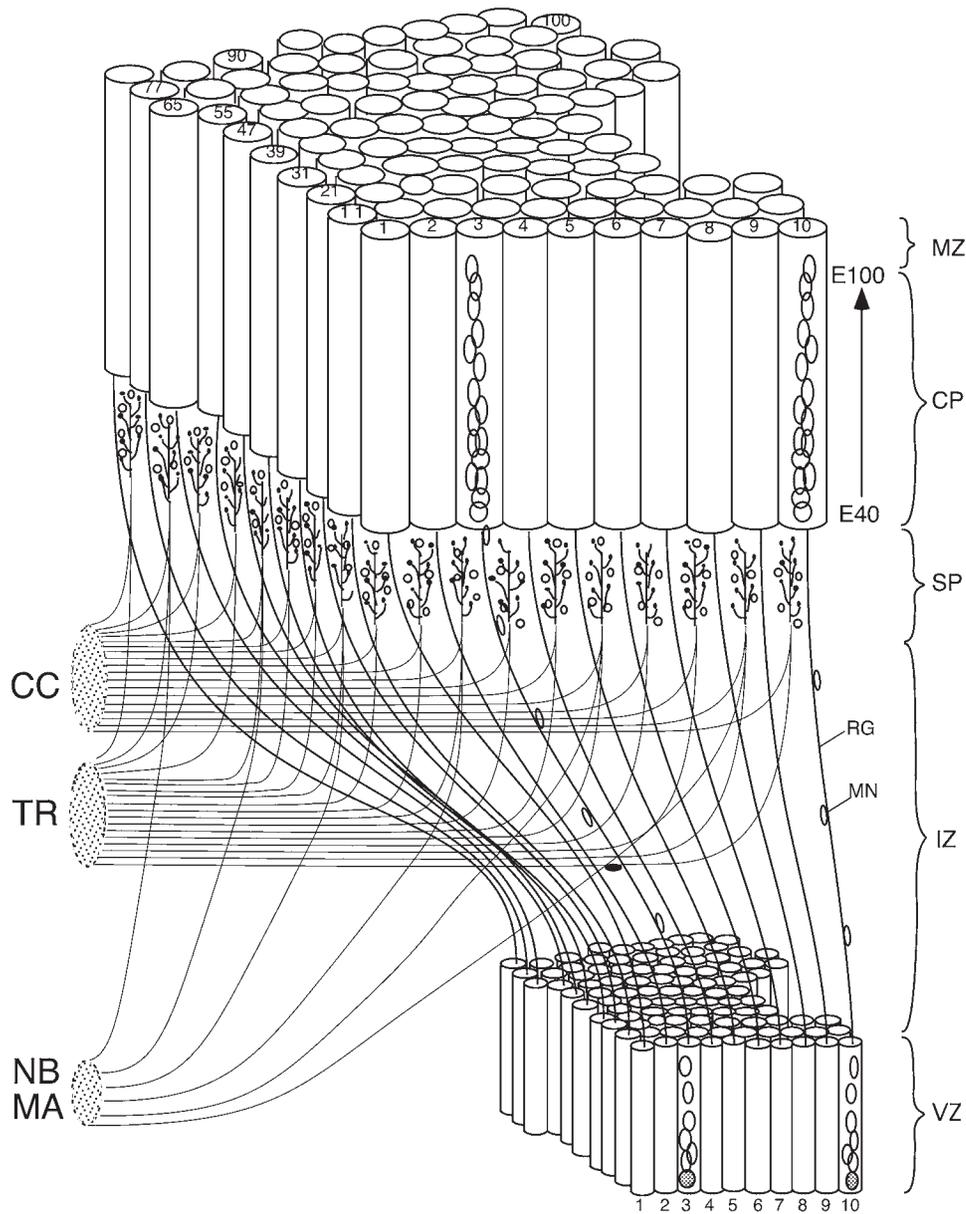

FIGURE 1.3 A three-dimensional illustration of the basic developmental events and types of cell-cell interactions occurring during the early stages of corticogenesis, before formation of the final pattern of cortical connections. This cartoon emphasizes radial migration, a predominant mode of neuronal movement which, in primates, underlies the elaborate columnar organization of the neocortex. After their last division, cohorts of migrating neurons (MN) first traverse the intermediate zone (IZ) and then the subplate zone (SP), where they have an opportunity to interact with “waiting” afferents arriving sequentially from the nucleus basalis and monoamine subcortical centers (NB, MA), from the thalamic radiation (TR), and from several ipsilateral and contralateral cortico-cortical bundles (CC). After the newly generated neurons bypass the earlier generated ones that are situated in the deep cortical layers, they settle at the interface between the developing cortical plate (CP) and the marginal zone (MZ), and eventually

form a radial stack of cells that share a common site of origin but are generated at different times. For example, neurons produced between E40 and E100 in radial unit 3 follow the same radial glial fascicle and form ontogenetic column 3. Although some cells, presumably neurophilic in the nature of their surface affinities, may detach from the cohort and move laterally, guided by an axonal bundle (e.g., horizontally oriented, black cell leaving radial unit 3 and horizontally oriented fibers), most postmitotic cells are gliophilic; that is, they have an affinity for the glial surface and strictly obey constraints imposed by transient radial glial scaffolding (RG). This cellular arrangement preserves the relationships between the proliferative mosaic of the ventricular zone (VZ) and the corresponding protomap within the SP and CP, even though the cortical surface in primates shifts considerably during the massive cerebral growth encountered in midgestation. (For details see Rakic, 1988.)

lineage analysis of transcription factors specific for either dorsal or ventral neocortex progenitor cells suggested that the majority of interneurons in the human cortex are derived from the VZ/SVZ of the dorsal neocortex (Letinic et al., 2002; Petanjek et al., 2009; Petanjek et al., 2008). This finding strongly suggests that the primate cortex may confer species-specific differences in basic developmental events compared to other mammalian species.

Considerable progress has been made in understanding the molecular mechanisms behind neuronal migration and the physical displacement of the cell perikarya during somal translocation across the densely packed tissue. Initially, based on an observation *in situ*, it was proposed that a single pair of binding, complementary molecules with gliophilic properties can account for the recognition of glial guides (Rakic, 1981). However, in recent decades many classes of recognition and adhesion molecules have been discovered and are being tested (e.g., Cameron and Rakic, 1994; Anton, Cameron, & Rakic, 1996; Hatten & Mason, 1990; Schachner et al., 1985; reviewed in Hatten, 2002). The subject is too large to be reviewed in detail here. However, it is important to mention that voltage- and ligand-gated ion channels on the leading process and cell soma of migrating neurons regulate the influx of calcium ions into migrating neurons (Komuro & Rakic, 1992, 1993, 1996; Rakic & Komuro, 1995). Calcium fluctuations, in turn, may trigger polymerization of cytoskeletal and contractile proteins essential for cell motility and translocation of the nucleus and surrounding cytoplasm.

It was clear that translocation of nucleus requires cytoskeletal rearrangement (Rivas & Hatten, 1995; Rakic, Knyihar-Csillik, & Csillik, 1996), and a host of molecules involved in this complex process have been identified. For example, Doublecortin and *Lis1* have been shown to be involved in cytoskeleton dynamics during neuronal migration (Gleeson, Lin, Flanagan, & Walsh, 1999; reviewed in Feng & Walsh, 2001), and their mutation in humans has been implicated in certain brain abnormalities such as Double Cortex (des Portes et al., 1998; Gleeson et al., 1998) and Lissencephaly Type I (Hattori, Adachi, Tsujimoto, Arai, & Inoue, 1994). Together these studies indicate that neuronal migration is a multifaceted developmental event, involving cell-to-cell recognition, differential adhesion, transmembrane signaling, and intracytoplasmic structural changes (Rakic et al., 1994).

Nuclear movement during both radial and tangential migration is a saltatory, two-step process alternating between resting and dynamic phases (Ang et al., 2003; Solecki, Model, Gaetz, Kapoor, & Hatten, 2004; Tsai & Gleeson, 2005). This process is evolutionarily conserved and involves a microtubule organizing center called centrosome that controls microtubule polymerization (Bornens, 2002). In radially migrating neurons, the centrosome controls the

formation of a microtubule network that surrounds the nucleus—the so-called perinuclear cage—and establishes a physical link between centrioles and nuclear membrane (Rakic, 1971; Gregory, Edmondson, Hatten, & Mason, 1988; Rivas & Hatten, 1995; Rakic et al., 1996; Solecki et al., 2004; Higginbotham & Gleeson, 2007; Tsai, Bremner, & Vallee, 2007; reviewed in Baudoin, Alvarez, Gaspar & Metin, 2008). A similar mechanism has been described in cells of the subventricular zone that migrate tangentially to the olfactory bulb in the postnatal brain (Schaar & McConnell, 2005) and, more recently, in radially migrating cortical neurons (Tsai et al., 2007). Together, these results suggest that the actin-myosin cytoskeleton might control nuclear movements in neurons exhibiting multiple (radial and tangential) modes of migration (Baudoin et al., 2008).

A simple model of selective molecular components involved in cell migration is provided on the diagram in figure 1.4. The initial discovery of the glial-guided radial migration in primates led to the proposal of the *radial unit hypothesis* (Rakic, 1988), which has served as a useful working model for research on the cellular and molecular mechanisms involved in normal and abnormal cortical development and evolution and will be summarized in the next section.

Radial unit hypothesis

The radial unit hypothesis of cortical development postulates that the embryonic cortical plate forms from vertically oriented cohorts of neurons generated at the same site in the proliferative ventricular zone, called proliferative units, which consist of radially deployed progenitors in different phases of the cell cycle (Rakic, 1978). Thus each radial unit consists of several clones (polyclones) that produce postmitotic neurons, which migrate to the cortex following glial fascicles spanning the fetal cerebral wall and forming ontogenetic columns (Rakic, 1988). After arriving at the cortical plate, the later-generated cells bypass earlier-generated ones and settle in an inside-out gradient of neurogenesis (Rakic, 1974). Thus the two-dimensional positional information of the proliferative units in the ventricular zone is transformed into a three-dimensional cortical architecture: the x - and y -axis position of the cells is provided by their site of origin, whereas the z -axis position is provided by their time of origin (figure 1.3).

The radial unit hypothesis relies on the proposal that neurons comprising a given radial column are clonally related, and this idea could be tested experimentally with the aid of the retroviral gene transfer method for *in vivo* analysis of cell lineages in the mammalian brain (Sanes, 1989). Use of this approach suggested that most progenitors originating in the same site of the ventricular

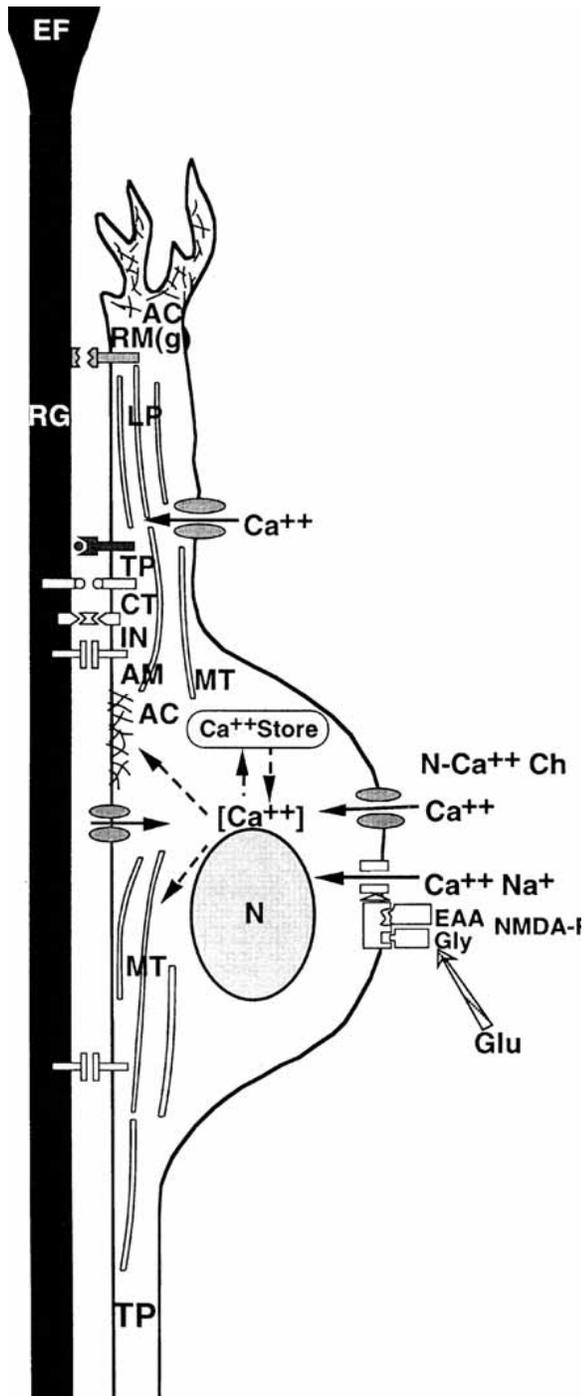

FIGURE 1.4 Model of a proposed cascade of cellular and molecular events that take place during the migration of postmitotic cells in the developing cerebral wall. After their last mitotic division in the ventricular zone, migrating cells extend a leading process (LP) that follows the contours of the radial glial fiber (RG) as it spans the expanding cerebral wall. The cytoskeleton within the LP and trailing process (TP) contains microtubules (MT) and actinlike contractile proteins (AC) that are involved in translocation of the cell nucleus (N) and the surrounding cytoplasm within the leading process until the cell enters the cortical plate. This system, maintained *in vitro* in slice preparations or imprint culture provides an opportunity to examine the role of the various molecules that are engaged in the recognition, adhesion, transmembrane signaling, and motility that underlie directed neuronal migration. The voltage-gated (N-type) and ligand-gated (NMDA-type) receptors/channels are thought to control calcium influx, which serve as messengers for execution of this movement. Abbreviations: AM, homotypic adhesion molecule; EAA, excitatory amino acid; EF, end foot of the radial glial fiber; Gly, glycine; LP, leading process; MT, microtubule; N, cell nucleus; TP, trailing process; RG, radial glial fiber; RM(g) gliophilic recognition molecule; TP, tyrosine phosphorylation. (Modified from Rakic, Cameron, & Komuro, 1994.)

even in the large and highly convoluted cerebrum, radial deployment of many clones is remarkably well preserved (Kornack & Rakic, 1995).

The radial unit hypothesis provides a conceptual frame to understand how changes in the dynamics of proliferation, migration, and survival of newly generated cells in the proliferative regions translates into changes in the thickness or surface area of the cortex during individual development and evolution (Rakic, 1988, 1995b). The study of this developmental mechanism has been done mainly using transgenic mice and retroviral approaches in nonhuman primates (e.g., Kornack & Rakic, 1995; Kuida et al., 1996, 1998; Zhong, Feder, Jiang, Jan, & Jan, 1996; Haydar, Kuan, Flavell, & Rakic, 1999). Based on these data on the time of cell origin and cell proliferation kinetics, we proposed that the number of cortical cells and the size and morphology of the cortex depends on the mode of mitotic division (symmetric versus asymmetric), the duration of the cell cycle, and the degree of programmed cell death in the proliferative zones (Rakic, 1988, 1995b), as is described in the next section. Since most genes involved in cell production and fate determination seem to be preserved during evolution, one might expect that the control of neuronal number and differentiation would be basically similar in all species (R. Williams & Herrup, 1988).

Determinants of cortical size

The size of the cortex varies greatly among mammals, but it is enormously enlarged in primates. This growth has not been homogeneous and has consisted in a great increase in surface area and a little increase in thickness

zone remain radially deployed in the cortex (Luskin et al., 1988; Kornack & Rakic, 1995; Tan et al., 1998; see, however, Reid et al., 1995). Furthermore, a number of studies in chimeric and transgenic mice have provided evidence that a majority of postmitotic, clonally related neurons move and remain radially distributed in the cortex (e.g., Nakatsuji, Kadokawa, & Suemori, 1991; Soriano, Dumesnil, Auladell, Cohen-Tannoudji, & Sotelo, 1995; reviewed in Rakic, 1995a). The use of the retroviral gene transfer method in the embryonic primate brain showed that

(the surface area of the human cortex is a thousandfold larger than that of the mouse, but its thickness is only about two or three times that of the mouse cortex). This asymmetric growth seems to be related to the anatomical and functional structure of the neocortex that has been described as formed by iterative units (named radial columns, cortical columns, or cortical modules), consisting in a columnar array of neurons that share a common basic scheme of intrinsic and extrinsic connectivity and subserve the same function (Mountcastle, 1997; Szentagothai, 1978; Goldman-Rakic, 1987). The larger the cortex in a given species, the larger the number of participating columnar units (Rakic, 1978, 1995b). The liberal use of the broad and undefined term “cortical column” has caused considerable confusion in the literature, since there is not a unique anatomical or functional columnar unit that applies to all cortical areas or species (Rakic, Ayoub, Dominguez, & Breunig, in press). In spite of this heterogeneity, there is consensus concerning the idea that the cortex is composed of an array of columnar units of operation.

Under this perspective, it seems that the addition of new functions to the cortex does not require a substantial increase in the thickness of the cortex, namely, in the number of components within the cortical units of operation (in spite of a very likely increase in their complexity), but would mainly correspond with the addition of new columnar units, which ultimately would contribute to the forming of new cortical regions and functional domains. In this respect, the radial unit hypothesis provides a mechanistic explanation of the large expansion of cortical surface without a concomitant significant increase in thickness during phylogenetic and ontogenetic cortical development (Rakic, 1988). It also shows how the genes controlling the number of founder cells in the mosaic of proliferative units at the ventricular surface set a limit on the size of the cortical surface during the development of the individual, as well as during the evolution of mammalian species (Rakic, 1995b). For example, a relatively small change in the timing of developmental cellular events could have large functional consequences: a minor increase in the length of the cell cycle or the magnitude of cell death in the ventricular zone could result in a large increase in the number of founder cells that form proliferative units (Rakic, 1988). Since proliferation in the ventricular zone initially proceeds exponentially because of the prevalence of symmetrical divisions, an additional round of mitotic cycles during this phase doubles the number of founder cells and, consequently, the number of ontogenetic radial columns (figure 1.5 and Rakic, 1995b). According to this model, fewer than four extra rounds of symmetrical cell divisions in the ventricular zone before the onset of corticogenesis can account for a tenfold difference in the cortical surface area. Since the mode of cell division changes to predominantly asymmetrical after the onset of corticogenesis,

one can predict that the cell production period in humans will be about two weeks longer than in macaques, but should enlarge the cortical thickness by only 10% to 15%, a result which is actually observed (Rakic, 1995b). Thus, as illustrated in figure 1.5, even a small delay in the onset of the second phase of corticogenesis results in an order-of-magnitude larger cortical surface because of the increasing number of founder cells at the ventricular zone. This has been observed in mice expressing higher levels of β -catenin that enhance the number of founder cells and can lead to the formation of ectopias as well as an expanded cortical plate that begins to form convolutions (Chenn & Walsh, 2002, 2003).

In addition, the number of cortical neurons will depend on the degree of survival of the generated cells, and thus one mechanism that regulates the number of cells produced in the ventricular zone is programmed cell death (PCD) or apoptosis. Although PCD has been considered a major factor contributing to the formation of the vertebrate brain (Glucksmann, 1952), contemporary research has focused mainly on the histogenetic cell death involved in the elimination of inappropriate axonal connections at the later stages of development (e.g., Rakic & Riley, 1983a, 1983b; Oppenheim, 1991). However, the discovery of several classes of genes involved in apoptosis, which were initially identified in invertebrates, created the opportunity to study this phenomenon in the mammalian cerebrum. For example, a family of enzymes called caspases has been shown to play an important role in apoptosis in a variety of organs and tissues (Ellis & Horvitz, 1991). We have demonstrated that in mouse embryos deficient in caspase 9 and 3, fewer cells are eliminated than in their littermates (Kuida et al., 1996, 1998). Reduction of apoptosis in the knockout mice for these caspases results in the formation of supernumerary founder cells in the cerebral ventricular zone. As a consequence, these mice form ectopic cells in the intermediate zone as well as a larger cortical plate with more radial units. Correspondingly, diminishment of the clearance rate of apoptotic cells in transgenic mice lacking a receptor crucial for the recognition of dying cells results in enlarged proliferative zones that lead to the formation of ectopias as well as an expanded cortical plate that begins to form convolutions (Haydar et al., 1999).

In both cases, by increase of the founder population or by reduction of apoptosis, the result is a larger cortical sheet that begins to buckle and forms incipient convolutions, without significant change in thickness of the developing cortical plate (Haydar et al., 1999; Chenn & Walsh, 2002). This result is a good example of how the mutation of a few key genes that control the reduction of cells could result in the expansion of the cortex and the appearance of convolutions during the evolution of the cerebral cortex (Rakic, 1995b).

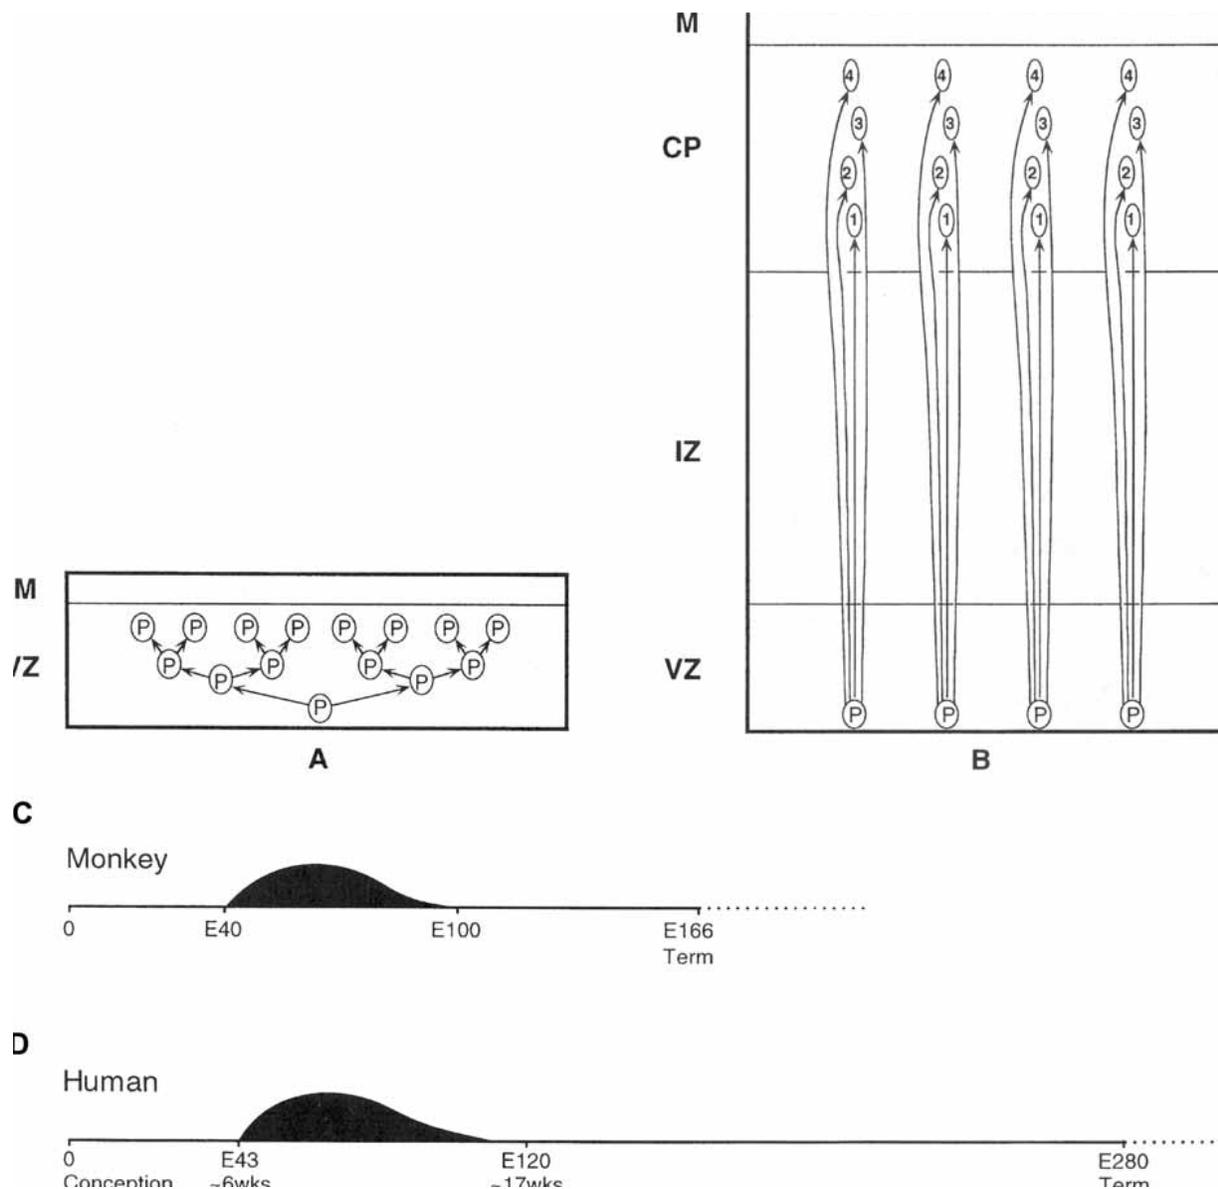

FIGURE 1.5 (A) Schematic model of symmetrical cell divisions that predominate before E40. At this early embryonic age, the cerebral wall consists of only the ventricular zone (VZ), where all the cells are proliferating, and the marginal zone (M), into which some cells extend radial processes. Symmetric division produces two progenitors (P) during each cycle and causes rapid horizontal lateral spread. (B) Model of asymmetrical or stem division that becomes predominant in the monkey embryo after E40. During each asymmetrical division a progenitor (P) produces one postmitotic neuron that leaves the ventricular zone and another progenitor that remains within the proliferative zone and continues to

divide. Postmitotic neurons migrate rapidly across the intermediate zone (IZ) and become arranged vertically in the cortical plate (CP) in reverse order of their arrival (1, 2, 3, and 4). (C) Diagrammatic representation of the time of neuron origin in the macaque monkey. The data were obtained from ^3H -thymidine autoradiographic analyses (from Rakic, 1995b). (D) Estimate of the time of neuron origin in the human neocortex based on the number of mitotic figures within the ventricular zone, supravital DNA synthesis in slice preparations of fetal tissue, and the presence of migrating neurons in the intermediate zone of the human fetal cerebrum. (From Rakic, 1995b.)

Protomap hypothesis

A major challenge to students of the cerebral cortex is how individual and species-specific cytoarchitectonic areas have emerged from the initially seemingly uniform ventricular zone and cortical plate. Both intrinsic and extrinsic factors have been suggested. One attractive model, known as the *tabula rasa* hypothesis, is that all cortical neurons are equipotent and that laminar and areal differences are induced by extrinsic influences exerted via thalamic afferents (Creutzfeldt, 1977). However, there was also considerable evidence that the cells generated within the embryonic cerebral wall contained some intrinsic information about their prospective species-specific cortical organization. The *protomap hypothesis* was proposed as an empirical generalization in an attempt to reconcile available experimental and descriptive data in this field (Rakic, 1988). It was based on the fact that all ontogenetic columns are mixtures of several clones and are not equal in each prospective cytoarchitectonic area (footnote 13 in Rakic, 1988). The protomap model suggests that the basic pattern of cytoarchitectonic areas emerges through synergistic, interdependent interactions between developmental programs intrinsic to cortical neurons and extrinsic signals supplied by specific inputs from subcortical structures. According to this hypothesis, neurons in the embryonic cortical plate—indeed even in the proliferative ventricular zone where they originate—set up a primordial map that preferentially attracts appropriate afferents and has a capacity to respond to this input in a specific manner. The prefix *proto* was introduced to emphasize the primordial, provisional, and essentially malleable character of the *map*, which is subject to considerable modification by the extrinsic influences exerted at later stages (Rakic, 1988).

The initial indication that developmental events in the proliferative ventricular zone foreshadow prospective regional differences in the overlying cerebral mantle comes from the observation that the neurogenesis of the primary visual cortex, which contains more neurons per radial unit than the adjacent areas, lasts longer (Rakic, 1976a). Furthermore, it has also been demonstrated that the mitotic index in the ventricular region subjacent to this area is higher than in adjacent regions (Dehay, Giroud, Berland, Smart, & Kennedy, 1993). In addition, initial establishment of cytoarchitectural and functional features specific to the visual cortex, such as the ocular dominance columns, form independently of thalamic inputs to this area (Crowley & Katz, 2000). Therefore, certain region-specific differences in the production of the ventricular zone can be detected even before neurons arrive at the cortex (Rakic, 1988; Kennedy & Dehay, 1993; Algan & Rakic, 1997). In addition, several lines of evidence indicate that, during the final cell division, one or both daughter cells start to express a variety of neuron-class-specific signaling molecules (LoTurco, Owens,

Heath, Davis, & Kriegstein, 1995; Lidow & Rakic, 1994). Postmitotic cells not only become committed to a neuronal fate but also become restricted in their repertoire of possible fates (McConnell, 1988). Numerous studies in which the cytology of postmitotic cells has been examined (e.g., Schwartz, Rakic, & Goldman-Rakic, 1991; LoTurco et al., 1995) and/or manipulated by a variety of methods such as spontaneous mutations (e.g., Caviness & Rakic, 1978; Rakic, 1995b), ionizing radiation (Algan & Rakic, 1997), retroviral gene transfer labeling (Parnavelas, Barfield, Franke, & Luskin, 1991), transgenic inserts (Kuida et al., 1996), and heterochronic transplantations (McConnell, 1988; McConnell & Kaznowski, 1991) all indicate that certain class-specific cell attributes are expressed before the migrating neurons arrive at the cortical plate and become synaptically connected. Remarkably, neurotransmitter secretion is unnecessary for proper brain formation (Verhage et al., 2000). In addition, retroviral tracing experiments and some clonal analyses suggest that the ventricular zone is comprised of a heterogeneous population of cells, and that cell lineage contributes substantially to the cell fate determination of neurons (Acklin & van der Kooy, 1993; Parnavelas et al., 1991; Kornack & Rakic, 1995; B. Williams & Price, 1995; Kuan, Elliott, Flavell, & Rakic, 1997). Emerging observations confirm and extend these findings both within the cortex, in migrating interneurons, and later postnatally (Rakic et al., in press; Merkle, Mirzadeh, & Alvarez-Buylla, 2007; Batista-Brito, Machold, Klein, & Fishell, 2008).

These findings raise the question of whether laminar and areal identities of cortical plate cells provide cues or chemoattractants for incoming afferent axons. Data from axonal tracing indicate that afferent connections from subcortical structures and other cortical regions find their way to the specific regions of the cortical plate either directly or by way of the subplate zone or both (Kostovic & Rakic, 1984, 1990; De Carlos & O'Leary, 1992; McConnell et al., 1994; Agmon, Yang, Jones, & O'Dowd, 1995; Catalano, Robertson, & Killackey, 1996; Richards, Koester, Tuttle, & O'Leary, 1997), suggesting the existence of region-specific attractants for pathfinding and target recognition. In support of this idea the development of correct topological connections in anophthalmic mice and in early enucleated animals indicates that basic connections and chemoarchitectonic characteristics can form in the absence of information from the periphery (e.g., Kaiserman-Abramof, Graybiel, & Nauta, 1980; Olavarria & van Sluyters, 1984; Rakic, 1988; Kennedy & DeHay, 1988; Kuljis & Rakic, 1990; Rakic & Lidow, 1995; Miyashita-Lin, Hevner, Wassarman, Martinez, & Rubenstein, 1999).

The gradients or region-specific distribution of various morphoregulatory molecules (or both) in the embryonic cerebral wall (e.g., Arimatsu et al., 1992; Levitt, Barbe, & Eagleson, 1997; Ferri & Levitt, 1993; Porteus, Bulfone,

Ciaranello, & Rubenstein, 1991; Bulfone et al., 1993; Cohen-Tannoudji, Babinet, & Wassef, 1994; Emerling & Lander, 1994; Donoghue & Rakic, 1999; Sestan, Rakic, & Donoghue, 2001; Bishop, Goudreau, & O'Leary, 2000) or layer-specific expression of POU-homeodomain genes (e.g., Frantz, Bohner, Akers, & McConnell, 1994; Meissirel, Wikler, Chalupa, & Rakic, 1997) may also contribute to the formation of specified axonal pathways. For example, electroporation of FGF8 applied before beginning of formation of thalamic connections has shown that morphoregulatory molecules can shift the anterior/posterior areal boundaries in the developing neocortex (Fukuchi-Shimogori & Grove, 2001). Thus tangentially and radially distinct landmarks in the postmitotic cells facilitate axonal pathfinding and target recognition that eventually lead to parcellation of the cerebral cortex.

It should be underscored that although the embryonic cerebral wall exhibits gradients of several morphoregulatory molecules, as well as other specific area-specific molecular differences, the protomap within the embryonic cerebrum provides only a set of species-specific genetic instructions and biological constraints. The precise position of interareal borders, the overall size of each cytoarchitectonic area, and the details of their cellular and synaptic characteristics in the adult cerebral cortex are achieved through a cascade of reciprocal interactions between cortical neurons and the cues they receive from afferents arriving from a variety of extracortical sources (Rakic, 1988). Such afferents may serve to coordinate and adjust the ratio of various cell classes with the subcortical structures, as has been shown in the primary visual system (Meissirel et al., 1997; Rakic, Suner, & Williams, 1991; Kennedy & Dehay, 1993; Rakic & Lidow, 1995). In summary, the concept of the cortical protomap includes the role of both intrinsic and extrinsic determinants in shaping the final pattern and relative sizes of the cytoarchitectonic areas.

Initial formation of synaptic connections

Acquiring areal and laminar positions and phenotypes comprises only the first and most fundamental steps in the formation of species-specific cortical development. However, an equally important next step is the formation of synaptic connections. It is a very large subject, is studied by most developmental neurobiologists, and by itself deserves more than a short section. It is in part covered in the subsequent chapters, and it is only briefly reviewed here to emphasize that in primates, and particularly in the human, it is a prolonged process that involves overproduction of cells, axons, and synapses and their later elimination in response to environmental influences. This process is often called neuroplasticity, and we consider it as a phase of the normal course of brain development. In the macaque monkey it

peaks after birth and lasts at least 3–4 years, and in the human it lasts 15–19 years.

Detailed studies in the rhesus monkey showed that both neurons and their axons are overproduced in the cerebral cortex during well-delineated stages of development. For example, there are about 40% more neurons in the monkey visual cortex during the second half of pregnancy than in the adult. Furthermore, a newborn monkey has almost 200 million callosal axons compared to less than 50 million in the adult (LaMantia & Rakic, 1990). The axons are lost at the rate of about 8 million per day or 50 per second during the first three weeks after birth. Thereafter, they are lost at an estimated rate of half a million per day or 5 per second until the adult value is reached. Similar magnitude of elimination of callosal axons has been reported for other mammalian species (e.g., Berbel & Innocenti, 1988). The functional significance of this loss of axons is not fully understood, but the prevailing hypothesis has been that activity-dependent stabilization plays a critical role.

In the rhesus monkey, during the first two to three months of postnatal life, synaptic density increases rapidly and reaches a peak that is about two times higher than in the adult. This synaptic density well above the adult level lasts throughout infancy and adolescence. We have calculated that about 1.8×10^{11} synapses are lost in the visual cortex of a single cerebral hemisphere during puberty in the monkey (Bourgeois & Rakic, 1993). The magnitude of this decline is stunning when expressed as loss of about 2500 synapses per second during this period. Since other areas, including association cortices, simultaneously undergo comparable synaptic loss, more than 30,000 synapses per second are deleted from the entire cortical mantle during monkey adolescence (Bourgeois & Rakic, 1993). In the human, in whom this period of life last about three times longer but the cortex is ten times larger, the synapses may be lost at the rate of 100,000 per second.

The decline in synaptic density is due primarily to elimination of excitatory junctions located on dendritic spines, while inhibitory synapses on dendritic shafts remain relatively constant. Other results showed that the density of major neurotransmitter receptors in the cortex also reaches a maximum level between two and four months of age and then declines to the adult level during the period of sexual maturation (Lidow, Goldman-Rakic, & Rakic, 1991). These findings revealed an unusual coordination between biochemical and structural differentiation and indicated that these events may be related to maturation of function.

The prolonged phase of postnatal development in primates provides unparalleled opportunity for competitive activity-driven stabilization among initially supernumerary inter- and intracortical connections. The formation of the final pattern of cortical connections is achieved through dynamic interactions that involve at least two well-defined

steps. In the first step, one set of axons project to the target structure guided by prespecified short-lived molecular markers, without regard to specific location on the individual neurons or their parts (Easter, Purves, Rakic, & Spitzer, 1985). In the second step, which is activity dependent, synaptic connections are sorted out and remain on only selective sets of neurons or their dendrites. Our experimental studies of the formation of binocular vision in primates provide a dramatic example of this biphasic development and support the hypothesis that competitive interactions between two or more populations of neurons play a significant role in the elimination of the axons and segregation of their synapses (Rakic, 1976a, 1977, 1981).

This phase of cortical development has a profound significance for understanding development of human cognitive abilities. Some implications are obvious. For example, our educational system, which postpones disciplined intellectual learning until later stages in life, may not be biologically optimal, as the first 15 years may be the most important formative phase as far as synaptic stabilization is concerned. It is well known that high-level professional musicians or athletes can be created only at a specific critical age, and there is no reason why other cognitive skills essential for human intellectual abilities are not set up also at this time. Our data provide biological support for intensive targeted intellectual training that starts in childhood if we expect optimal results.

Timing of cortical genesis in the human

Since our ultimate goal is understanding the development of the neocortex in humans, the comparison of selected cellular features of the human cortex at different prenatal stages with that of the macaque monkey may help to determine the corresponding time and sequence of developmental events in these species. This determination is essential if we want to apply the findings obtained from experimental animals to the understanding of human cortical development (e.g., Chalupa & Wefers, 2000). To this end, Poliakov's comprehensive histological studies of cortical development in human fetuses, published originally in the Russian literature (e.g., Poliakov, 1959, 1965) have been reviewed in more detail elsewhere (Sidman & Rakic, 1982), but are presented here summarized in figure 1.6 and compared with the timing of corresponding events in the macaque monkey.

Stage I Initial formation of the cortical plate (from approximately the 6th to the 10th fetal weeks). During the 7th fetal week, postmitotic cells begin to migrate from the ventricular zone outward to form a new accumulation of cells at the junction of the intermediate and marginal zones. By the middle of this period, synapses of unknown origin are present above and below the cortical plate (Molliver,

Kostovic, & van der Loos, 1973; Zecevic, 1998). This stage corresponds approximately to the level of cortical development found in the monkey fetus between E40 and E54, depending on the region.

Stage II Primary condensation of the cortical plate (through approximately the 10th and 11th fetal weeks). At this stage the cortical plate increases in thickness, becomes more compact, and is clearly demarcated from the fiber-rich part of the intermediate zone, which seems to have fewer cells per unit volume, indicating that the first major wave of migration is almost spent (figure 1.6). The end of this stage corresponds approximately to the E55–E59 period in the monkey when the majority of neurons of layers 5 and 6 are generated in most regions of the cortex (Sidman & Rakic, 1982; Marin-Padilla, 1988).

Stage III Bilaminar cortical plate (most pronounced during the 11th to the 13th fetal week). The uniform and compact cortical plate of the second stage becomes subdivided into an inner zone occupied mainly by cells with relatively large, somewhat widely spaced oval nuclei and an outer zone of cells with densely packed, darker, bipolar nuclei (figure 1.6). This heterogeneity results from the more advanced maturation of the deep-lying neurons that had arrived at the cortical plate during earlier developmental stages, plus the addition of a new wave of somas of immature neurons that take up more superficial positions. This period is also characterized by the appearance of the cell-sparse, fiber-rich subplate zone situated below the cortical plate. This transient embryonic zone in the human fetus is particularly wide in the regions subjacent to the association areas (Kostovic & Rakic, 1990). The third stage corresponds roughly to the level of development achieved in the monkey between E59 and E64.

Stage IV Secondary condensation (from the 13th to the 15th fetal week). During this period of gestation, the ventricular zone becomes progressively thinner, while the subventricular zone remains relatively wide (figure 1.6). The cortical plate again becomes homogeneous in appearance and resembles, in a sense, a thickened version of Stage II. The reason for this change may be that, in Stage IV, most of the young neurons in the cortex become considerably larger as they differentiate, while relatively few new immature neurons enter the cortical plate. The result is a more uniform appearance. At the end of this stage, an accumulation of large cells appears below the cortical plate, and the subplate zone enlarges further (Kostovic & Rakic, 1990). Depending on the cortical region, this stage appears in the monkey between E64 and E75.

Stage V Prolonged stage of cortical maturation (from the 16th fetal week continuing well into the postnatal period).

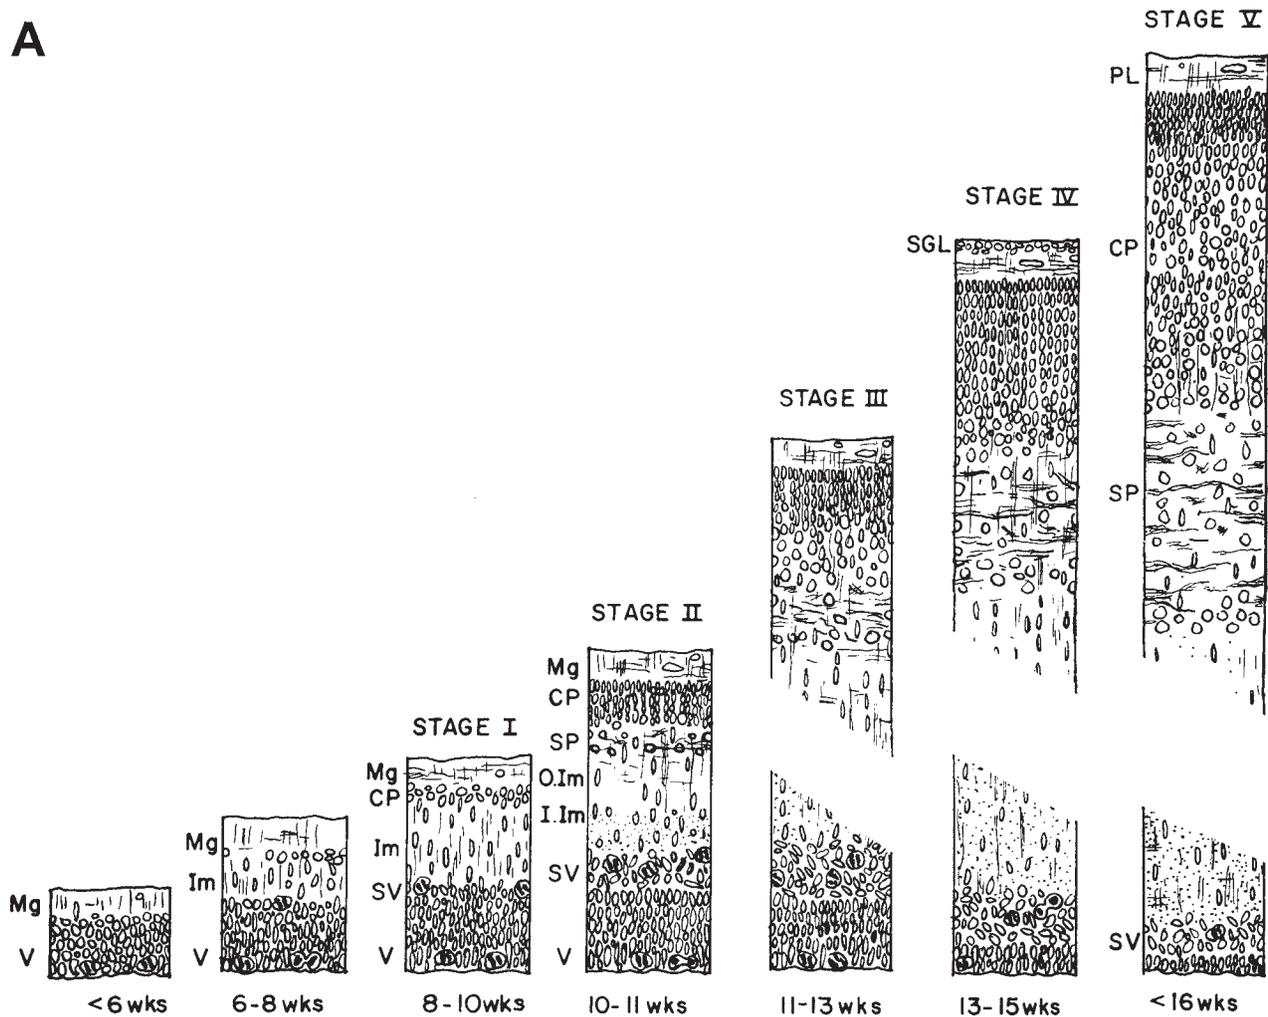

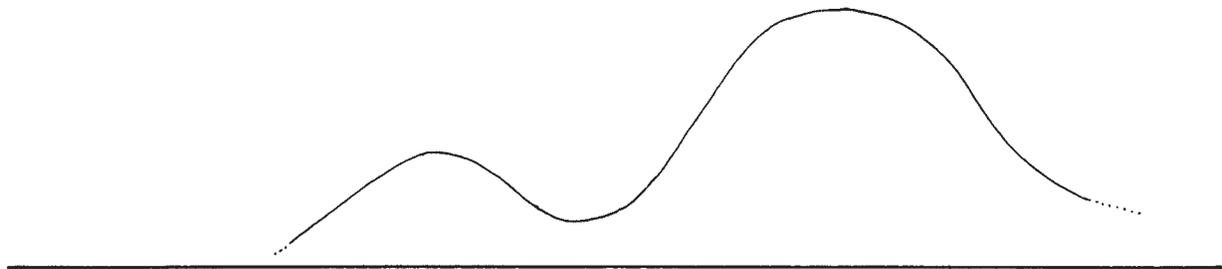

A**B**

FIGURE 1.6 (A) Semidiagrammatic drawings of the human cerebral wall at various gestational ages listed in fetal weeks below each column. The stages refer specifically to an arbitrarily chosen cortical area situated midway along the lateral surface of the hemisphere (detailed in Sidman & Rakic, 1982). Because there is a gradient of maturation, as many as three of five stages of cortical development may be observed in different regions of the neocortex in the same fetal brain. In the three columns on the right, the intermediate zone is not drawn in full because the thickness of the cerebral wall is increased markedly compared with earlier stages and cannot fit into

the drawing. In addition, in the last three stages the subplate zone, situated below the cortical plate, appears (Kostovic & Rakic, 1990). (B) The curve below the drawing schematically indicates waves of cell migration to the neocortex assessed by the density of migrating neurons in the intermediate zone. Abbreviations: CP, cortical plate; Im, intermediate zone; I.Im and O.Im, inner and outer intermediate zones, respectively; Mg, marginal zone; PL, plexiform layer; SGL, subpial granular layer; SP, subplate zone; SV, subventricular zone; V, ventricular zone; wks, age in fetal weeks. (From Rakic, 1988.)

Morphological data are inadequate to determine for how long neurons continue to migrate to the human neocortex after 16 weeks or how many do so, and hence the line at the right side of the curve is dotted in figure 1.6*B*. By the fifth month, relatively few neuronal precursors seem to be proliferating in the reduced ventricular zone of the human cerebral hemispheres. However, the interneurons, which continue to be generated in the subventricular zone and ganglionic eminence, are still being added to the cortex between the 20th and 25th weeks of gestation (Letinic et al., 2002). A comparison of the autoradiographic results in the monkey (Rakic, 1974, 1977) with comparable stages in human (Rakic & Sidman, 1968; Marin-Padilla, 1988; Kostovic & Rakic, 1990) indicates that most neurons of the human neocortex are generated before the beginning of the third trimester of gestation. Toward term, the ventricular zone disappears, the subplate zone dissolves, and as the intermediate zone transforms into the white matter, only a vestige of the subplate cells remain as interstitial neurons (Kostovic & Rakic, 1980). It should be emphasized that during neurogenesis and after completion of neurogenesis, glial cells are generated and migrate across the cerebral wall. This phenomenon is particularly pronounced in the human forebrain where glial cells including oligos largely outnumber neurons. After all cortical neurons have been generated and attained their final positions, their differentiation, including the formation of synapses, proceeds for a long time and reaches a peak only during the second postnatal year. The subject of synaptogenesis in the cerebral cortex of both macaque monkeys and humans was reviewed in the second edition of this volume (Bourgeois, Goldman-Rakic, & Rakic, 2000) and not much new research has been done in this area since.

The human factor

As mentioned before, traditional research on the cerebral cortex of mammals has recognized the quantitative differences (e.g., in the period of neurogenesis, number of progenitors, and duration of the cell cycle) that simply relate to the expansion of the forebrain, and particularly the great increase in size of cerebral cortex in primates, although other unique human characteristics have been neglected, perhaps because so few investigators work on the development of the human cerebrum. In this chapter we have exposed in some detail those differences, giving some insight on their possible contribution to the specification of the human cortical features. To finish this chapter, we would like to summarize those differences—and some others not mentioned before—that we think might contribute to establishing the differences in the cognitive potential of the primate, and specifically of the human, cortex.

- There is a pronounced gradient of maturation across the large hemispheres in primates (Donoghue & Rakic, 1999) that is much less visible in species with smaller forebrains, and especially in species with marked altricial growth strategies, such as mice and rats, that exhibit a short and fast brain development.

- Radial glial cells are particularly prominent in the embryonic primate cerebrum; they start expressing GFAP at the very start of corticogenesis (Levitt & Rakic, 1980; Levitt et al., 1981), and a subset of them transiently stop dividing (Schmechel & Rakic, 1979).

- The primate SVZ is dramatically enlarged and exhibits much more complexity in cellular organization in primates than in other species (Smart et al., 2002; Bystron et al., 2008). Another related feature is the appearance, in mid-gestation in human (~22 weeks) and monkey (~E72), of a band of tangentially orientated axons that divides the SVZ into inner and outer sublayers in some parts of the cortex (Bystron et al., 2008).

- A subpial granular layer has been described in humans that has not been observed in rodents. This is a long-known feature of human development (e.g., Brun, 1965) that is however systematically ignored at the present time.

- The reported differences in the developmental processes between species are reflected in the final cellular output, and, for example, the proportion of GABAergic interneurons exhibits a marked difference between rodents and primates: GABAergic interneurons represent approximately 15% of the total population of neurons in the rat neocortex (Beaulieu, 1993; Micheva & Beaulieu, 1995; Meinecke & Peters, 1987), whereas in the primates and the human, this proportion reaches 20% in the visual cortex and up to 25% in other cortical areas (Hendry, Schwark, Jones, & Yan, 1987; Beaulieu, Kisvarday, Somogyi, Cynader, & Cowey, 1992; Del Rio & DeFelipe, 1996). In addition, some GABAergic cell types like the double-bouquet cells are absent in rodents but can be detected in carnivores and are much more abundant and well developed in primates and more specifically in humans (Yanez et al., 2005). Double-bouquet interneurons are characterized by the presence of a long and narrow descending bundle of axons that are distributed following a microcolumnar pattern in the neocortex. The axons of double-bouquet cells establish hundreds of synapses with a narrow column of tissue, and therefore they have been proposed as key elements in the microcolumnar organization of the cortex, acting on pyramidal cells from different layers within the minicolumns (DeFelipe, Hendry, Hashikawa, Molinari, & Jones, 1990; Jones, 2000; Yanez et al., 2005).

Regarding excitatory neurons, differences have been reported in the size and pattern of arborization of projection neurons: pyramidal cells from the human prefrontal cortex

are bigger than those from other species, have larger and more complex basal dendritic fields, and also have a higher density of dendritic spines (Campbell & Morrison, 1989; Benavides-Piccione, Ballesteros-Yanez, DeFelipe, & Yuste, 2002; Elston, Benavides-Piccione, & DeFelipe, 2001; Elston et al., 2006). This increase is beyond scaling of cell structure and reflects specific specializations that allow human pyramidal cells from highly associative cortices to receive more synaptic inputs from more diverse origins, and therefore to be capable of integrating more information (Elston, 2003). In addition, specific subtypes have been described, such as the spindle cells that seem to be specific to some mammalian orders, and these are particularly abundant in restricted cortical regions of great apes and especially in humans (Nimchinsky et al., 1999; Allman, Hakeem, & Watson, 2002; Marino et al., 2007).

These marked differences in the cellular composition of the neocortex, from predecessor cells to GABAergic interneurons or glial cells, have to be taken into consideration if we are poised to understand the distinctively human aspects of behavior and cognition and the uniquely human cognitive disorders such as autism, dyslexia, or schizophrenia that probably involve genetic anomalies affecting the regulation of human-specific developmental features.

2 Early Development of Neuronal Circuitry of the Human Prefrontal Cortex

IVICA KOSTOVIĆ AND MILOŠ JUDAŠ

ABSTRACT The early development of cortical circuitry provides the biological substrate for human cognitive and psychological maturation. Neuronal circuitry of the human frontal cortex appears around the eighth postconceptional week (8 PCW) with two synaptic strata, engagement of fetal neurons, and spontaneous activity. Midfetal and late-fetal cortex show transient lamination, differentiation of subplate, deep synaptogenesis, and growth of thalamocortical afferents. Cortical interaction with thalamic afferents occurs around 24 PCW. Late preterm and neonatal periods are characterized by growth of cortico-cortical fibers and resolution of transient circuitry. During early infancy (2–6 months) rapid synaptogenesis coincides with reorganization of cortico-cortical pathways. Initial environmentally driven “cognitive” circuitry consists of increased number of synapses, differentiated layer V pyramids, “dormant” layer III pyramids and appearance of inhibitory neurons. Full maturity of layer III pyramids, local circuitry neurons and maximal number of synapses is not achieved until 12–24 months when circuitry is layer III “centered” and socially driven. In summary, endogeneous and sensory-driven circuitry develops during prenatal life, initial “cognitive” circuitry appears in late infancy, and maximal number of synapses and full maturity of layer III develop during early childhood.

In revealing the neurobiological basis of cognitive and psychological development in humans, neuroscientists mostly depend on close correspondence between structural, functional, and behavioral features during specific phases of development (Casey, Giedd, & Thomas, 2000; Casey, Tottenham, Liston, & Durston, 2005; Hammock & Levitt, 2006; Kagan & Baird, 2004; Levitt, 2003). Because the neural circuitry that underlies cognitive development is expected to be simpler in the developing than in the adult brain, the developmental approach should provide an easier analysis of principal elements of the neuronal circuitry: synapses, presynaptic axons, and postsynaptic neurons.

It is difficult to correlate structure and function in the developing neuronal circuitry of the frontal lobe because of

its complexity (Goldman-Rakic, 1987), life-long maturation (Chugani, Phelps, & Mazziotta, 1987; Fuster, 2002; Giedd et al., 1999; Goldman-Rakic, 1987; Huttenlocher & Dabholkar, 1997; Kostović, Petanjek, Delalle, & Judaš, 1992; Petanjek, Judaš, Kostović, & Uylings, 2008; Sowell et al., 2004) and the existence of human-specific functions (Preuss, 2004; Werker & Vouloumanos, 2001).

Which component of the prefrontal cortical circuitry develops already in utero, that is, before birth? And, knowing that typical prefrontal executive functions develop postnatally, what would be its functional roles during fetal life? In other words, what functions may the prefrontal cortex subserve before the onset of cognition, during the so-called precognition period of life? One would also like to pinpoint qualitative and quantitative features of the maturational status of prefrontal circuitry at the end of the first postnatal year: what level of maturation of prefrontal cortex is required for the onset of cognition and language?

In this review, we summarize the data available on early development of human frontal lobe circuitry, describe new data on neurogenetic events obtained with neuroimaging and fine neurohistological studies, and propose structural criteria for delineation of phases in prefrontal circuitry development. We cover the period from the appearance of the cortical plate and establishment of first cortical synaptic contacts (at 8 PCW) to the third year of life when pyramidal neurons of layer III attain size and complexity greater than those of layer V pyramidal neurons, and language and cognition are already well established (see table 2.1). The following frontal cortical regions will be described: dorsolateral, dorsomedial, orbitomedial, precingulate (area 32), and anterior cingulate (area 24).

Development of neuronal circuitry of the human prefrontal cortex during the early fetal period

STRUCTURAL ORGANIZATION The first cortical cells appear in the neocortical preplate or primordial plexiform layer (Bystron, Rakic, Molnar, & Blakemore, 2006; Bystron,

IVICA KOSTOVIĆ and MILOŠ JUDAŠ Croatian Institute for Brain Research, School of Medicine, University of Zagreb, Zagreb, Croatia

TABLE 2.1
Early development of human frontal lobe circuitry

Period	Age Range	Description of Circuitry	Type of Circuitry	Type of Activity
Embryonic	6–7 PCW	Nonsynaptic preplate network	Oscillating, spontaneous	Endogenous
Early fetal	8–14 PCW	Two synaptic strata, in SP and MZ; monoaminergic afferents; regional differences	Transient spontaneous modulated by monoamines	Endogenous + brain stem and cholinergic basal forebrain
Midfetal and late fetal	15–23 PCW	Transient lamination, prominent SP, and deep synaptogenesis	Transient spontaneous, modulated by extrinsic thalamic afferents	Endogenous
Early preterm	24–32 PCW	The peak of SP, thalamic afferents in CP	Transient circuitry and permanent thalamocortical afferents coexist	Sensory-sensitive asynchrony (EEG), experience independent
Late preterm	33–35 PCW	Synaptogenesis in CP, pyramidal differentiation, cytoarchitectonic belts	Coexistence of increasingly permanent and transient circuitry	Sensory-sensitive synchrony (EEG), experience expectant
Neonatal	1–2 months	Long afferents within the target; layer V pyramids differentiation; ubiquitous layer IV	Permanent circuitry with transient elements	Sensory-driven, layer V centered
Early infancy	2–6 months	Reorganization of corticocortical pathways; rapid synaptogenesis and spinogenesis	Permanent circuitry with resolving transient elements	Sensory-driven; columnar processing
Late infancy	7–12 months	Long connectivity established; layer III pyramids “dormant”, areal differentiation; granular-dysgranular	Initial “cognitive” circuitry	Environmentally driven; extrinsic-intrinsic through local circuitry
Early childhood	12–24 months	Maturity of layer III pyramids and local circuits; maximal synaptogenesis	Cognitive	Socially driven; layer III centered

PCW, postconceptional weeks; SP, subplate; MZ, marginal zone; CP, cortical plate.

Blakemore, & Rakic, 2008; Zecevic & Milosevic, 1997) (figure 2.1A). Soon thereafter, the formation of the cortical plate (CP) at 8 PCW (figure 2.1B) marks the transition from embryonic to fetal period and prefrontal neocortical anlage is now composed of three architectonic zones: marginal zone (MZ), CP, and the presubplate, PSP (Bystron et al., 2008; Kostović & Rakic, 1990). These zones contain two main classes of neurons, radially oriented postmigratory neurons within the CP and randomly oriented and early maturing neurons located above and below the CP, that is, in the MZ and PSP, respectively (Bystron et al., 2008; Kostović, 1990; Marin-Padilla, 1983; Meyer, Schaaps, Moreau, & Goffinet, 2000; Verney, Lebrand, & Gaspar, 2002; Zecevic & Milosevic, 1997).

Between 13 and 14 PCW (the end of the early fetal period, figure 2.1C), the deep part of the hitherto densely packed CP transforms into a wider lamina that appears pale in Nissl-stained preparations and merges with PSP, thus forming a new, prominent, and transient zone—the subplate zone (SP) (Kostović & Rakic, 1990; Kostović & Judaš, 2007). This marks the onset of the typical midfetal lamination pattern.

Importantly, the early fetal cerebral wall (telencephalic pallium) shows early regional differences in the thickness and appearance of MZ, CP, and SP across mediolateral, rostrocaudal, and dorsoventral extent. Dorsal fetal pallium, as a forerunner of neocortex, displays thicker and condensed CP, narrow MZ, and wider PSP. The CP becomes thinner toward the interhemispheric fissure where dorsal pallium continues into the medial pallium. The pallium of the cortical limbus (hem) is thin and convoluted with wide MZ, thin and convoluted CP, and almost invisible PSP. The CP is initially not developed in the hippocampal anlage. This early regional specification probably reflects the activity of intrinsic patterning mechanisms (Rakic, 1988, 2006) whereby patterning centers generate, across the dorsal telencephalon, graded expression of transcription factors acting on cortical progenitor cells (Grove & Fukuchi-Shimogori, 2003; O’Leary, Chou, & Sahara, 2007). Thus the frontal telencephalon becomes specified by specific transcription factors, such as the basic fibroblast growth factor (bFGF), expressed in the ventricular zone of the rostral (anterior) telencephalon.

Although this early patterning of the cortical protomap (Rakic, 1988) occurs in humans probably during the second

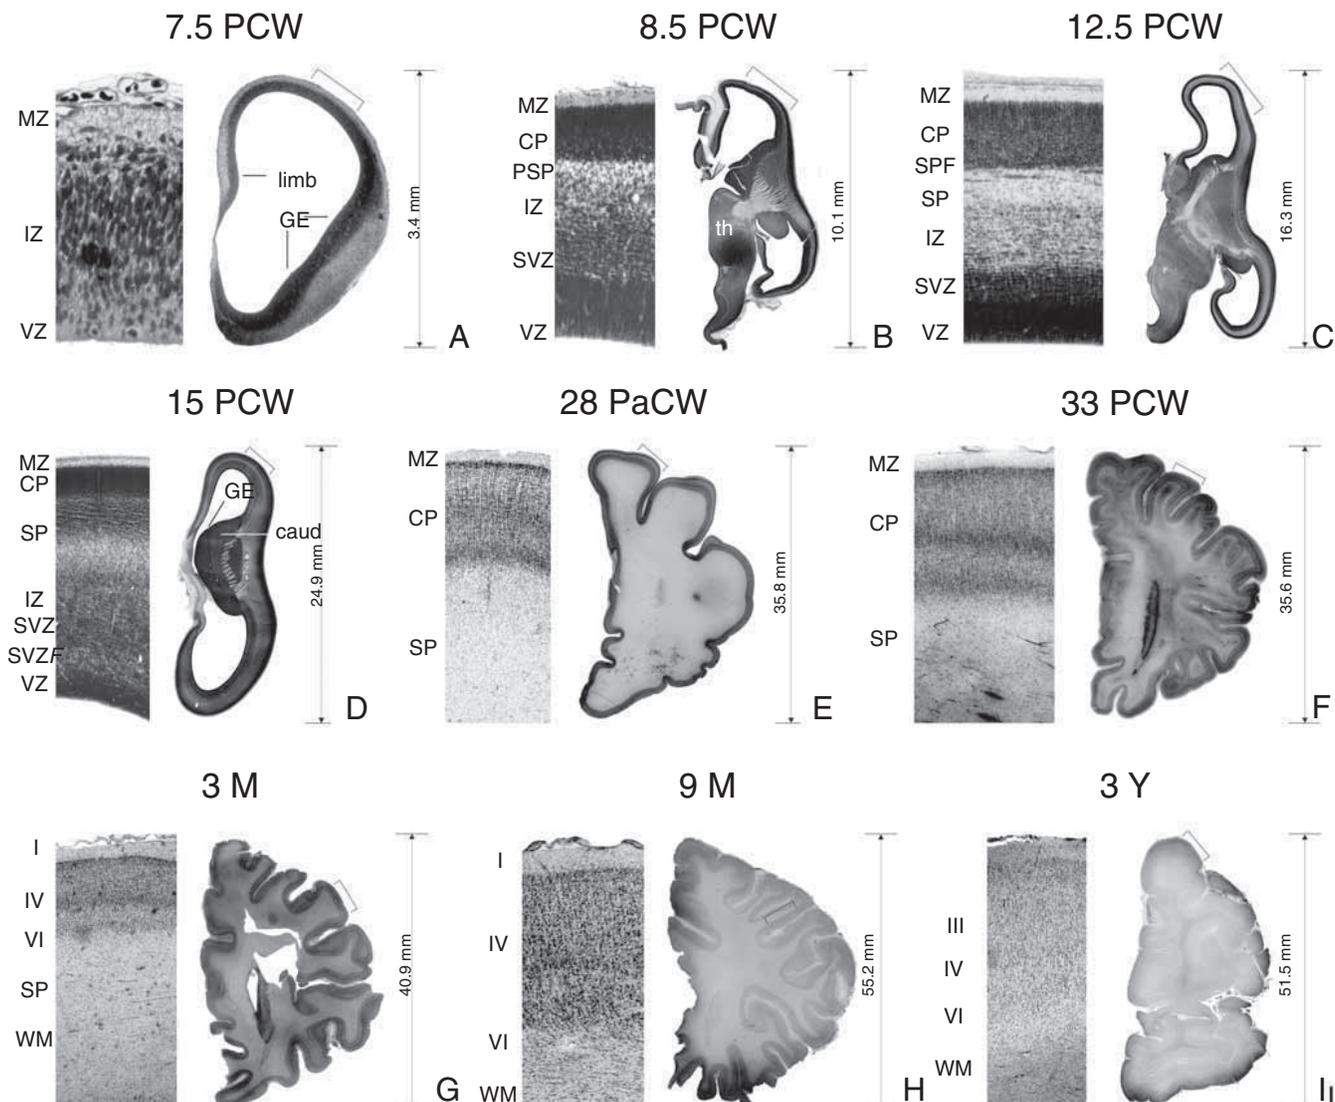

FIGURE 2.1 Development of cytoarchitectonic layers in the prefrontal cortex from the embryonic phase (before the appearance of the cortical plate) to the third year, that is, at 7.5 postconceptional weeks (PCW) (A), 8.5 PCW (B), 12.5 PCW (C), 15 PCW (D), 28 PCW (E), 33 PCW (F), 3 months (G), 9 months (H), and 3 years (I). All layers in prenatal phases are transient, and their laminar changes reflect neurogenetic events: proliferation, migration, differentiation, ingrowth of afferent pathways, and areal differentiation.

month of embryonic life—that is, even before the formation of the cortical plate—the specification of cortical areas continues during the fetal period, and thalamic input seems to have a significant role in the final differentiation of cortical areas.

NEUROGENETIC EVENTS Major neurogenetic events are production of young postmitotic neurons in the ventricular zone and their migration through the intermediate zone (figure 2.6). Comparison with data in monkey (Rakic, 1988, 2006) shows that in the early fetal period, neurons destined

for superficial (associative) layer III are not born yet. Molecular specification of early cortical neurons was proven using different markers for GABA (Bystron et al., 2006, 2008; Zecevic & Milosevic, 1997; Rakic & Zecevic, 2003) and reelin (Meyer & Goffinet, 1998; Rakic & Zecevic, 2003). For studying early cortical development in a clinical setting it is very important that early transient proliferative, migratory, and synaptic zones were successfully visualized by *in vivo*, *in utero* imaging around 13 PCW (Judaš et al., 2005; Kostović, Judaš, Škrablin-Kučić, Štern-Padovan, & Radoš, 2006).

for superficial (associative) layer III are not born yet. Molecular specification of early cortical neurons was proven using different markers for GABA (Bystron et al., 2006, 2008; Zecevic & Milosevic, 1997; Rakic & Zecevic, 2003) and reelin (Meyer & Goffinet, 1998; Rakic & Zecevic, 2003). For studying early cortical development in a clinical setting it is very important that early transient proliferative, migratory, and synaptic zones were successfully visualized by *in vivo*, *in utero* imaging around 13 PCW (Judaš et al., 2005; Kostović, Judaš, Škrablin-Kučić, Štern-Padovan, & Radoš, 2006).

NEURONAL CIRCUITRY AND FUNCTIONAL ORGANIZATION The neuronal circuitry of the early prefrontal cortex consists of a small number of synapses, dendrites of postmigratory neurons, and presynaptic axons arising from modulatory extrathalamic subcortical systems. As described for the midlateral telencephalic wall (Molliver, Kostović, & van der Loos, 1973) and the anterior cingulate cortex (Kostović & Krmpotić, 1976) of human fetuses, early synapses display bilaminar distribution and are located above and below the cortical plate. Such bilaminar distribution of early synapses was also demonstrated in equivalent stages (embryonic day 60) of fetal rhesus monkeys (Bourgeois, Goldman-Rakic, & Rakic, 1994).

In the developing human cortex, prospective postsynaptic elements for the early synapses were revealed by Golgi impregnations (Mrzljak, Uylings, Kostović, & van Eden, 1988; Mrzljak, Uylings, van Eden, & Judaš, 1990; Mrzljak, Uylings, Kostović, & van Eden, 1992) and electron microscopy (Kostović & Rakic, 1990), the most likely candidates being neurons of the subplate zone (Kostović & Molliver, 1974; Kostović & Rakic, 1990). However, radially oriented neurons of the immature cortical plate also extend their dendrites in the marginal zone (Marin-Padilla, 1983; Molliver et al., 1973; Mrzljak et al., 1988) and the presubplate (Kostović & Rakic, 1990; Kostović & Judaš, 2007; Mrzljak et al., 1988) and thus represent putative postsynaptic sites for at least some synapses.

There is substantial evidence for the presence of presynaptic axons within early synaptic strata of the human cerebral cortex. Modulatory afferents arrive early from the monoaminergic brainstem tegmentum (Nobin & Björklund, 1973; Zecevic & Verney, 1995) and cholinergic basal forebrain (Kostović, 1986). Although thalamocortical axons are still in the stage of pathway selection, their involvement in the early circuitry cannot be excluded (Allendoerfer & Shatz, 1994; Kostović & Judaš, 2002, 2007; Molliver et al., 1973). Short presynaptic input is also provided by subplate neurons that express glutamate and GABA (Antonini & Shatz, 1990), as well as several neuropeptides (Allendoerfer & Shatz, 1994; Delalle, Evers, Kostović, & Uylings, 1997; Kostović, Štfulj-Fučić, Mrzljak, Jukić, & Delalle, 1991).

FUNCTIONAL ORGANIZATION At this early age, supragranular neurons involved in long cortico-cortical networking necessary for cognitive functions are not born yet. There are no imaging or functional recording studies of the early human prefrontal cortex. Therefore, we have to rely on experimental studies in animals with similar patterns of circuitry organization. These studies indicate that subplate cells communicate with both nonsynaptic (Albrieux, Platel, Dupuis, Villaz, & Moody, 2004; Dupont, Hanganu, Kilb, Hirsch, & Luhmann, 2006; Voigt, Opitz, & DeLima, 2001) and synaptic contacts (Friauf & Shatz, 1991) and produce

spontaneous endogenous oscillations that do not depend on sensory input. These results suggest that, long before the onset of cognition, the prefrontal cortex of early human fetuses has neuronal circuitry involved in spontaneous endogenous activity.

Development of neuronal circuitry in the human prefrontal cortex during the midfetal and late fetal period

STRUCTURAL ORGANIZATION Transient fetal lamination of the prefrontal cortex (figure 2.1D) is characterized by prominent SP (Kostović & Rakic, 1990; Kostović & Judaš, 2007), thick and consolidated CP, and the presence of transient sublayers in the MZ (Kostović, Jovanov-Milošević, Krsnik, Petanjek, & Judaš, 2004/2005). The SP contains an abundant extracellular matrix (Kostović, Judaš, Radoš, & Hrabač, 2002), “waiting” thalamocortical fibers (Kostović & Goldman-Rakic, 1983; Kostović & Rakic, 1984, 1990; Rakic, 1977), and relatively mature polymorphic neurons of quite variable morphology (Kostović, 1990; Mrzljak et al., 1988, 1990, 1992). Transient midfetal zones are easily visualized by both in vitro (Kostović et al., 2002) and in vivo MR imaging (Kostović, Judaš, et al., 2006). The most prominent transient zone is the SP, easily delineated on MRI scans owing to the presence of abundant and hydrophilic extracellular matrix (Kostović et al., 2002).

During the midfetal and late fetal period the prefrontal cortical areas, as cytoarchitectonically defined in the adult brain by Brodmann (1909) or von Economo and Koskinas (1925), still do not display two defining features, that is, granular layer IV and large pyramidal neurons in sublayer IIIC. At the beginning of this period, layer III neurons are not even born. In addition, the prominent SP determines the lamination pattern, which is very different from that of the postnatal cortex.

However, architectonic differences between major prefrontal cortical regions (dorsolateral, orbitomedial, and orbitolateral) are already visible on Nissl-stained histological sections. Transient fetal zones display regional differences on in vitro MR images of formalin-fixed brains (Kostović, Judaš, et al., 2002) as well as on in vivo, in utero MR images (Kostović, Judaš, et al., 2006). The dorsolateral prefrontal region shows two characteristic features: very thick SP and tangential waves of migratory neurons in the superficial part of the SP, just below the CP.

NEUROGENETIC EVENTS During the midfetal period, neurons and glial cells are continuously produced in ventricular and subventricular zones (Rakic, 1988, 2006). The subventricular zone is highly developed in the primate brain and seems to be the source of interneurons and glial cells (Bystron et al., 2008; Rakic, 2006). The overall increase in the number of mitotic cycles seems to represent the

cellular basis of prefrontal cortex expansion during human evolution and development (Rakic, 2006).

As neurons are continuously produced, they also continue to migrate through the intermediate zone and SP. Neurons migrating during the midfetal period are destined to supragranular layers and probably correspond to prospective pyramidal neurons of layer III that give rise to associative and commissural cortical pathways (Schwartz, Rakic, & Goldman-Rakic, 1991). The major pattern of migration of principal, pyramidal neurons is radial migration along radial glial cells (Rakic, 2006). This mechanism is particularly important for the thick cerebral wall of the midfetal primate and human brain where neurons have to travel for a long distance from the site of origin in the ventricular-subventricular zones to their final destination in superficial cortical layers. For example, in the midfetal human prefrontal cortex, radially migrating neurons have to traverse 5 to 9 mm thick SP. As seen on Nissl-stained histological sections, massive waves of migratory neurons, together with rows of glial cells, form a transient sublayer within the superficial SP (figure 2.1D) of the human prefrontal cortex, which was first noted by von Economo and Koskinas (1925).

During the midfetal period, the growth of subcortico-cortical and cortico-subcortical projection pathways reaches its peak intensity. Thalamocortical pathways grow through the intermediate zone during the pathway selection stage (figure 2.2A), and through the SP during the regional target selection stage. The major input for the prefrontal cortex may be traced by selective histochemical staining of growing fiber tracts (Kostović & Goldman-Rakic, 1983) (see also figures 2.3A, 2.3B). The growth of thalamocortical pathways partially overlaps with continuous growth of afferent fibers from basal forebrain in the external capsule. Fibers from the amygdala were not directly visualized, but this nuclear complex matures very early (Nikolić & Kostović, 1986), and it is very likely that projection to orbitomedial cortex matures in parallel with thalamic projection.

Cortico-subcortical pathways from the prefrontal cortex are more difficult to trace in the human brain. In the rhesus monkey, developing corticostriatal projections are in spatial register with striatal cytoarchitectonic and AChE-rich units (Goldman-Rakic, 1981). In the human striatum, these units develop during midgestation, indicating that midgestation represents a developmental window for growth and establishment of human prefrontal corticostriatal pathways (Vukšić, Radoš, & Kostović, 2008).

The growth of other subcortical efferent pathways—for example, long corticopontine and corticospinal axons of layer V pyramidal neurons—is less well known. Two lines of evidence suggest that subcortical efferent pathways may have reached their target structures/levels. First, microtubule maturation in cell bodies of prefrontal layer V is

accelerated after 18 PCW, and expression of specific genes seems to be required for proper targeting of their axons (Chen, Rašin, Kwan, & Šestan, 2005). Second, corticospinal fibers originating in the human frontal motor region arrive at the spinal cord already at 24 PCW (Eyre, 2007; Eyre, Miller, Clowry, Conway, & Watts, 2000).

NEURONAL CIRCUITRY AND FUNCTION The most differentiated neurons in the midfetal frontal cortex are polymorphic SP neurons and Cajal-Retzius cells of the MZ. The number of synapses has increased in the SP and MZ, and transient circuitry of the SP displays remarkable complexity. There is electron microscopy evidence that SP neurons are postsynaptic elements, since synapses are readily found on their proximal dendrites and cell bodies (Kostović & Rakic, 1990). The vast majority of synapses are asymmetric and therefore probably excitatory. Subplate neurons display a striking variety of neuronal morphologies (Mrzljak et al., 1988, 1990).

As shown in rhesus monkeys (Meinecke & Rakic, 1992) and carnivores (Antonini & Shatz, 1990), many SP neurons synthesize GABA, while approximately 60% of SP neurons may synthesize glutamate (Antonini & Shatz, 1990). Presynaptic elements for SP circuitry originate from monoaminergic and cholinergic afferents and other SP neurons, while thalamic axons and axons of neurons residing in the CP may represent an additional presynaptic input (Allendoerfer & Shatz, 1994). As a rule, GABAergic neurons coexpress various neuropeptides (Allendoerfer & Shatz, 1994; Delalle et al., 1997; Kostović, Štfulj-Fučić, Mrzljak, Jukić, & Delalle, 1991).

To summarize, rich presynaptic input from modulatory, nonsensory sources impinges upon a complex, transient population of neurons. Intrinsic neurons are interconnected. Thus one network communicates with external input while the other network is endogenous and very likely oscillatory.

Development of prefrontal neuronal circuitry in early preterm infants

The early preterm period is important for human development because preterm infants older than 24 PCW can survive and thus become exposed to interaction with environment. In addition, sensory stimulation is possible even in utero.

STRUCTURAL ORGANIZATION The prefrontal cortical regions gradually differentiate while transient fetal zones change their appearance and thickness. An initial lamination appears in the middle of the CP (figure 2.1E). The SP is at its developmental peak (Kostović, Lukinović, et al., 1989; Kostović & Rakic, 1990) and shows regional variations in thickness. The cytoarchitectonic immaturity of the

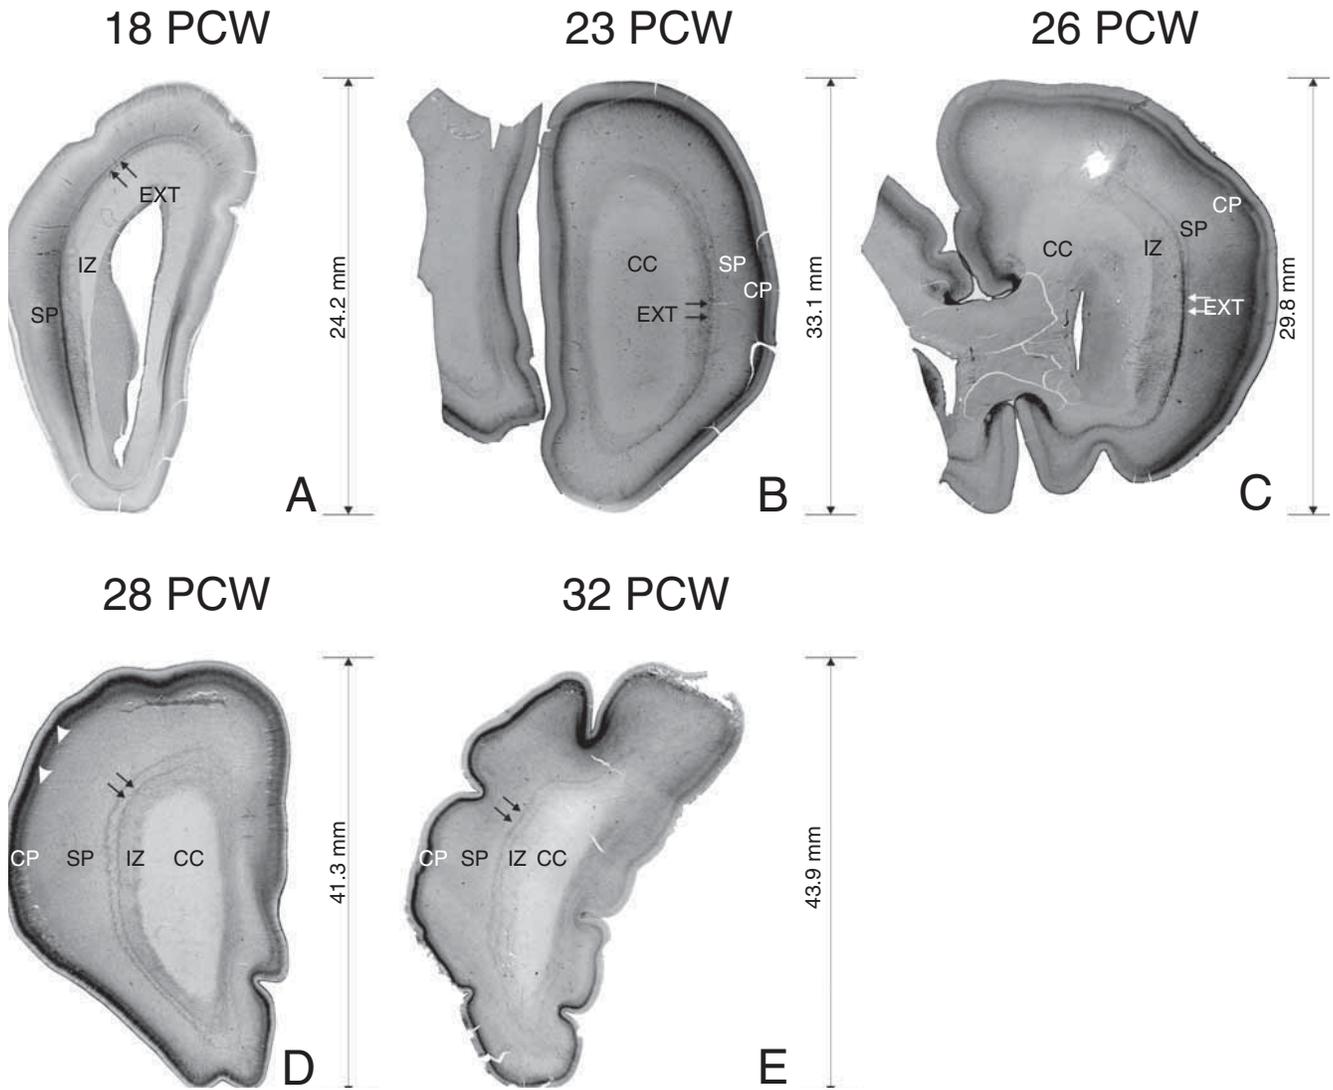

FIGURE 2.2 Laminar shifts, regional and areal differences in acetylcholinesterase (AChE) histochemical staining in the human prefrontal cortex at different developmental phases. At 18 PCW (A), AChE-reactive fibers originating in the basal forebrain, external capsule system (EXT), and thalamocortical/internal capsule system gradually invade the subplate. At 23 PCW (B), AChE-reactive fibers accumulate transiently in the superficial part of the SP. After

24 PCW, AChE-reactive fibers gradually penetrate into the cortical plate, as illustrated in 26 PCW specimen (C). There is a parallel decrease in staining of the subplate zone. At 28 PCW (D), strong AChE reactivity is present in the cortical plate (arrowheads). Gradual decrease in the overall AChE-staining is observed at 32 PCW (E). Double arrows point to the external capsule, that is, the deep border of the subplate zone.

early preterm prefrontal cortex is also visible in the MZ, which has several sublayers and contains well-developed but transient subpial granular layer (Kostović et al., 2004/2005).

Transient lamination of the prefrontal cortex in human preterms was well documented by acetylcholinesterase (AChE) histochemistry (Kostović, 1990). There is a transient columnar arrangement (figure 2.2D) of the strong AChE-staining in the prefrontal cortex, with regionally characteristic distribution (Kostović, 1990). The differences between orbital, lateral, dorsolateral, and orbitomedial cortex became more obvious and roughly correspond to the incipient gyral landmarks (Kostović, Petanjek, et al., 1992). In summary,

structural data on laminar, regional, and radial organization show transient patterns of organization of prefrontal cortex in preterm infant.

NEUROGENETIC EVENTS The proliferative zones (ventricular and subventricular) in preterm infants gradually cease to produce neurons. However, the bulging of the ventricular zone, the so-called ganglionic eminence, remains thick and voluminous. According to the evidence obtained in primates (Bystron et al., 2008; Rakic, 2006) after 24 PCW this zone produces predominantly glial precursors. In our Golgi studies (Mrzljak et al., 1988, 1990) we have seen many migratory neurons in early preterm infants.

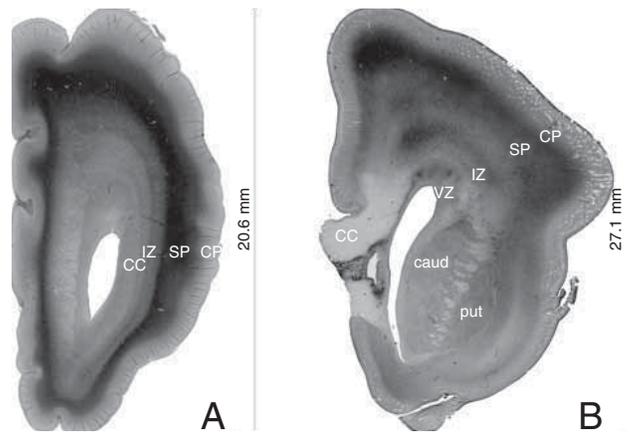

FIGURE 2.3 The subplate (SP) is characterized by an abundant extracellular matrix, as demonstrated by PAS-Alcian Blue histochemical staining (*A*). The subplate extracellular matrix also contains a high amount of axonal guidance molecules, as shown by

immunostaining for fibronectin (*B*). Note gradients of extracellular matrix and fibronectin concentration within the “waiting” compartment of the subplate zone.

Therefore, it is possible that in the prefrontal pallium neurogenesis and migration last several weeks longer than in primary cortical areas.

While there is cessation of proliferative processes, both pyramidal and nonpyramidal neurons continue to differentiate. SP neurons continue to grow (Mrzljak et al., 1992) and express different neuropeptides such as NPY (Delalle et al., 1997) and somatostatin (Kostović, Štfulj-Fučić, et al., 1991), as well as GABA. The distribution of synapses changes significantly after 24 PCW: synapses begin to appear within the deep portion of the CP and bilaminar pattern of synaptic distribution gradually disappears. The number of synapses in the deep cortex (SP plus deep CP) is higher than in the superficial cortex (superficial CP plus MZ).

The predominance of deep synapses in early preterms and deep-to-superficial synaptogenesis after 28 PCW are structural factors important for generation of cortical dipole (from surface to intermediate zone) and changing surface positive potentials (Molliver, 1967). According to our studies (Kostović & Goldman-Rakic, 1983; Kostović & Judaš, 2002; Kostović & Rakic, 1984, 1990) the most intense neurogenetic process in the preterm cerebrum is growth of projection and callosal pathways.

FUNCTIONAL ORGANIZATION The main feature distinguishing preterm cortex from midfetal and late fetal cortex (figures 2.1*B*, 2.1*C*, 2.1*D*) is the presence of strong thalamic input from mediodorsal nucleus (Kostović & Goldman-Rakic, 1983). In the primary sensory areas, the thalamic input is anatomical basis for evoked potentials (for a review of literature, see Kostović & Jovanov-Milošević, 2006). After 24 PCW, thalamic afferents establish synaptic contacts with CP neurons (Molliver et al., 1973). In the somatosensory cortex of preterm infants, pain stimuli from the skin may provoke cortical response as

detected by infrared monitoring (Fitzgerald, 2005). It is not known whether information from primary cortex in early preterms is conveyed further to prefrontal cortical areas. This seems to be unlikely because of the immaturity of cortico-cortical pathways. Thus the prefrontal cortex in early preterms receives predominantly nonsensory information via mediodorsal-prefrontal projection. Thalamic axons in early preterm infants make synapses with cells in both SP and CP (Kostović & Jovanov-Milošević, 2006; Kostović & Judaš, 2006, 2007).

The contact of thalamocortical axons with subplate neurons is a powerful activator of transient endogeneous cortical circuitry. The initial contact with cortical plate cells is a forerunner of extrinsic circuitry. Prolonged coexistence of these two types of circuitry, the extrinsic and transient intrinsic, is the salient feature of cortical development in humans (Kostović & Judaš, 2006, 2007). The gradual changes in organization of transient and “permanent” circuitry may form the basic framework for changing EEG (Vanhatalo & Kaila, 2006). Slow activity transients (SAT) are generated as early as 24 PCW (Tolonen, Palva, Andersson, & Vanhatalo, 2007; Vanhatalo & Kaila, 2006), transform at 30 PCW, and disappear after birth (Vanhatalo & Kaila, 2006). Excitatory extrinsic cholinergic input to the SP also originates in the basal forebrain. Subplate neurons are glutamatergic (Antonini & Shatz, 1990) and GABAergic (Meinecke & Rakic, 1992) or GABA-peptidergic neurons (Allendoerfer & Shatz, 1994). There is significant increase in number of peptidergic neurons in preterm infants (Delalle et al., 1997).

While functional relationship between thalamic axons, subplate neurons, and cortical plate neurons in primary cortical areas was clearly demonstrated in experimental studies in carnivores (Allendoerfer & Shatz, 1994) and rodents (Hanganu, Kilb, & Luhmann, 2002), the prefrontal

circuitry at this early age was not studied in monkeys, which may serve as a possible model for human circuitry. It would be of particular interest to reveal interaction of “extrinsic” and “intrinsic” circuits at synaptic and transmitter levels and correlate this with cortical potentials (Khazipov & Luhmann, 2006; Tolonen et al., 2007). In early preterm infants “intrinsic” transient circuitry of the SP may still be the main generator of spontaneous, endogenous oscillations (Vanhatalo & Kaila, 2006) and spontaneous activity transients (Tolonen et al.). The transient circuitry of the SP in the frontal lobe may have output to caudate nucleus (Goldman-Rakic, 1981) and contribute to generation of movements in the preterm infant.

One of the most intriguing questions is when in the human prefrontal cortex GABAergic neurons became inhibitory. In experimental studies GABA was shown to act as excitatory transmitter during early phases of cortical development (Vanhatalo & Kaila, 2006) due to the immaturity of KCC transporter (Vanhatalo et al., 2005). The switch to excitatory function occurs relatively late in the rat, at the age corresponding to neonatal period in humans.

Very little is known about connections of prefrontal cortex with basal ganglia and brain stem. In the nonhuman primates, corticostriatal pathways terminate in full register with striatal cytoarchitectonic compartments at embryonic day 105 (Goldman-Rakic, 1981). In humans, striatal cell islands and AChE patches appear at 10 PCW and become maximally developed between 28 and 32 PCW (Graybiel & Ragsdale, 1978; Letinić & Kostović, 1996; Vukšić et al., 2008). The efferent pathways from the frontal cortex form the Muratoff’s fascicle (Petrides & Pandya, 2007), and this fiber system seems to be the source of afferents to well-developed moduli in the human fetal putamen. In the context of transitory cortical circuitry and connections, it is interesting that the first general, variable movements appear during the preterm infant period (Hadders-Algra, 2007).

Development of neuronal circuitry of the human prefrontal cortex during the last two months of gestation

STRUCTURAL ORGANIZATION During the last two months of gestation, the frontal cortex and related subcortical nuclei grow rapidly. All primary gyri and sulci are recognizable at the cortical surface (figure 2.1F), as demonstrated by in vivo MR imaging, which, in comparison to postmortem material, provides a more accurate picture of convolitional development.

However, in classical neuroanatomical studies it was not fully appreciated that at this age laminar and areal cytoarchitectonic organization remains surprisingly immature. For example, the transient SP is still interposed between growing white matter and six-layered cortical plate. The

six-layered cortical plate was described as Grundtypus by Brodmann (1909). In this six-layered pattern (figure 2.1F) one can distinguish individual layers, but cell sizes, morphology, and aggregation within these layers are significantly different from those in the postnatal cortex. First, layer III pyramidal neurons are small, and characteristic sublayer IIIc cannot be delineated. Second, layer IV is densely granular (figure 2.1F), and this granularity continues into premotor and primary motor cortex of the frontal lobe. Therefore, the criterion of layer IV granularity (agranular–dysgranular–granular) cannot be used to delineate frontal cortical areas as in the adult brain. Third, layer VI is wide and very cellular with gradual transition toward the SP. Fourth, layer I contains numerous large neurons, many of which show characteristics of Cajal-Retzius cells on Golgi preparations. The most obvious sign of immaturity is the presence of the SP, which can be demonstrated with some simple staining techniques such as PAS-Alcian Blue staining (Kostović, Judaš, et al., 2002).

However, the SP gradually diminishes in size after 32–35 PCW. The substrate for the gradual diminishment of the subplate on MR images is the decrease in the amount of extracellular matrix and other growth-related guidance molecules. The decrease in thickness and signal intensity of the SP is the hallmark of cerebral cortex on MR images in the preterm infant (Kostović, Judaš, et al., 2002). The ingrowth of long cortico-cortical pathways into the layers of the CP is another important factor in diminishment of the SP. Parallel to the decrease in the size of the SP there is development of corona radiata composed of thalamocortical and other projection fibers. The corona radiata fibers form segment III of von Monakow (1905) and continue in gyral white matter, but tight connection of the gyral white matter with cortical layers is interrupted by existence of the SP.

NEUROGENETIC EVENTS Data on neuronal proliferation in nonhuman primates (Rakic, 1988, 2006) obtained in stages comparable to human development (Kostović & Rakic, 1990) indicate that we cannot expect production of new neurons in the prefrontal cortex of the late preterm infant. The notable size of proliferative ventricular-subventricular zones and ganglionic eminence are most likely related to proliferation of astroglia and oligodendroglia. The presence of areas of immature cells around the anterior horn of lateral ventricles, which are characteristic for frontal lobe, probably reflect waves of cells on the way to more superficial cortical layers. It is also very likely that some late-arriving neurons still migrate because the migratory radial route is longer in prefrontal cortex than in other cortical regions.

Growth of dendrites is a significant event in preterm infant (Mrzljak et al., 1988, 1990). This phase of differentiation is influenced by glutamatergic thalamic afferents (Mrzljak et al., 1988, 1990) and is described as a second phase of

dendritic differentiation in the prefrontal cortex (Petanjek et al., 2008). Parallel to this event there is initial development of characteristic dendritic orientation in nonpyramidal, local circuitry neurons (Mrzljak et al., 1988; Kostović, Judaš, & Petanjek, 2008). The most robust neurogenetic event in the preterm infant is growth of long cortico-cortical pathways. Callosal fibers are in the phase of growth around ventricles (Kostović, Judaš, et al., 2002) and show significant increase in number, described as exuberance (Chalupa & Killackey, 1989; Innocenti & Price, 2005).

There is no reliable chemical marker for direct demonstration of long cortico-cortical associative fibers. The DT tractography demonstrated preliminary results without identifying source(s) of associative pathways described in adult prefrontal cortex (Petrides & Pandya, 2007). The conventional MRI shows periventricular zone rich in extracellular matrix (Judaš et al., 2005), which corresponds to axonal strata containing long associative fascicles such as fronto-occipital and superior longitudinal medial fasciculus described by von Monakow (1905) in developing fetal and child brain. In addition, fiber bundles that contain efferent associative pathways from the rostral prefrontal cortex (Petrides & Pandya, 2007), such as external capsule and cingulate fasciculus, are well developed in the preterm infant.

FUNCTIONAL ORGANIZATION There is further maturation of evoked and event-related potentials: the gradual appearance of synchronous EEG activity and slow activity transients become less frequent. Analysis of general movements that depend on transient circuitry (Hadders-Algra, 2007) shows characteristic “writhing” general movements (Hadders-Algra, 2007). Because of the significant synaptogenesis in superficial layers of the cortical plate, cortical dipole switches from predominantly deep to predominantly superficial generation of electrical activity (Molliver, 1967). Accordingly, preterm infants show surface-negative cortical potentials that change to surface-positive potentials during the early postnatal period.

As stated for early preterm infants, the significance of sensory input for maturation of the prefrontal cortex is not known. In experiments performed in monkey fetuses delivered 3 months before the term and exposed to normal light, intense visual stimulation did not affect the rate of synaptic production (Bourgeois, Jastreboff, & Rakic, 1989). Accordingly, one can assume that fetal afferent input to prefrontal cortex before the birth will not affect the rate of synaptic production.

Neonatal period

STRUCTURAL ORGANIZATION The development of gyri and sulci continues with formation of tertiary convolutional pattern (Armstrong, Schleicher, Omran, Curtis, & Zilles,

1995). The prefrontal cortex is cytoarchitecturally immature, and the main reason for this immaturity is that granular layer IV, a main recipient of thalamocortical input, remains well developed in all frontal areas (i.e., in both prospective granular and prospective dysgranular areas). In layer I (the former fetal marginal zone) there is concentration of neurons, and well-developed Cajal-Retzius cells are still present (Krpmotić-Nemanić, Kostović, Vidić, Nemanić, & Kostović-Knežević, 1987).

The newborn cortex has immature laminar organization with prominent layer IV, dense layer II, absence of magnopyramidity of layer IIIc, and wide transition between layer VI and the white matter—cytoarchitectonic remnants of the subplate zone (figure 2.4). The precise delineation of dysgranular areas (Broca’s area 44, posterior orbital cortex) from prefrontal granular areas is not possible on the basis of cytoarchitectonic criteria (Judaš & Cepanec, 2007).

NEUROGENETIC EVENTS The neonatal period is dominated by dendritic differentiation (figure 2.5), growth and reorganization of callosal fibers, and growth of short cortico-cortical fibers. Dendritic development is evident in all classes of neurons (Mrzljak et al., 1990). At birth, layer V pyramidal neurons have larger and more complex dendritic trees than those of layer IIIc (Petanjek et al., 2008). Pyramidal neurons of layers V and III display the first phase of spinogenesis and intense growth of basal dendrites. Interneurons of layer IV develop characteristic phenotypes and can be distinguished. The supragranular layers contain double-bouquet neurons, basket neurons, and multipolar and bitufted nonpyramidal neurons (Mrzljak et al., 1990).

It is interesting that subplate neurons show continuous dendritic growth (Mrzljak et al., 1988, 1990, 1992). The growth of short cortico-cortical pathways was not directly demonstrated in the human prefrontal cortex, but in the human visual cortex DiI tracing demonstrated growth of short cortical pathways during corresponding phases of development (Burkhalter, 1993). Synaptogenesis is quantitatively significant neurogenetic event in the neonatal cortex, and there is rapid increase in the formation of synapses (Huttenlocher & Dabholkar, 1997; Kostović, Judaš, Petanjek, & Šimić, 1995).

FUNCTIONAL ORGANIZATION During the neonatal period, thalamocortical circuitry is established and there is a substrate for interaction with other brain regions and sensory environment. This process is very important for shaping of fine connectivity within the cortical columns (Penn & Shatz, 1999). During the neonatal period, the anatomical substrate of electrical activity is rapidly changing because of exponential increase in the number of synapses, deep synaptic activation, retraction of exuberant callosal axons (Chalupa & Killackey, 1989; Innocenti & Price, 2005), and ingrowth of

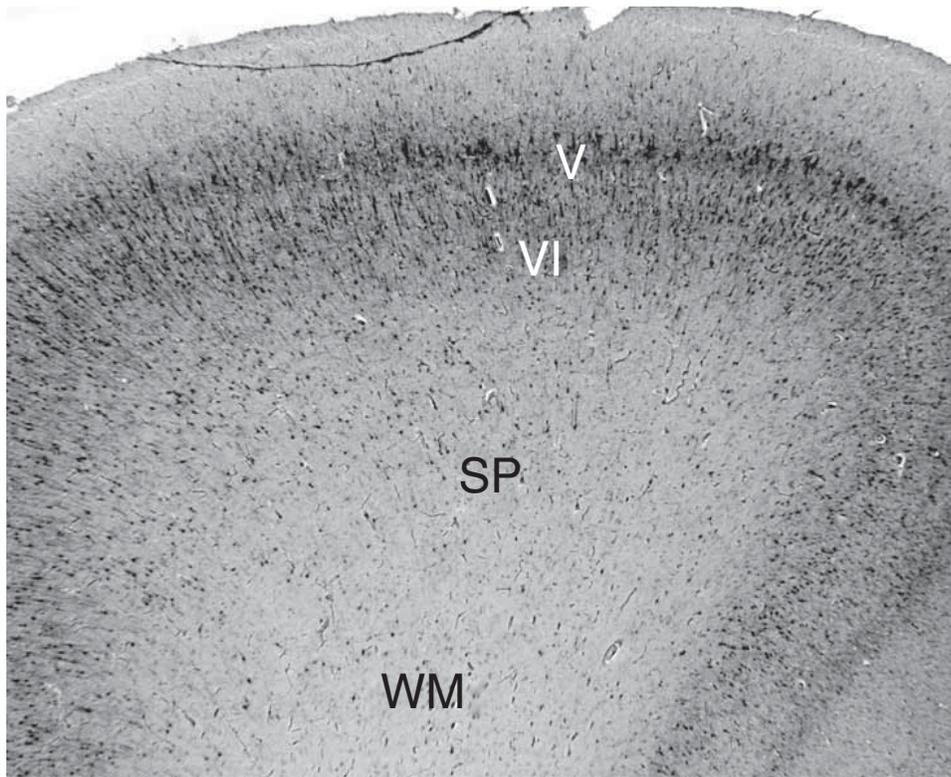

FIGURE 2.4 Transient subplate neurons are present in the postnatal human cerebral cortex, as revealed by MAP2-immunohistochemistry of the middle frontal gyrus. MAP2-positive

neurons are seen extending from deep cortical layer VI through the SP into the core of the gyral white matter (WM).

cortico-cortical fibers. As a consequence the cortical dipole changes and the cortical surface response becomes predominantly positive (Novak, Kurtzberg, Kreuzer, & Vaughan, 1989). The EEG shows more continuous activity (Dreyfus-Brisac, 1979). Slow activity transients may be still present in the full-term newborn (Vanhatalo et al., 2005; Vanhatalo & Kaila, 2006). This phenomenon, together with prolonged existence of transient circuitry and immaturity of cortico-cortical connectivity, points to the overall functional immaturity of the cortex. Supragranular local circuitry neurons have nonmyelinated axons and immature dendritic arborizations (Mrzljak et al., 1990). This immaturity of neuronal circuitry correlates well with immaturity of the psychological basis for recruiting and sustaining attention to a stimulus that is guided primarily by its physical features (Kagan & Baird, 2004).

Infancy

STRUCTURAL ORGANIZATION The laminar and areal differentiation shows substantial differences between early (2–3 months) and late infancy (7–12 months). In the early infant cortex (figure 2.1G) granular layer IV is present throughout polar, orbital, medial, and dorsolateral prefrontal cortex (Kostović, 1990), as well as in the fronto-opercular region (Judaš & Cepanec, 2007). In the late infant cortex (figure 2.1H) dysgranular areas of posterior orbital and fronto-opercular cerebral cortex may be delineated with greater confidence. Accordingly, Amunts, Schleicher, Ditterich, and Zilles (2003) found left-right asymmetry in Broca's region (Brodmann's areas 44 and 45) in 1-year-old infants. The other difference between early and late infancy is the presence of transient subplate. In early infants (2–3 months) the subplate is visible as transitional layer situated between layer VI and white matter core of frontal gyri (Kostović, Petanjek, et al., 1992). The presence of transient subplate elements obscures measurements of cortical thickness on MRI scans (Giedd et al., 1999; Sowell et al., 2004). Further structural differences between early and late infant brain are related to the maturation of pyramidal neurons of layers V and III (figure 2.5). Progressive differentiation of pyramidal neurons continues in infancy in both supragranular and infragranular layers (Mrzljak et al., 1988, 1990, 1992; Petanjek et al., 2008). During the first postnatal month, the extent of dendritic differentiation is similar in pyramidal neurons of layers III and V. However, after the third month, layer IIIC pyramidal cells display a seemingly "dormant" period with no significant overall dendritic growth from 3 to 16 months (Petanjek et al., 2008).

NEUROGENETIC EVENTS During infancy there is continuing growth of short cortico-cortical and intracortical

connections, retraction of exuberant callosal projections, development of dendrites of both pyramidal and inhibitory neurons, explosive synaptogenesis, naturally occurring cell death, and incipient myelogenesis (figure 2.6). The growth of short cortico-cortical connections continues at least until the 6th postnatal month, but may continue even after this period (Burkhalter, 1993). The retraction of exuberant axons occurs before the 6th postnatal month (Innocenti & Price, 2005), which is in agreement with experimental results in monkey (Chalupa & Killackey, 1989; LaMantia & Rakic, 1990). In the newborn monkey there are 3.5 times more callosal axons than in the adult (LaMantia & Rakic, 1990). Synaptic density increases rapidly during the first postnatal year (Huttenlocher & Dabholkar, 1997). Similar results were obtained in counting of spines in the human prefrontal cortex (Kostović, Petanjek, et al., 1992). After the 7th postnatal month, the growth of cortico-cortical pathways subsides, and predominant neurogenetic events are synaptogenesis, dendritogenesis, and myelogenesis.

FUNCTIONAL ORGANIZATION It is not known how the prefrontal cortex participates in behavior of infants during the first postnatal months. The first novel phase of behavior with clear involvement of the prefrontal cortex is goal-directed behavior (Kostović, Judaš, et al., 1995) demonstrated in the human version of the delayed response test (Diamond & Goldman-Rakic, 1989) where engagement of prefrontal cortex may be demonstrated between 7 and 10 months of postnatal age. It is obvious that this complex behavior depends on a new level of cortico-cortical and intrinsic cortical circuitry organization. The construction and shaping of this circuitry lasts almost a year and may be divided into early (2–3 months) and late phases (4th month onward).

Both phases are characterized by transitional patterns of cortical organization. These phases correspond to two transitions described for psychological development during the first year (Kagan & Baird, 2004). During the early infancy phase (2–3 postnatal months) there is a rapid increase in number of synapses and growth of short cortico-cortical pathways (Burkhalter, 1993; Huttenlocher & Dabholkar, 1997; Kostović, Petanjek, et al., 1992). In addition, there is a rapid dendritic development of pyramidal neurons (Petanjek et al., 2008).

During the first postnatal months some subplate neurons continue to grow and maintain transient circuitry. Some authors consider transient subplate circuitry as a framework for general movements during the neonatal period and early infancy (Hadders-Algra, 2007). However, participation in other transient phenomena cannot be excluded. It is not known whether subplate resolution is related to retraction of callosal and long associative fibers that entered this zone but never reached cortical plate layers. It is also not known what is the contribution of these pathways to transient cortical

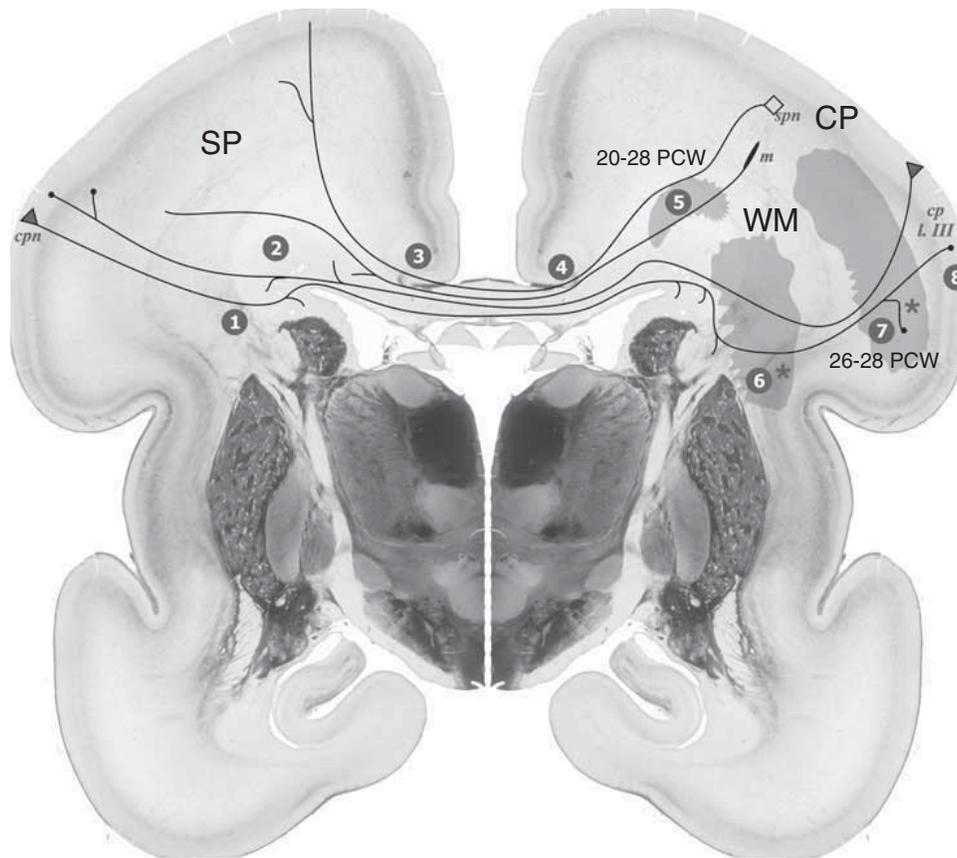

FIGURE 2.6 Growth of corpus callosum fibers through complex guidance zones and decision points. Numbers denote eight sequential decision points in the ipsilateral hemisphere, at the hemispheric midline, and in the opposite hemisphere. Asterisks indicate areas

of intermingling with thalamocortical fibers. Abbreviations: *cp*, cortical plate; *cpn*, cortical plate neuron; *l. III*, developing layer III; *m*, migrating neuron; SP, subplate; *spn*, subplate neuron.

circuitry. Although the pruning of exuberant callosal connections in the human brain occurs during the first six months of postnatal life, the moderate reduction in size of the corpus callosum was noted already in preterm infants (Innocenti & Price, 2005).

We proposed that the subplate exists as a cytoarchitectonic entity during growth of long cortico-cortical pathways and that some subplate circuitry elements exist also during the late transitional phase of growth of short cortico-cortical connectivity pathways (Kostović & Rakic, 1990; Kostović, 1990; Kostović, Petanjek, et al., 1992). This late phase of transient circuitry is resolved between 7 and 10 months of postnatal life when cortico-cortical connectivity is established and when prefrontal cortex exhibits first executive functions (Diamond & Goldman-Rakic, 1989; Fuster, 2002; Goldman-Rakic, 1987). This finding suggests that the disappearance of transient circuitry (which existed in parallel with permanent circuitry elements since 24 PCW) should precede the onset of goal-directed behavior and ability to retrieve schemas from past events that are no longer in the perceptual field. We describe this new cognitive phase, which develops after the 7th postnatal month, as environmentally

driven and as marking the onset of characteristic executive function with resolution of spatiotemporal relationships.

As stated earlier, the maturation of layer III neurons displays a “dormant” period between the 3rd and 15th postnatal months (Petanjek et al., 2008). According to these data, the differentiation of associative neurons of layer III speeds up after the 15th month, during the period of intensified social interaction.

The development of subplate peptidergic neurons follows a similar time schedule. In the newborn, NPY and somatostatin neurons are important constituents of the subplate (Delalle et al., 1997; Kostović, Štfulj-Fučić, et al., 1991). However, by 6 months, their number decreases, and this low number is maintained during childhood (Delalle et al., 1997).

Modulatory pathways from basal forebrain and brain stem change their transient fetal pattern during early infancy (Kostović, Škavić, & Strinović, 1988; Brown, Crane, & Goldman, 1979). However, important developmental shifts in their density and distribution occur during childhood and adolescence (Brown et al., 1979).

There is a correlation between synaptogenesis (Huttenlocher & Dabholkar, 1997), formation of dendritic spines

(Kostović, Petanjek, et al., 1992; Petanjek et al., 2008), and elaboration of dendrites in layer V and III pyramidal neurons (Petanjek et al., 2008). This indicates that in the early cognitive phase the main event in the formation of prefrontal neuronal circuitry is differentiation of pyramidal neurons and their synaptic connections.

In conclusion, the circuitry of the early cognitive phase (7–12 months) is characterized by finalization of growth of short cortico-cortical pathways, rapid growth of layer V pyramidal dendrites (Petanjek et al., 2008), initial differentiation of inhibitory neurons, especially double-bouquet interneurons (Mrzljak et al., 1990), and the disappearance of the subplate.

Early childhood: The second year

STRUCTURAL ORGANIZATION During the second year, areal specification of the prefrontal cortex is in its final phase but not yet completed. Two main cytoarchitectonic features of the prefrontal cortex, magnopyramidality of layer IIIc and granularity of layer IV, help to distinguish dorsolateral, dorsolateral-medial, polar, orbital, medial, and precingulate areas. At the beginning of the second year layer IIIc pyramidal neurons are still in the “dormant” period characteristic of infancy (Petanjek et al., 2008). However, the maturation of their cytoskeleton advanced significantly when compared with findings in early infancy (Jovanov-Milošević, Petrović, Judaš, & Kostović, 2008).

At the end of the second year (figure 2.17), layer IIIc pyramidal neurons become larger than those in layer V and dorsolateral prefrontal areas acquire magnopyramidal appearance (figure 2.5). Around the second birthday, dendrites of layer IIIc pyramidal neurons enter the second phase of significant elongation. In contrast to the biphasic pattern of growth of layer III pyramidal neurons, pyramidal neurons of layer V projection neurons show a linear pattern of development confined to infancy.

NEUROGENETIC EVENTS Three main neurogenetic events characterize early childhood: (1) synaptogenesis, (2) dendritic differentiation of both pyramidal and nonpyramidal local circuitry neurons, and (3) myelogenesis (figure 2.7). The formation of synapses is progressive and more intense during the second year of life (Huttenlocher & Dabholkar, 1997; Kostović, Petanjek, et al., 1992; Petanjek et al., 2008). The number of dendritic spines reaches its maximum at 2.5 years of life (Kostović, Petanjek, et al., 1992; Petanjek et al., 2008). The differentiation of dendrites in layer IIIc neurons shows a similar trend: after a yearlong “dormant” period, pyramidal neurons display a second period of dendritic growth at the end of the second year (Petanjek et al., 2008).

Based on quantitative parameters described for human prefrontal cortex (discussed earlier), the differentiation of

dendritic trees and growth of fine, distal dendrites is another major histogenetic event in both pyramidal and nonpyramidal neurons during the second year of life. It seems likely that these new postsynaptic sites participate in establishment of late-maturing intracortical circuitry.

The prefrontal cortex of the rhesus monkey contains 13 different classes of neurons that constrain the propagation of pyramidal cell excitation in different projections including local circuits (Lewis, Hashimoto, & Volk, 2005; Lund & Lewis, 1993).

The process of myelination involves also predominantly long cortico-cortical pathways. Some long cortico-cortical pathways such as corpus callosum mature as late as 10 years of life (Yakovlev & Lecours, 1967). The most interesting is myelination of intracortical fibers that form the final, fifth segment of the cortical white matter (von Monakow, 1905) described as radii. The intracortical portion of myelinated fibers cannot yet be demonstrated with conventional MR imaging and was described in classical myeloarchitectonic studies (von Monakow, 1905; Yakovlev & Lecours, 1967).

FUNCTIONAL ORGANIZATION During the second year, new cognitive functions gradually develop (Kagan & Baird, 2004). These new competences are largely integrated in the prefrontal cortex: production of meaningful speech, the capacity to infer selected mental states in others (theory of mind), the first signs of conscious awareness, and feeling of the self (Kagan & Baird, 2004; Werker & Vouloumanos, 2001).

The maturational shift that is most likely to underlie these complex environment-brain interactions is related to intrinsic cortical circuitry. First, it concerns the level of differentiation of layer IIIc pyramidal neurons achieved around the second birthday. Second, it is related to differentiation of GABAergic inhibitory interneurons: double-bouquet, calretinin-containing neurons; chandelier, parvalbumin-containing neurons; and wide-arbor basket, parvalbumin-containing neurons. Activation of interneurons serves to constrain the propagation of pyramidal cell excitation in local and long-range as well as intrinsic and associative projections.

The increased number of postsynaptic (Mrzljak et al., 1990; Petanjek et al., 2008) and presynaptic intrinsic elements (Anderson, Classey, Conde, Lund, & Lewis, 1995) between 2 and 2.5 years corresponds to peak density of dendritic spines and synapses observed in this period. This correspondence was shown in studies of synaptogenesis (Huttenlocher & Dabholkar, 1997) and spinogenesis (Kostović, Petanjek, et al., 1992; Kostović, Judaš, & Petanjek, 2008; Petanjek et al., 2008). It seems that this second cognitive phase requires the presence of supernumerary synapses in order to selectively stabilize functional circuitries through interaction with different environmental cues.

Neurodevelopmental events in cortical histogenesis

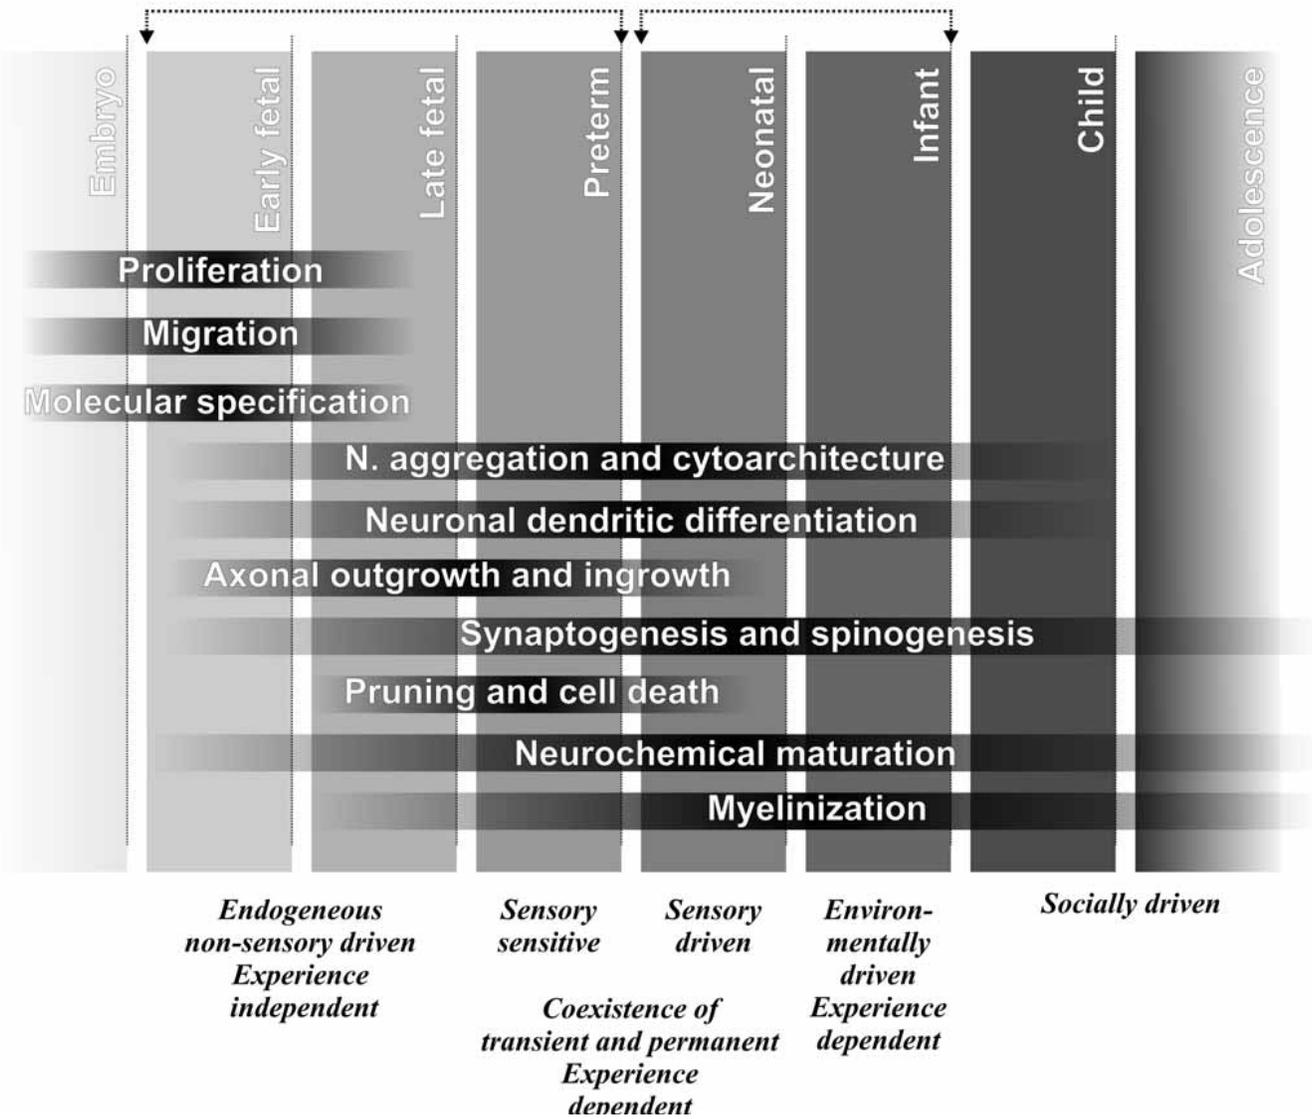

FIGURE 2.7 Simplified graphic representation of timing and intensity of neurogenetic events and different types of interaction with environment. Note the differences in intensity of neurogenetic events during prenatal and postnatal development.

Overview of the developmental phases of prefrontal circuitry during the first 2 years of life

The data presented systematically in previous paragraphs clearly suggest that development of prefrontal circuitry begins during the early fetal life, in parallel with development of regions destined for motor and sensory functions (Kostović & Rakic, 1990).

These early circuits are oscillatory, endogeneous, and very likely based on nonsynaptic contacts because we did not see synapses before the formation of the cortical plate. The first

synaptic circuitry involves postsynaptic elements situated in characteristic bilaminar distribution above and below the cortical plate (figure 2.8A). This phase is endogeneous and nonsensory driven. The crucial event in the development of fetal circuitry occurs after 13 PCW when cortical plate loosens and new prominent subplate zone develops. This typical fetal circuitry consists of (1) postsynaptic elements: well-differentiated GABAergic and glutamatergic subplate neurons, Cajal-Retzius cells of the marginal zone, and basal and apical arborizations of quite immature pyramidal neurons; (2) presynaptic elements: short and long axons of

glutamatergic and GABAergic subplate neurons; and (3) modulatory elements: afferents from monoaminergic brain stem neurons and cholinergic neurons from rostral cell groups of the basal forebrain.

Thalamic afferents from mediodorsal nucleus project heavily to the subplate zone. The phase of typical fetal lamination lasts until 21–23 PCW (figure 2.8B) when thalamocortical fibers accumulate below the cortical plate. This phase we describe as endogeneous due to the fact that frontal cortex cannot receive extrinsic inputs because primary cortical regions are not yet driven by sensory inputs.

In contrast to the rich synaptic and transmitter organization of the subplate zone with its GABA and glutamatergic cell networks (Meinecke & Rakic, 1992; Allendoerfer & Shatz, 1994) triggered by cholinergic and monoaminergic input (Dupont et al., 2006; Molliver, 1967; Zecevic & Verney, 1995), the cortical plate is immature and does not contain synaptic contacts (Molliver et al., 1973). The pyramidal neurons show the initial phase of maturation (Mrzljak et al., 1988, 1990, 1992) by both qualitative and quantitative criteria. Nonpyramidal neurons of the cortical plate are immature (Mrzljak et al., 1988) because they are born after 18 PCW.

The next phase of circuitry development occurs at age corresponding to preterm birth after 24 PCW (figure 2.8C) and is characterized by penetration of CP by thalamocortical fibers from mediodorsal nucleus (Kostović & Goldman-Rakic, 1983). It is not known what kind of information is

conveyed through mediodorsal nucleus, but activation of cortex is expected in this period.

In late preterm infants cortico-cortical, commissural fibers of the corpus callosum and long associative pathways establish the first cortico-cortical network. These connections also display transient exuberancy like corpus callosum (Innocenti & Price, 2005). However, many commissural axons and associative pathways do not necessarily make synapses at this stage. The overall number of synapses is relatively small in comparison to postnatal stages (Bourgeois et al., 1994; Huttenlocher & Dabholkar, 1997; Kostović, Petanjek, et al., 1992; Petanjek et al., 2008; Rakic, 2006).

The synchronous appearance of EEG suggests a certain degree of cortical integration (Albrieux et al., 2004; Khazipov & Luhmann, 2006; Kostović, Judaš, et al., 1995; Tolonen et al., 2007; Vanhatalo & Kaila, 2006; Vanhatalo et al., 2005). Efferent pathways to subcortical targets (Eyre, 2007; Eyre et al., 2000) and striatum (Goldman-Rakic, 1981; Kostović, 1984; Vukšić et al., 2008) set up the stage for later involvement in executive functions.

The circuitry in the preterm period is different from neonatal because long associative pathways are still growing, elaborate transient subplate circuitry coexists with permanent connectivity of cortical layers (thalamocortical circuitry), and areal differentiation is in its initial stage. During the neonatal period cortex becomes accessible to environmental sensory inputs. Accordingly, thalamocortical circuitry drives cortical activity in sensory cortical areas.

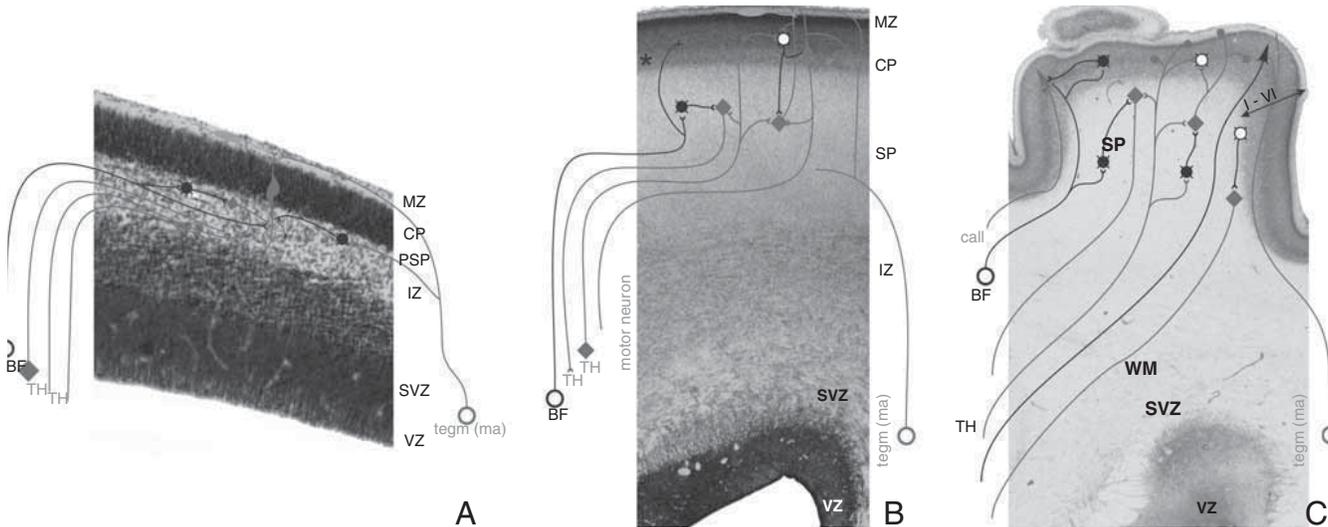

FIGURE 2.8 The reconstruction of neuronal connections in the human fetal frontal cortex. At 10 PCW (A), early modulatory afferents are present in transient fetal subplate (SP) and marginal zone (MZ). In the midfetal cortex at 24 PCW (B), thalamocortical afferents and SP neurons are dominant elements of deep transient cortical circuitry. The relocation of afferents from SP into the CP with subsequent synaptogenesis are illustrated for early

preterm infant cortex at 34 PCW (C). (After Kostović & Judaš, 2007, with permission of Elsevier Science Publishers.) Abbreviations: BF, basal forebrain; TH, thalamus; tegm (ma), tegmental monoaminergic afferents. Black squares depict GABAergic subplate neurons, and white circles depict GABAergic neurons of the cortical plate. Glutamatergic neurons are depicted as diamond shapes.

The redistribution of thalamocortical terminals during the early preterm period, the redistribution of cortico-cortical fibers during the perinatal (late preterm and neonatal) period, and gradual changes in the transient pattern of cortical organization all suggest that there is a profound reorganization of developing prefrontal circuitry. We described this series of perinatal neurogenetic events as the “first” reorganization (Kostović, 1990), whereas early postnatal changes of cortico-cortical systems were described as the “second” reorganization (Kostović, 1990). After each reorganization, one can recognize a new phase of circuitry development, with more advanced level of functional organization (Kostović, 1990).

However, the main prefrontal circuitry elements, pyramidal neurons of layer III, remain small and immature during the neonatal period, and growth of their dendrites lags behind those of layer V pyramidal cells. Thus the sensory-driven neonatal phase observed in development of primary cortical areas (Kostović & Judaš, 2006, 2007) may have a limited influence on functions of frontal cortex because of the immaturity of cortico-cortical connections. This period is followed by two transitional phases that prepare the prefrontal cortex for its executive and goal-directed functions. These phases are characterized by existence of transient elements in layer I and subplate, the rapid increase in synaptogenesis, and the differentiation of cortical interneurons. Between 2 and 6 postnatal months, infants increasingly respond to environmental stimuli. The first overtly cognitive phase occurs between 7 and 10 months, after the disappearance of transient fetal circuitry elements, significant increase in number of synapses, and the completion of growth of short cortico-cortical fibers.

The “cognitive” prefrontal circuitry shows further quantitative and qualitative changes during the second postnatal year. Dendrites of layer IIIc pyramidal neurons enter the “second” growth spurt at the end of the second year, after a protracted dormant period. The number of synapses also continues to increase. These processes reach their peak around the second birthday, when they contribute to the emergence of speech and verbal communication.

3 The Cognitive Neuroscience of Human Uniqueness

TODD M. PREUSS

ABSTRACT Until recently, neuroscientists have lacked powerful means for studying the human brain, and so have relied on studies of nonhuman species for understanding human brain organization. Moreover, the Darwin-Huxley claim that the human mind and brain, while highly developed, are qualitatively similar to those of other species encouraged the concentration of research in a very few “model” nonhuman species. Several recent developments challenge the traditional model-animal research paradigm and provide the foundations of a new neuroscience. First, evolutionary biologists now understand that living species cannot be arrayed along a single, unbroken sequence of phylogenetic development: species can differ qualitatively. Second, neuroscientists are documenting remarkable variations in the organization of cerebral cortex and other brain regions across mammals. Third, new noninvasive methods from histology, neuroimaging, and genomics are making the human brain accessible for direct, detailed study as never before. Finally, these same methods are being used to directly compare humans to other species (including chimpanzees, the species most closely related to humans), providing the foundations of a new and richly detailed account of how the human brain both resembles and differs from that of other species.

Evolution isn't what it used to be

What distinguishes the human brain from that of other animals? This is one of the most profound questions that neuroscience confronts, yet surprisingly it has not attracted a great deal of empirical investigation, nor have the answers offered heretofore been particularly revealing. Humans have big brains relative to body size—that much is agreed upon—but what is different about the contents of those big brains?

We should perhaps start by asking why, despite the great advances made in neurosciences over the past few decades, we have so little solid information about how the human brain differs from and resembles that of other animals. One reason, clearly, is that neuroscientists have had relatively limited means for studying humans, compared to the means available for studying nonhuman species. The most powerful methods at our disposal for studying brains—genetic manipulations, tracer injections, microelectrode recording and

stimulation—require the use of invasive, and often terminal, experimental procedures. Given this fact, neuroscientific research has tended to focus on nonhuman species. To be sure, neuroscience has maintained a tradition of human research, beginning with clinical neurology and strengthened today by the availability of a suite of remarkable noninvasive imaging tools. Nonetheless, there remains an important gap between human and nonhuman studies: the techniques available for studying animals permit much more detailed investigations involving finer levels of organization, and the use of model animals facilitates better experimental design. The result is that many of our ideas about human brain organization are actually inferences drawn from studies of nonhuman species.

What is the scientific basis for making inferences about human brain organization from the study of nonhuman species? The answer, seemingly, is the principle of evolution, which asserts that there was continuity between the human species and other animals through Earth history. We rightly honor Charles Darwin for having the profound insight that all animals are descended from one (or a few) progenitor species and providing the evidence necessary to convince scientists of the truth of that insight (Darwin, 1859). But Darwin did more than that. Darwin viewed the forces of evolution—mainly natural selection—as means of improvement, so that those species that have been subjected to more selection are better species. In this way, Darwin provided a naturalistic explanation of the Great Chain of Being (*scala naturae*), the idea that life forms can be arranged along a linear scale from the simple and base to the complex and refined. The concept of a scale of being long predated Darwin, having its origins (in the Western tradition, at least) in Aristotelian philosophy (Lovejoy, 1964). (Some pre-Darwinian versions of the scale of being go beyond the merely human, extending through the grades of angels up to the Almighty.) Darwin took the metaphysical Great Chain of Being, which seems very strange to most of us today, and turned it into something familiar—the phylogenetic scale (Richards, 1987, 1992). Accordingly, depictions of evolutionary history from the 1860s through the 1960s commonly represented evolution as a process of ascent, with Man at the top (figures 3.1A, 3.2A, 3.2B). Although some historians have

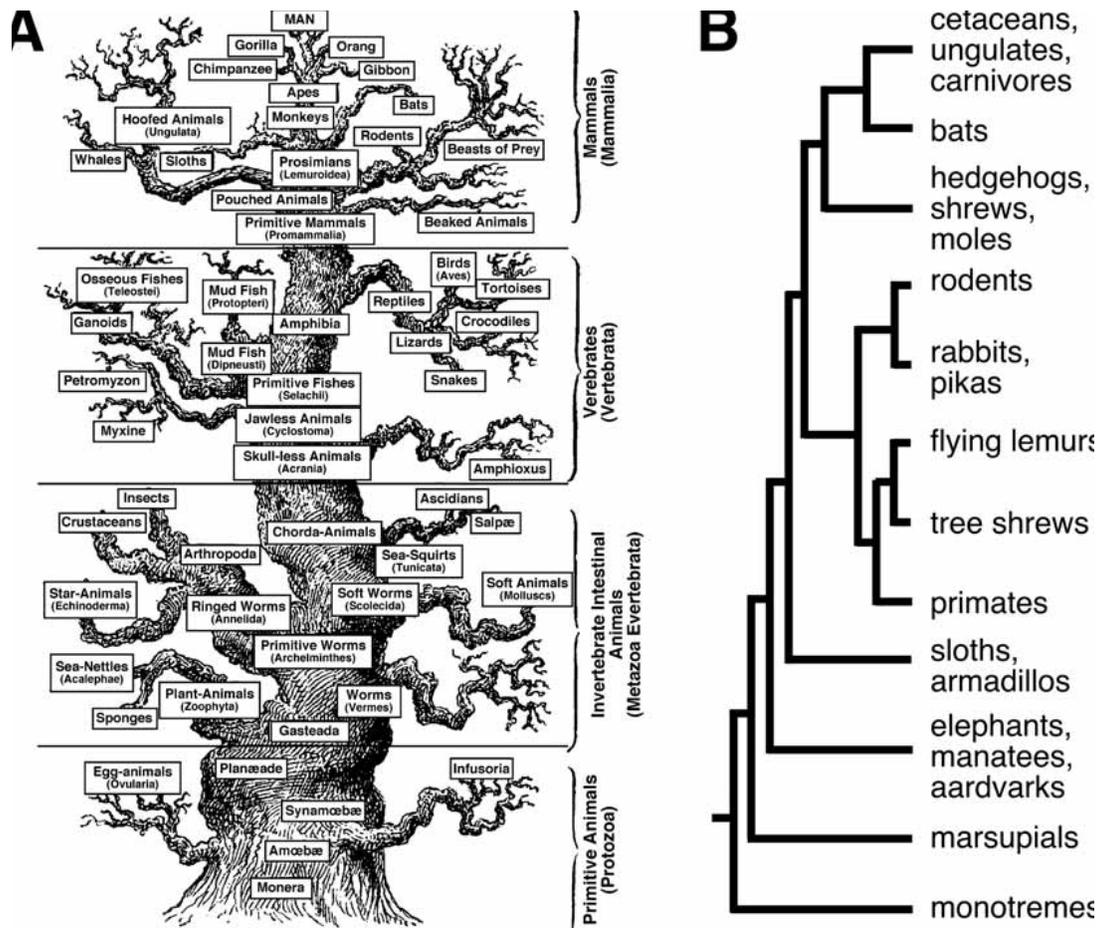

FIGURE 3.1 Changing views of evolutionary history, contrasting (A) an early phylogenetic tree from Ernst Haeckel (1874, 1879), an early supporter of Darwin, and (B) a modern phylogeny of mammals from recent comparative molecular studies, based on Murphy and colleagues (2001). In Haeckel's tree (A), the course of evolution is upward, and it culminates in humans. Other species are relegated to side branches. The modern tree (B) has no orientation, except

with respect to time, and one locates primates or humans merely from the shape of the tree. The tree is drawn with the present-day time horizontal to the right, but the direction of the time axis is arbitrary. Note that I have translated some of the German terms for various primate groups differently than in the original English edition of Haeckel's work (Haeckel, 1879) to better conform to modern usage.

credited Darwin with the idea that evolution has no direction or orientation, it is clear from even a casual reading of Darwin (see especially Darwin, 1871) that he firmly believed in the phylogenetic scale, and that human beings are at the top—that we are the most advanced form of animal life.

Darwin's work marks the beginning of evolutionary biology, but like other branches of science, evolutionary biology underwent revolutionary changes during the 20th century, resulting in a worldview that Darwin would probably have found at once very familiar and very strange. Detailed studies of evolutionary mechanisms made it clear that adaptation is a local process, fitting populations to their particular circumstances. Adaptation does not necessarily involve increased complexity; in fact, it often results in simplification or loss of structures and functional capacities, as in the case of many parasitic organisms. Yet parasites are arguably just as well adapted to their circumstances as the

organisms they infest. Furthermore, evolutionary history has proven to be anything but an unblemished chronicle of progressive improvement: cosmic collisions and tectonic upheavals repeatedly shuffled the deck.

There is another important transformation in the way evolutionary biologists came to view the history of life, and like the study of adaptation, this transformation was ultimately rooted in another of Darwin's profound insights. The sole figure in the *Origin of Species* (Darwin, 1859) depicts evolution as a branching process, with ancestral lineages splitting to form multiple daughter species. Early evolutionists did not recognize any contradiction between the phylogenetic scale and the phylogenetic tree; as a result, early trees typically had a narrow, vertical orientation (figures 3.1A; 3.2A, 3.2B). The contradictions became clear, however, when the lack of a unitary direction to evolutionary history was appreciated. If every lineage is shaped by selection

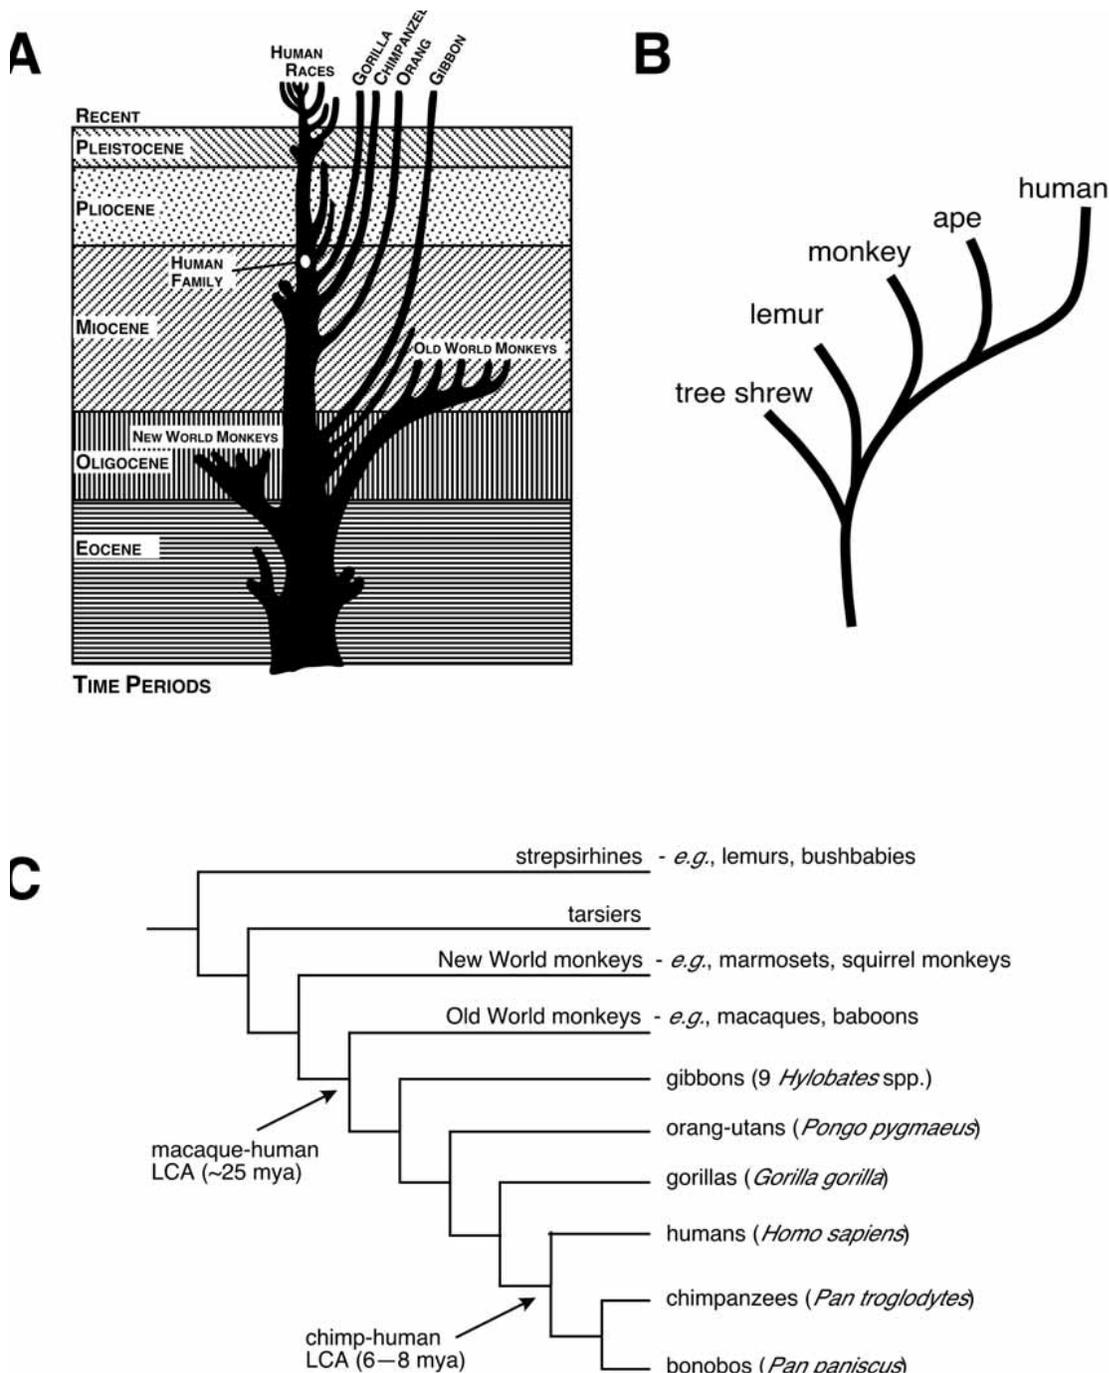

FIGURE 3.2 Changing views of primate evolution, contrasting the vertical, human-oriented trees of (A) Grafton Elliot Smith (1924) and (B) W. E. Le Gros Clark (1959), with (C) a modern branching diagram of the primate order, based primarily on Fleagle (1999). Elliot Smith and Le Gros Clark were both neuroanatomists and primatologists, and their views were enormously influential in shaping our understanding of primate evolutionary history and primate brain evolution (Preuss, 1993, 2007a, 2007b). In their trees, like Haeckel's tree (figure 3.1A), evolution is a progression toward a human apex. In Elliot Smith (A), even living members of the primate order, like New World and Old World monkeys, are treated as though they were extinct side branches. Le Gros Clark (B)

considered living forms like tree shrews, lemurs, monkeys, and apes to be the living embodiments of grades of organization or stages of evolution leading to humans. Modern trees (such as C; modified from Preuss, Cáceres, Oldham, & Geschwind, 2004) place all living forms on the present-day time horizon, and again, the direction of the time axis is arbitrary. Furthermore, there are many equivalent ways of arraying modern groups along the current time horizon, since tree branches can be rotated around any of the internal nodes. Humans, therefore, can be placed at the top of the list, the bottom of the list, or somewhere in between (as shown in C). LCA, last common ancestor.

pressures specific to its circumstances, then the main axis of the tree can be understood to represent time, rather than also serving as an index of advancement. With this recognition, evolutionary trees have become much wider and more rectangular, emphasizing that evolutionary history is a matter of diversification through time (figures 3.1B, 3.2C).

There has been at least one more important change in evolutionists' view of life. Darwin emphasized the continuity of life, and asserted that discontinuities between humans and our closest living relatives would invalidate the theory of evolution. Accordingly, he proposed a research program that encouraged scientists to seek in nonhuman species simplified rudiments of characteristics that are well developed in humans (Darwin, 1871). Huxley (1863) took a similar approach to the brain. For modern evolutionists, by contrast, continuity is seen in strictly historical terms: species are understood to be connected by the continuity of generations through time. Any set of *living* species can, however, differ in ways that encompass no living intermediates. We know, for example, that cetaceans (whales and dolphins) were thoroughly transformed by evolution from terrestrial quadrupeds (related to modern sheep and cows) to fishlike aquatic forms through a series of intermediate forms, replacing, step by step, anatomical features suited for terrestrial life with features suited to aquatic life. We know this because there happens to be a spectacular fossil record documenting the extinct intermediate forms (Gingerich, Haq, Zalmout, Khan, & Malkani, 2001; Thewissen, Williams, Roe, & Hussain, 2001). But there are no *modern* intermediate forms, no array of living species that spans the gap between the aquatic cetaceans and their terrestrial kin. Thus there is no reason to maintain the narrow interpretation of continuity promulgated by Darwin and Huxley, and no reason to insist that every aspect of the human brain or mind be present in some lesser form in other species (see also Penn, Holyoak, & Povinelli, 2008). In the light of modern evidence about evolutionary change, we can see that Darwin and Huxley confounded two different kinds of continuity.

One of the most important aspects of the modern understanding of evolution, therefore, is the change in how biologists view the similarities and differences among animals. If you are troubled by the term “human uniqueness” in the title of this essay, you’re in good company—Darwin, with his emphasis on continuity, would have been troubled, too. But modern evolutionary biology regards each species as a unique outcome of evolutionary history. To be sure, any two species will share some features in common, by virtue of being descended from a common ancestor. But as one restricts comparisons to closer and closer relatives, the set of shared features will become more limited. Humans have forward-facing eyes and nails, rather than claws, on our fingertips; we share these features with other primates,

but not with other mammals (unless, like cats, with their forward-facing eyes, they evolved them independently). Finally, every species will have features that evolved in its own lineage after that lineage branched off from the line leading to its closest relatives. These are its species-specific features. Thus every species can be regarded as a mosaic of characteristics, some that are shared with other species and some that are specific to it.

Model-animal versus comparative approaches to neuroscience

When it comes to the issue of how the brains of different species resemble and differ from one another, there is no question that the majority of neuroscientists would stand with Darwin. Most neuroscientists study nonhuman species, and, moreover, most research effort is concentrated on one of the standard model animals, such as *Drosophila*, *C. elegans*, rats, mice, or macaque monkeys. The emphasis on studies of model animals, which comes to us from the biomedical research tradition and from experimental psychology, is predicated on the assumption that there are major or basic features of organization that are widely shared across animals, and that the differences, whatever they are, are relatively minor and unimportant (Logan, 2001, 2005; Preuss, 2000a). Of course, propagandists for different model species argue endlessly about why their model is the best—highlighting the fact that species do, after all, differ—but the assumption that we can get at the basics by studying a few species is rarely questioned. Neuroscientists working in the zoological tradition tend to take a broader, more comparative view (e.g., Striedter, 2005), but that approach has been marginalized in the neurosciences as the model-animal paradigm has become the accepted approach to biomedicine. Most neuroscientists simply take generality for granted, in effect treating it as a property of the models themselves. Modern publications reporting results in rats or mice typically do not even identify the species in the title. Common model animals like fruit flies, rats, and mice are no longer treated as subjects so much as standardized reagents (Logan, 2002, 2005).

The assumption of generality, and the resulting concentration of research effort in a few model species, seemed until recently to rest on a solid empirical foundation. Brain organization was regarded as evolutionarily conservative, at least across mammals. Mammalian brains might vary in size, and possibly also in degree of “differentiation” (a term meaning quite different things to different people), but the internal organization of the brain, especially at the level of the local cellular architecture and local connectivity, was understood to be largely invariant. Cortex, in particular, was said to exhibit a “basic uniformity” across species (Rockel, Hiorns, & Powell, 1980; see also Creutzfeldt, 1977; Mountcastle, 1978; Phillips, Zeki, & Barlow, 1983; Szentagothai, 1975).

During the 1970s, however, evidence began to accumulate indicating that at least the larger-scale organization of cerebral cortex was not so uniform across species: different mammalian groups evolved different complements of cortical areas (e.g., Allman, 1977; Kaas, 1977; see also Allman, 1999; Kaas, 2007). As comparative studies of connectivity have advanced, it has become evident that the way cortical areas are organized into functional networks can vary markedly across species (reviewed by Preuss, 2007a, 2007b). In recent years, too, the empirical basis for the claim of basic uniformity at local levels of organization has collapsed, with variations in cell phenotypes, local connectivity, laminar organization, and modular organization proving to be ubiquitous. Even among closely related mammalian species, there can be marked differences at these finer levels of cortical organization (for reviews, see DeFelipe et al., 2007; DeFelipe, Alonso-Nanclares, & Arellano, 2002; Elston, 2007; Hof & Sherwood, 2005, 2007; Preuss, 1995, 2001; Sherwood & Hof, 2007).

The implications of these results for the practice of neuroscience and for our understanding of the human brain are profound. Since brains are diverse, any attempt to discover general or shared features of organization requires comparative studies—generalizing from just a few “standard” species just will not do. If we can acknowledge the pitfalls of extrapolating results from one mouse strain to another, or from mice to rats (Cantallops & Routtenberg, 2000; McNamara, Namgung, & Routtenberg, 1996; Rekart, Sandoval, & Routtenberg, 2007), should we not be at least as mindful of the pitfalls of extrapolating from mice to humans? Evolutionary biology provides standards and methods for rigorous comparative studies, methods that have been adopted in many areas of biology—comparative genomics, for example, which would be impossible without the analytic tools of modern phylogenetics—but these methods are still unknown to most neuroscientists.

No less problematic than the concentration of so much research in so few species is the limited research directly comparing humans to other species. If one accepts the modern view of evolution, then it is clear there must be ways that humans are like other animals and ways that we are distinctive. How can we identify and distinguish these similarities and differences except by means of comparative studies of humans and other animals? Furthermore, if we want to understand in detail what is distinctively human about our brains, the most informative approach is to compare humans to the animals that are most closely related to us: the other hominoids. The primate superfamily Hominoidea consists of humans, chimpanzee, bonobos, gorillas, orangutans, and gibbons: Collectively, this group of lineages (or “clade”) is the sister group of Old World monkeys (the clade that includes macaque monkeys), the two groups sharing a common ancestor about 25 million years ago

(figure 3.2C). The lineage most closely related to humans is the chimpanzee-bonobo clade, with which we shared a common ancestor about 6–8 million years ago. If we take evolutionary biology seriously, we should expect that hominoids, as a group, possess brain characteristics that are absent in Old World monkeys (and vice versa), and that each hominoid species—humans included—should possess brain features lacking in the other species.

Human brain specializations: New methods, new discoveries

What, then, do we know about how human brains differ from those of chimpanzees and other hominoids? Until recently, one could answer this question quite succinctly: not much. One fact that is undisputed is that humans have very large brains, even when body size is factored out: humans are only slightly larger than chimpanzees in average adult body size, but human brains average around 1,200–1,300 cubic centimeters (cc), compared to a little less than 400 cc for chimpanzees (de Sousa & Wood, 2007; Kaas & Preuss, 2008). Most of this increase occurred during the last 2 million years, after the genus *Homo* evolved from *Australopithecus*-like ancestors, embarking on a lifestyle that involved reliance on stone tools and a diet that included an important component of animal flesh.

Beyond these facts, there have been few points of general agreement. Since certain human brain functions appear to be highly lateralized compared to nonhuman primates (Corballis, 2007), it’s natural to suppose that the well-documented anatomical asymmetries of the human brain, such as the larger extent of the planum temporale in the left hemisphere than in the right (Geschwind & Levitsky, 1968), must also be human-specific. Apes, however, possess at least some of the asymmetries seen in humans, including the asymmetry of the planum temporale (e.g., Gannon, Holloway, Broadfield, & Braun, 1998; Hopkins, Marino, Rilling, & MacGregor, 1998). This is a surprising result, since the planum is involved in language and is sometimes identified with Wernicke’s area. Do humans, with our greatly enlarged brains, possess cortical areas in addition to those present in apes and other nonhuman primates? It seems plausible that they do—certainly Brodmann (1909) and others (e.g., Crick & Jones, 1993) have supposed that humans must possess new areas to support new, human-specific brain functions. Modern cortical mapping studies, however, suggest mainly commonalities in the complement of cortical areas in humans and macaques (Petrides & Pandya, 1994), the latter being the most widely studied nonhuman primates. There is evidence, furthermore, that nonhuman primates possess homologues of Broca’s and Wernicke’s areas (Preuss, 2000b), which suggests that the evolution of new human functions did not necessarily require the addition of new cortical areas. In settling

the general question of new areas, however, we remain hamstrung by the lack of modern, comprehensive brain maps for humans and other hominoids—the state-of-the-art chimpanzee cortical map is nearly 60 years old (P. Bailey, Bonin, & McCulloch, 1950). At present, there is not even unanimity about whether the evolutionary expansion of the human brain involved the disproportionate expansion of the association cortex or whether expansion was more nearly global (see the review of Rilling, 2006), although I feel the evidence strongly supports the former view (Preuss, 2004b). Other, no less fundamental, aspects of human brain organization have received even less attention. In some cases, like the local cellular and histological organization of the brain, the lack of attention probably reflects simple indifference: if cortical organization is uniform across species, as has been supposed, why waste one's time looking for differences? In other cases, the lack of attention probably reflects the lack of appropriate techniques: if studying brain connectivity requires invasive and terminal procedures, then you cannot study connectivity in humans, nor can you do so in other hominoids, which are also off-limits for invasive neuroscience research.

Fortunately, the development of new methodologies, combined with new ways of thinking, has begun to transform our understanding of the human brain. For the sake of discussion, I will group the methodologies into three categories—comparative histology, comparative neuroimaging, and comparative genomics. Although seemingly a very disparate group of techniques, they have in common the quality that they do not require invasive and terminal experimental procedures, and for this reason they can all be used to study humans directly and to compare humans to chimpanzees or to just about any other species. It is their noninvasive character that makes these techniques so extraordinarily valuable for understanding human brain specializations.

COMPARATIVE HISTOLOGY One does not normally associate the word “histology” with “new,” but in fact there is much that is new in histology, and it has contributed some of the most remarkable recent discoveries about hominoid and human brains. Histology today has at its disposal a fantastic set of tools for localizing specific molecules within the brain—antibodies, lectins, riboprobes, as well as conventional histochemical stains—and because specific molecules tend to be associated with specific cell compartments, cell types, laminae, modules, and areas, these tools make possible a molecular dissection of brain structure. In addition, there are new stereological methods for counting cells and other elements in the brain that constitute a major advance over traditional counting methods (Schmitz & Hof, 2005; West, 1999). Finally, there are new storage solutions that are far superior to formalin for maintaining the long-term viability of tissue for molecular analysis (Hoffman & Le, 2004). Modern cryopreservative solution greatly enhances the value

of tissue archives, so studies can make use of tissue harvested from individuals who die of natural causes, and need not rely entirely on tissue obtained from terminal experiments.

What we have learned using these techniques, in the context of comparative studies, is that hominoids and humans possess specialized neuronal phenotypes and specialized columnar, modular, and laminar arrangements of nerve cells (Hof & Sherwood, 2007; Preuss, 2004a; Sherwood & Hof, 2007). A particularly dramatic example is the discovery of a distinctive class of large, spindle-shaped neurons in layer 5 of anterior cingulate and fronto-insular cortex, termed “spindle cells” (Nimchinsky et al., 1999) or “von Economo neurons” (Allman, Watson, Tetreault, & Hakeem, 2005). These are present in humans and other hominoids (except gibbons), but are much larger and more numerous in humans. They are absent in other primate and most other mammalian species examined to date. In a clear case of convergent evolution, however, large spindle-shaped cells are present in homologous regions of some large-brained cetaceans (Hof & Van Der Gucht, 2007). It has been proposed that spindle cells evolved to facilitate rapid transmission of emotion- and reward-relevant information in large-brained, highly social hominoids and cetaceans (Allman et al.; Watson & Allman, 2007).

Many additional neuronal and neuritic specializations have been described in hominoids. These include an additional distinctive class of layer 5 pyramidal cell in anterior cingulate cortex, specialized by virtue of expressing calretinin, a calcium-binding protein expressed only in interneurons in most mammalian groups (Hof, Nimchinsky, Perl, & Erwin, 2001). Raghanti and colleagues have described hominoid specializations of the density and morphologies of serotonergic (Raghanti et al., 2008b) and cholinergic fibers (Raghanti et al., 2008a) in frontal cortex, including areas 9 and 32.

There have been fewer comparative studies of the microarchitecture of human language cortex than one might have supposed. Although apes and humans apparently have similar morphological asymmetries in Wernicke's area, there appear to be asymmetries at finer levels of organization. Buxhoeveden, Casanova, and their colleagues report that the spacing of cellular columns in cortical area Tpt, located on the planum temporale, is asymmetrical in humans, being wider on the left than the right, but not in chimpanzees and macaques (Buxhoeveden, Switala, Litaker, Roy, & Casanova, 2001).

While we would expect to find changes in brain regions that support functions known to have changed in human evolution, it is significant that the changes are widespread and include regions not conventionally thought to be evolutionarily “advanced.” Thus the spindle cells and the morphological specializations of serotonergic and cholinergic fibers noted above are present in limbic cortex (areas 24

and 32). Nor are specializations necessarily limited to cortex: the basal forebrain magnocellular neurons of New World and Old World monkeys express the peptide galanin in the cytoplasm, whereas those of apes and humans do not; moreover, the basal forebrain of hominoids, but not monkeys, exhibits plexus of galanin-containing processes of extrinsic origin (Benzing, Kordower, & Mufson, 1993; Kordower & Mufson, 1990).

Currently, we know about as little about the cognitive and behavioral specializations of humans as we do about human brain specializations (Subiaul, Barth, Okamoto-Barth, & Povinelli, 2007) and thus should be alert to the possibility that specializations will turn up in places we do not expect, including sensory systems. A case in point: In 1999, my laboratory discovered, quite by accident, that the histology of human primary visual cortex (area V1) differs strikingly from that of apes or any monkey species that has been examined (Preuss, Qi, & Kaas, 1999). We documented a distinctive modular organization of human layer 4A, with cell bodies and neurites that label with SMI-32 and MAP2 antibodies (markers for neurofilaments and microtubules, respectively) distributed in a meshlike arrangement, with the mesh surrounding unlabeled territories. Subsequently, we found that the mesh is densely immunoreactive for Cat-301 (figure 3.3), an antibody considered a selective marker for elements of the magnocellular (M) pathway of the visual system, and that the intervening territories contain small cells that strongly express calbindin, a calcium-binding protein (Preuss & Coleman, 2002). We have speculated that the cortical processing of motion and contrast information, which is mediated by the M pathway, was modified in human evolution; additional evidence for such changes comes from studies of higher-order visual areas (discussed later). Whether or not this particular functional interpretation is correct, the structure of layer 4A of humans is very different from that of other primates. No other primate examined to date possesses patches of strong labeling in layer 4A with SMI-32, or MAP2, or Cat-301. Like humans, chimpanzees display dense calbindin expression in layer 4A, but calbindin is distributed homogeneously in chimpanzees rather than in the patchy manner characteristic of humans. In Old World and New World monkeys, layer 4A is calbindin poor, although some other layers express it strongly. As it happens, this is just one example of many variations in the organization of the primary visual cortex, variations that distinguish humans from other hominoids, hominoids from macaque monkeys, and different monkey species from each other (Preuss, 2004a).

COMPARATIVE NEUROIMAGING The foregoing discussion illustrates the power of histological techniques to resolve differences in the microarchitecture of the brain between even very closely related species. New neuroimaging techniques make it possible to compare the connectivity and

regional organization of the brain, and so provide insight into the evolution of the higher-order organization of the brain. As with the histological techniques, the imaging techniques are noninvasive, and so make it possible to compare humans and nonhuman primates on something like a level playing field.

The earliest applications of comparative imaging involved structural magnetic resonance imaging (MRI) scans (usually T1-weighted scans) to study morphometry—quantifying the sizes and proportions of the different cerebral lobes across species (Rilling & Insel, 1999b; Rilling & Seligman, 2002; Semendeferi & Damasio, 2000; Semendeferi, Damasio, Frank, & Van Hoesen, 1997; Semendeferi, Lu, Schenker, & Damasio, 2002), the size of the cerebellum (MacLeod, Zilles, Schleicher, Rilling, & Gibson, 2003; Marino, Rilling, Lin, & Ridgway, 2000), the sizes of white matter structures (Rilling & Insel, 1999a; Schenker, Desgouttes, & Semendeferi, 2005; Schoenemann, Sheehan, & Glotzer, 2005), and patterns of interhemispheric asymmetries (Gilissen, 2001; Hopkins et al., 1998). In principle, there is little in this morphometric work that could not have been done with standard histological methods: sectioning and staining brains, and then taking measurements on the sections. In practice, however, MRI morphometrics offers many advantages: it can make use of live individuals, and even when fixed brains are scanned, data acquisition and analysis are much faster and less labor intensive than with histological material, and the fixed brains remain intact after examination so they can be put to other uses. The result is that MRI facilitates study of a wider range of species than would be practical were the same questions to be addressed histologically.

As noted earlier, the lack of information about brain connectivity in species such as humans and chimpanzees that cannot be studied with invasive tracing techniques has been one of the greatest obstacles to understanding brain organization in those species. The situation has improved considerably in recent years with the introduction of diffusion-tensor imaging (DTI) (Conturo et al., 1999; Mori & van Zijl, 2002; Mori & Zhang, 2006; Ramnani, Behrens, Penny, & Matthews, 2004). DTI measures the aggregate direction and magnitude of water diffusion in brain voxels. Since water tends to diffuse along, rather than across, the hydrophobic myelin sheaths of axons, the direction of water diffusion reflects the direction of fibers in a voxel. With this information, it is possible to reconstruct fiber tracts through the white matter between regions of interest in the brain. Compared to traditional chemical techniques, DTI has significant limitations: its spatial resolution is too coarse to track from neuron to neuron; it does not work well in gray matter, where fiber coherence is low; and it is vulnerable to false positives and false negatives. While studies designed to evaluate what DTI can and cannot reliably determine are continuing, it is apparent that, at least for certain pathways,

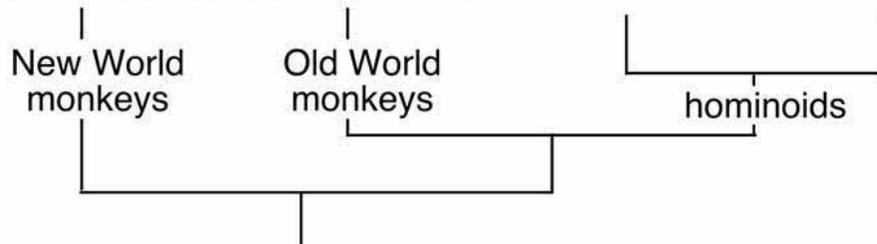

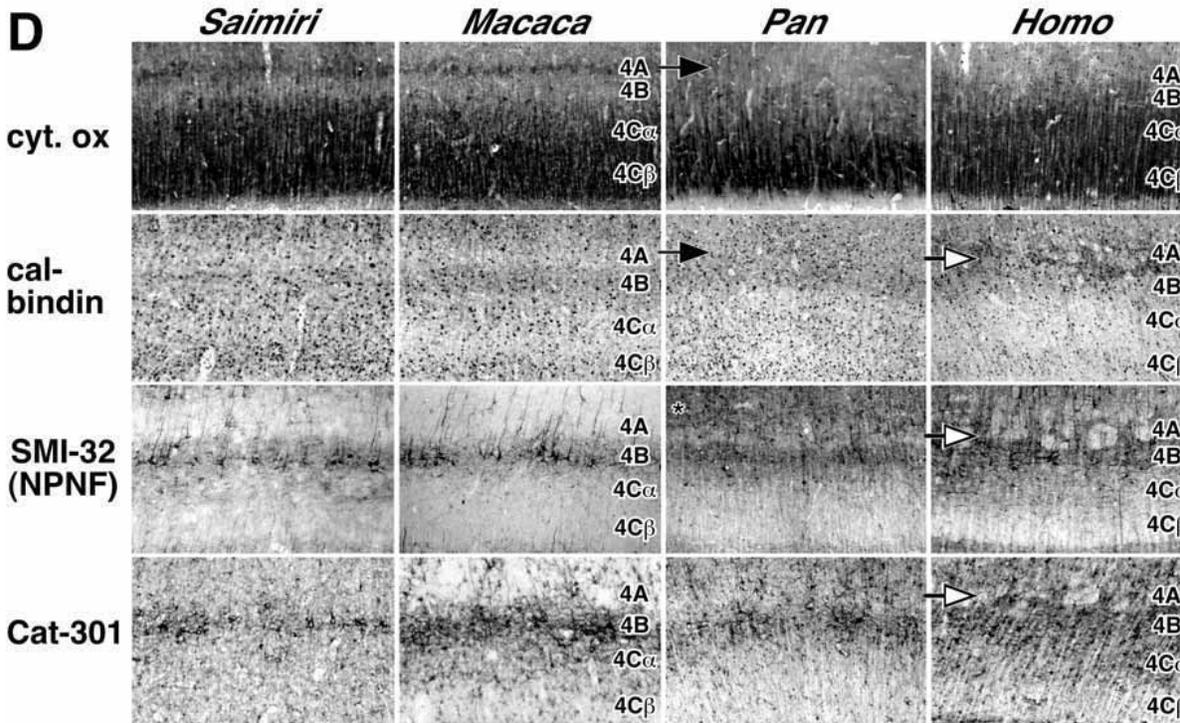

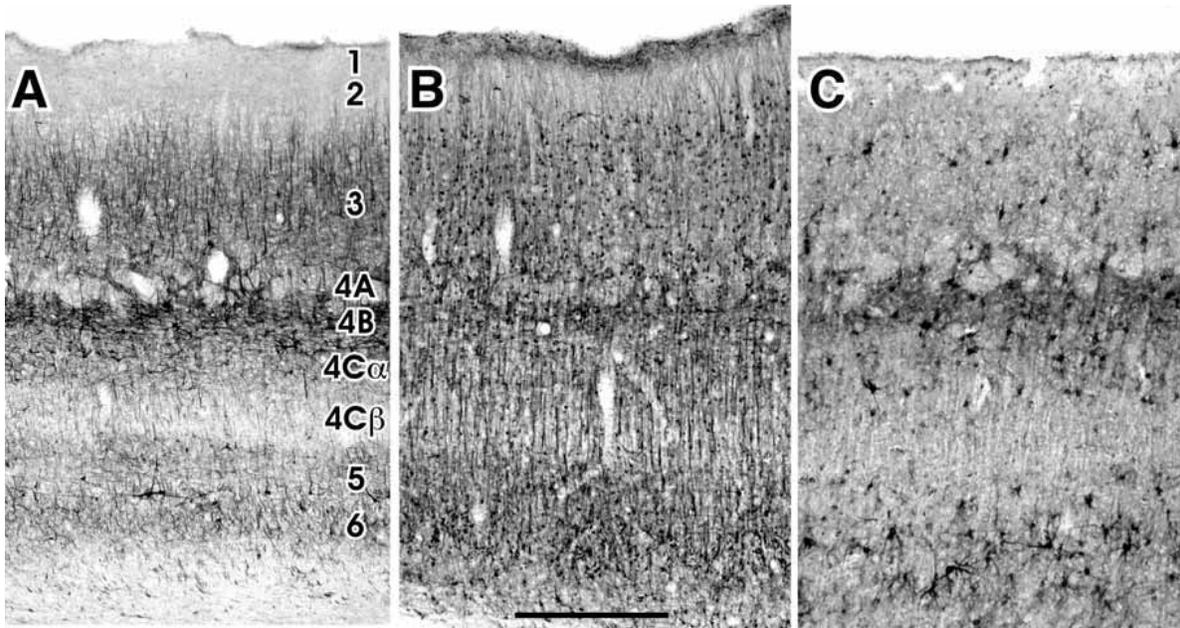

FIGURE 3.3 Evolutionary modification of human primary visual cortex according to Preuss and Coleman (2002). (A–C) Human primary visual cortex labeled for nonphosphorylated neurofilaments with the SMI-32 antibody (A), an antibody to MAP2 (B), and antibody Cat-301 (C), which labels the proteoglycan-rich extracellular matrix. All three preparations show the distinctive compartmental pattern of human layer 4A. Scale = 500 microns. (D) Comparative analysis of evolutionary changes in layer 4A and 4B of hominoid and human primary visual cortex. Sections from a New World monkey (*Saimiri*, squirrel monkey), an Old World monkey (*Macaca*), and two hominoids (*Pan*, chimpanzee; *Homo*, human), were labeled with four different preparations: cytochrome oxidase (cyt. ox.), antibodies for calbindin, the SMI-32 antibody for nonphosphorylated neurofilaments, and the Cat-301 antibody for extracellular matrix proteoglycan. The evolutionary relationships

between the four taxa are represented by the branching diagram at the bottom of the figure. The ancestors of all four groups probably possessed a cytochrome-oxidase-dense band in layer 4A, a band subsequently lost in hominoid evolution, as it is absent in *Pan* and *Homo*, as indicated by the black arrow. This difference may reflect the reduction or loss of projections to layer 4A from the parvocellular layers of the lateral geniculate nucleus. Calbindin immunoreactivity is weak in layer 4A in *Saimiri* and *Macaca*, but strong in *Pan* and *Homo*, as indicated by the black arrow, suggesting that increased calbindin expression in this layer is a hominoid specialization. (Hominoids also show much stronger staining of the cortex superficial to layer 4A, as indicated by the asterisk in *Pan*.) The distinctive, patchy compartmentation of human layer 4A can be seen in the calbindin, SMI-32, and Cat-301 preparations, as denoted by the white arrows in *Homo*.

accurate reconstructions can be obtained (e.g., Behrens, Berg, Jbabdi, Rushworth, & Woolrich, 2007; Conturo et al., 1999; Dauguet et al., 2007; Parker et al., 2002; Schmahmann et al., 2007).

The advantage of DTI, of course, is that it can be used to study connectivity noninvasively, so it can be used with humans, chimpanzees, and other primates. It can even be used with fixed brains, which makes a wide variety of species accessible for connectivity studies for the first time (e.g., Kaufman, Ahrens, Laidlaw, Zhang, & Allman, 2005). Some of the first comparative studies undertaken with DTI have compared humans and macaque monkeys, examining thalamocortical (Croxon et al., 2005), corticopontine (Ramnani et al., 2006), and prefrontal cortex (Croxon et al.) connectivity. Recently, Rilling and colleagues published the first comparative study of humans, chimpanzees, and macaques, focusing on the arcuate fasciculus (AF), a white matter tract that in humans interconnects Broca's and Wernicke's areas (Geschwind, 1970; Glasser & Rilling, 2008). Rilling and colleagues (2008) tracked pathways between the posterior superior temporal lobe (Wernicke's area) and inferior frontal cortex (Broca's area) in all three species, but only chimpanzees and humans were found to have a distinct AF. Moreover, only in humans did the AF consistently include fibers tracking to the middle temporal gyrus, in addition to the fibers between Broca's and Wernicke's areas (figure 3.4). Functional imaging studies in humans (reviewed by Glasser & Rilling, 2008) indicate that the cortex of the middle temporal gyrus is involved in representing word meaning. Noting evidence that inferotemporal visual cortex appears to be situated more posteriorly and inferiorly in humans than in macaques, Rilling and colleagues suggest that the cortex of the middle temporal gyrus was enlarged and modified in human evolution, and may constitute an evolutionary novelty.

In addition to comparative structural neuroimaging, it is possible to do comparative functional imaging, using functional MRI (fMRI) or positron-emission tomography (PET).

Functional MRI is now routine in humans, but the need to prevent head movement in the scanner has meant that its application in nonhuman primates has largely been restricted to macaque monkeys, which can be physically restrained. Although many macaque studies have employed these animals in the role of human models, some workers have made a point of documenting differences between humans and macaques. These studies have identified macaque-human differences in the responsiveness of contrast- and motion-related regions of the dorsal extrastriate visual cortex and posterior parietal cortex (Denys et al., 2004; Orban, Claeys, et al., 2006; Orban et al., 2003; Orban, Van Essen, & Vanduffel, 2004; Tootell et al., 1997; Vanduffel et al., 2002), the differences being sufficient to complicate the interpretation of human-macaque homologies (Serenó & Tootell, 2005) and to suggest that humans possess areas macaques lack (Orban, Claeys, et al.).

It is unlikely that we will soon have fMRI studies of awake, behaving chimpanzees, as imaging equipment is no match for these enormously powerful animals. Yet it is possible to do functional scanning in chimpanzees, using a modification of the 18F-fluoroodeoxyglucose (FDG)-PET technique. In this approach, originally developed for macaques, the experimenter provides the animal with the FDG at the start of testing session, and then, after the level of FDG plateaus (45–60 minutes), the animal is anesthetized and PET scanned. This technique was recently used to compare awake, resting-state brain activity in humans and chimpanzees (Rilling et al., 2007). The results demonstrated commonalities between species: both exhibited activation in medial frontal and posteromedial cortices, components of the “default-mode” network thought to be involved in emotion-laden recollection and mental self-projection (e.g., Buckner & Carroll, 2007; Buckner & Vincent, 2007; Gusnard & Raichle, 2001; Raichle & Snyder, 2007). Humans, but not chimpanzees, however, also showed activation of lateral cortical regions in the left hemisphere associated with language and conceptual representation.

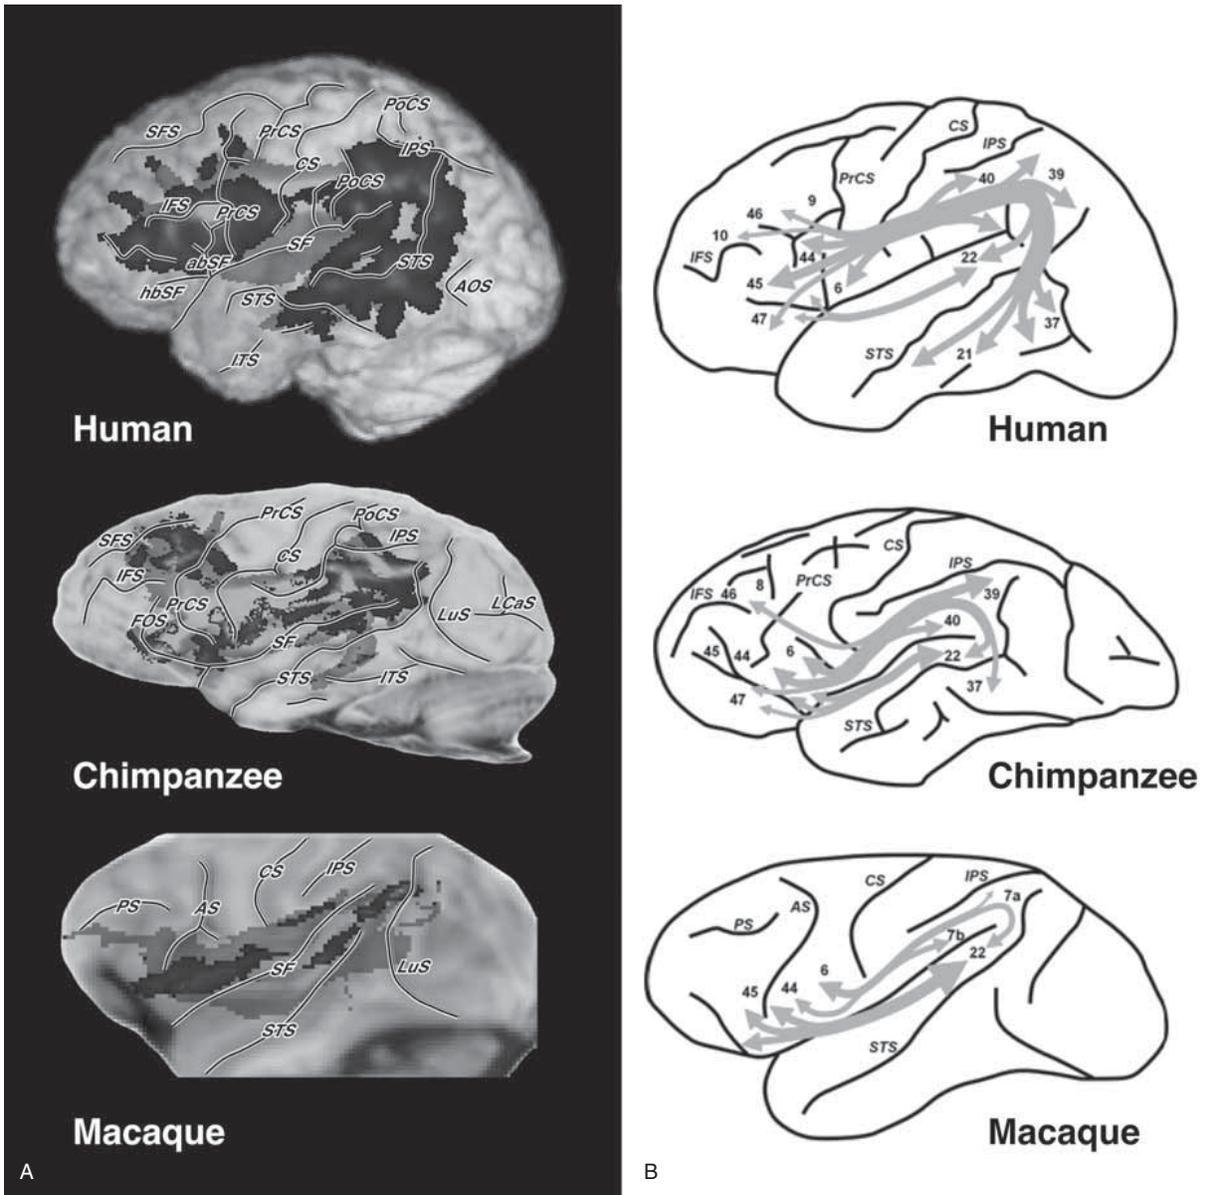

FIGURE 3.4 Evolution of the human arcuate fasciculus (AF), which interconnects frontal and temporal language areas, based on the comparative diffusion-tensor imaging (DTI) results of Rilling and colleagues (2008). (A) Average tractography results from the left hemispheres from 10 humans, three chimpanzees, and two macaque monkeys. (B) Schematic representation of the results shown in A, representing the cortical endpoints of the tracts in terms of Brodmann's areas. Both humans and chimpanzees have a distinct AF, although in humans the AF includes strong connec-

tions with the temporal cortex below the superior temporal sulcus (STS), including area 21, a region where word meaning is represented. Chimpanzees have very few fibers in the AF that extend to the cortex inferior to the STS. Macaques do not have a definite AF: fibers traveling between the posterior frontal cortex and posterior temporal lobe take a more ventral route, passing deep to the insula, and include few if any fibers with endpoints inferior to the STS. (See color plate 1.)

Although fMRI scanning of awake chimpanzees currently seems impractical, it may be valuable to do fMRI scanning of anesthetized chimpanzees. Although cortical activity is reduced with light anesthesia, it is not eliminated. Patterns of regional coactivation that reflect patterns of anatomical connectivity can be ascertained using so-called functional connectivity MRI (fcMRI), even under light anesthesia

(Vincent et al., 2007), and possibly the same can be done with chimpanzees. This technique would provide a valuable addition to DTI as a source of information for exploring the evolution of human brain networks.

COMPARATIVE GENOMICS In recent years, few branches of science have so firmly captured the public imagination—

and that of scientists, too—as the field of comparative genomics, particularly as it pertains to the genetic differences that distinguish human beings from chimpanzees. The story line is compelling: humans and chimpanzees are nearly identical genetically—98–99% similar, apparently (King & Wilson, 1975; Marks, 2002)—so that differences in brain size, language ability, and “intelligence” would seem to be the consequences of a small set of genetic changes. With advances in the technical means for sequencing nucleic acids and with the accumulation of knowledge about the gene sequences of humans, chimpanzees, and other mammals from the various genome projects, we are now in a position to identify the genetic specializations of human beings. These specializations turn out to be far more extensive than expected, and include not only changes in gene sequences and gene expression, but also rearrangements, duplications, and losses of blocks of DNA.

Many of the gene-sequence differences that distinguish humans from other animals are the result of random substitutions (genetic drift), so it is necessary to cull these from the list of sequence differences to identify those that were likely to have been produced by natural selection. The culling is done statistically: genes under selection are expected to have ratios of nonsynonymous-to-synonymous sequence changes (i.e., nucleotide substitutions that produce amino-acid substitutions versus those that do not) greater than expected by chance. Among the genes that appear to have undergone positive selection in the human lineage are those for *FOXP2* (forkhead box P2) (Enard, Przeworski, et al., 2002), *MCH1* (microcephalin) (Evans et al., 2005), and *ASPM* (abnormal spindlelike microcephaly associated) (Mekel-Bobrov et al., 2005). *FOXP2* is of special interest because mutations of the gene are associated with language disorder, while specific mutations of *MCH1* and *ASPM* are associated with microcephaly. The suggestion, then, is that selection on these genes is related to the evolution of language (*FOXP2*) and increased brain size (*MCH1*, *ASPM*). Complementary to these single-gene studies, geneticists have also used high-throughput approaches (i.e., bioinformatic methods for comparing thousands of genes in genomic databases), identifying hundreds of DNA elements likely to have undergone sequence changes as the result of positive or negative selection (Arbiza, Dopazo, & Dopazo, 2006; Bustamante et al., 2005; Clark et al., 2003; Harris & Meyer, 2006). Some of selection-modified sequences are protein-coding genes, while others are regulatory elements. Relaxation of selection pressure has also been a factor in human genetic evolution, resulting, for example, in the transformation of numerous olfactory receptor genes into nonfunctional pseudogenes (reviewed by Roquier & Giorgi, 2007).

King and Wilson (1975), noting the ~1% difference in protein-coding gene sequences between humans and chimpanzees, suggested that the anatomical and behavioral dif-

ferences between these species are mainly the result of evolutionary changes in gene expression. Whole-genome sequencing projects have paved the way for comparative studies of gene expression by providing the information required to make gene microarrays. Microarrays are comprised of probes representing a significant fraction of the genes in the genome. Messenger RNA extracted from tissue is labeled with a fluorescent marker, and the amount of mRNA bound to specific probe sequences provides an index of the strength of expression of specific genes in the tissue sample. In this way, gene expression in homologous tissues can be compared across species. A number of such studies have now been carried out (Cáceres et al., 2003; Enard, Khaitovich, et al., 2002; Khaitovich et al., 2005; Uddin et al., 2004; see also Gu & Gu, 2003; Hsieh, Chu, Wolfinger, & Gibson, 2003), and, as with the high-throughput sequence studies, they suggest that hundreds of genes underwent expression changes in human evolution (Preuss et al., 2004). Evolutionary changes in promoter sites and transcription factors that could account for these expression changes are areas of active investigation (e.g., Donaldson & Gottgens, 2006; Hammock & Young, 2005; Heissig et al., 2005; Pollard, Salama, King, et al., 2006; Rockman et al., 2005; Spiteri et al., 2007; Vernes et al., 2007). Understanding the functional significance of the changes has been challenging, owing in part to the variety of functional classes of genes involved. Recently, Oldham, Horvath, and Geschwind (2006) addressed this issue using network-analytic approach. They identified several sets of gene-coexpression “modules” common to humans and chimpanzees, along with a cortical module comprising multiple genes involved in energy metabolism that was present in humans but nearly absent in chimpanzees. Related to the latter module also were a number of genes involved in synapse formation and function.

These microarray studies have several limitations. One is that the microarrays used were constructed with gene sequences from humans, and sequence differences between humans and the other species examined bias the results (Hsieh et al., 2003; Preuss et al., 2004). Human-chimpanzee sequence differences can be corrected for, but comparisons with more distantly related species are problematic. New techniques for quantifying gene expression using mass resequencing should overcome these problems. Another limitation is that expression studies to date have been restricted to comparisons of adult brain tissues. Presumably, some of the most important differences between humans and nonhuman primates, including increased brain size, reflect changes in gene expression occurring in early development. Identifying these will require comparing fetal tissues from humans and apes, and availability of needed materials is problematic.

Identifying sequences and expression changes is just the first step in relating genetic to phenotypic changes:

if we want to know how genetic changes are affecting human phenotypes, we have to determine where and how those genes are acting in humans compared to other primates. This is where expression studies have an advantage over sequence studies. In sequence studies, one can know that a particular gene was selected for in human evolution, but since most genes are expressed in multiple tissues and cell types, one does not know which tissue or tissues were the targets of selection. Expression studies compare RNA samples from homologous tissues from different species, so they can provide starting points for comparative studies of those tissues. In one of the first attempts to do so, Cáceres and colleagues (Cáceres, Suwyn, Maddox, Thomas, & Preuss, 2007) compared the expression of *THBS4* (thrombospondin 4) in frontal cortex of humans, chimps, and macaques. Experimental studies in rodents and cell culture suggest that thrombospondin proteins stimulate neurons to make synapses

(Christopherson et al., 2005; Susman et al., 2007), and thus increased expression in human cortex suggests evolutionary changes in synaptic turnover or plasticity. Thrombospondins are, however, expressed by a variety of brain cell types (neurons, glia, endothelial cells) and mediate many functions in addition to synaptogenesis. Cáceres and colleagues examined the expression of *THBS4* protein in frontopolar cortex, and found the *THBS4* protein is distributed much more densely within the cortical neuropil (where synapses are concentrated) of humans than in other species (figure 3.5). This finding is consistent with a link between changes in thrombospondin expression and synaptic dynamics in human evolution, but it is far from proof. Additional study is required, but now we have a good idea where to look. Through studies like these, we can use our rapidly growing knowledge of changes in any gene sequence or expression level to drive “phenotype discovery” at the cell and tissue levels (Preuss et al., 2004).

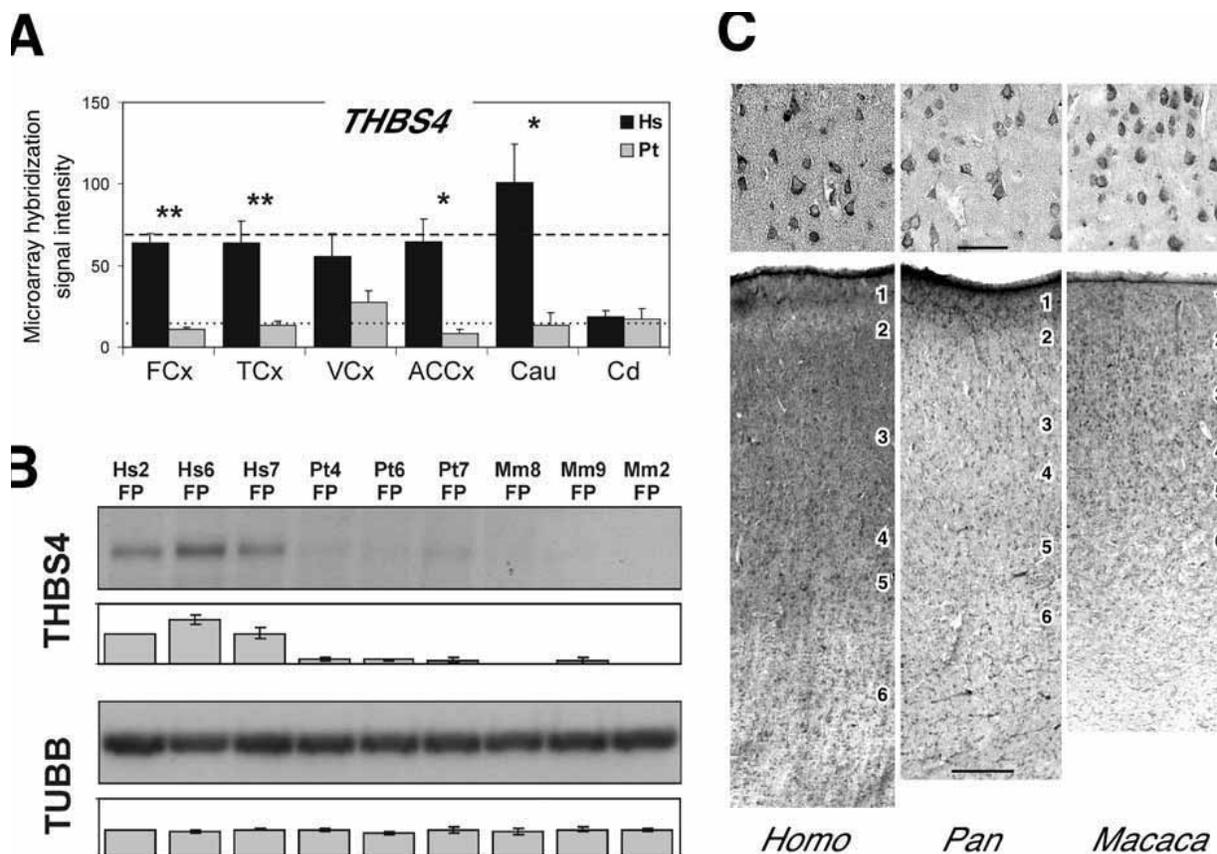

FIGURE 3.5 Increased expression of the thrombospondin 4 (*THBS4*) gene and protein in human brain evolution, according to Cáceres, Suwyn, Maddox, Thomas, and Preuss (2007). (A) Microarray analysis of *THBS4* mRNA levels in different brain regions of humans (Hs, *Homo sapiens*) and chimpanzees (Pt, *Pan troglodytes*). Expression levels were significantly higher in human frontal cortex (FCx), temporal cortex (TCx), anterior cingulate cortex (ACCx), and caudate (Cd). (B) Western blots showing higher levels of *THBS4*

protein levels in frontal cortex from three individual humans (Hs), compared to three chimpanzees (Pt) and three rhesus macaques (*Macaca mulatta*, Mm). Tubulin (TUBB) served as a loading control. (C) Immunocytochemistry for *THBS4* in sections for frontopolar cortex yielded much denser labeling of humans than of chimpanzees or macaques. The difference was especially strong in the neuropil space surrounding neuronal somas. Scales are 50 microns in the upper panel and 250 microns in the lower panel.

Phenotype discovery would not be an important matter if it really were the case that the differences between humans and chimpanzees come down to just a few key genes. Recent studies, however, indicate that the genetic differences between humans and chimpanzees have been substantially understated (Cohen, 2007c), and the actual difference in total DNA sequence is closer to 4% than 1% (Britten, 2002; Varki & Altheide, 2005). The increase reflects the discovery that multiple duplications and deletions of DNA blocks occurred independently in human and chimpanzee evolution (J. Bailey & Eichler, 2006; Cheng et al., 2005; Sikela, 2006). This implies, perhaps surprisingly, that humans have genes that chimpanzees do not have, and vice versa (Eichler et al., 2001; Hayakawa et al., 2005; Johnson et al., 2001; Popesco et al., 2006; Sikela, 2006; Varki & Altheide, 2005). Moreover, these differences are just part of a much larger set of macromolecular difference between humans and nonhuman primates. For example, humans and nonhuman primates have different complements of expressed, but untranslated, RNAs, molecules that are thought to regulate mRNA translation (Berezikov et al., 2006; Pollard, Salama, Lambert, et al., 2006; Zhang, Peng, Wang, & Su, 2007). Humans also exhibit specializations in the way the multiple domains of protein-coding genes are spliced to form expressed proteins (Calarco et al., 2007). Finally, there are human specializations of the posttranslational modifications of proteins, specializations that may be especially relevant to infectious and neurodegenerative disease (Brooks, 2004; Gearing, Tigges, Mori, & Mirra, 1996; Varki, 2006; Walker, Rosen, & LeVine, 2008). There is thus a myriad of macromolecular differences between humans and other species, the functional and phenotypic significance of which awaits elucidation. The large number of genetic differences between humans and chimpanzees is all the more impressive when one considers how little reliable empirical evidence we have about the psychological, neurobiological, and other phenotypic differences between humans and chimpanzees (e.g., Gagneux & Varki, 2001; Gibbs, Collard, & Wood, 2002; Varki et al., 1998).

Conclusions

As neuroscientists, the species we would most like to understand, and most need to understand, is our own. Our discipline, however, rests largely on a foundation of studies in nonhuman species, and a very small set of nonhuman species at that. That strategy might have seemed reasonable when one could seriously maintain that the important features of brains were basically the same across species and when we lacked the means to study the human brain directly in much detail. The situation has now changed. We know that evolution produced a diversity of brain organizations and that the human brain, like that of every other species, possesses species-specific features in addition to features shared with

other animals. We have just begun the work of identifying the shared and distinctive features of the human brain. The powerful noninvasive neuroscientific methods that have recently become available provide us with the means to pursue this project, for not only do they make the inner workings of the human brain more accessible to us, but they also make it possible for us to compare humans and other species as never before.

The advent of our modern understanding of the evolutionary relationship between humans and other animals, and the development of these new investigative techniques, should prompt a reevaluation of neuroscientific research strategies and resource allocation. The science we have built, centered on the model-animal paradigm and supported by biomedical funding agencies, is in important respects the wrong kind of science for elucidating the structure, functions, and diseases of the human brain. If we want to understand how humans resemble and differ from other animals—a goal that is central not only to the broad intellectual program of neuroscience but also critical for advancing its biomedical goals—then we need rigorous comparative studies, studies that involve more species than just the anointed few models (Preuss, 2000a, 2006). I am not suggesting that we abandon our model species, but rather that those species are not enough.

If our goal is to understand humans, the nonhuman species we can least afford to do without are the great apes, and most especially chimpanzees. As the examples cited in this essay demonstrate, the strategy of comparing humans and chimpanzees, our closest relatives, is a critical component of any research program that would make specific and well-founded claims about the human brain or other aspects of human biology. Tragically, just at the point in time that we have acquired the technical means to carry out these comparisons, in the form of noninvasive neuroscience technologies, we are on the brink of losing the other essential resource: the chimpanzees. Wild chimpanzee populations are on a path to extinction. Nevertheless, the National Institutes of Health, which holds a large fraction of the chimpanzees resident in the United States, has decided to no longer support the propagation of their captive chimpanzees, resulting in the eventual elimination of its colonies (Cohen, 2007a, 2007b). Remaining zoo populations are likely too small to be sustainable. Unless we take rapid action to maintain these uniquely valuable animals and do so in a way that makes them accessible to benign, noninvasive research, our ability to understand what makes us human will be forever diminished.

ACKNOWLEDGMENTS The author is grateful to acknowledge the support of the James S. McDonnell Foundation (JSMF 21002093), the Yerkes National Primate Research Center under NIH/NRCC grant RR00165, and the Center for Behavioral Neuroscience under the STC program of the National Science Foundation (IBN-9876754).

4 Unraveling the Role of Neuronal Activity in the Formation of Eye-Specific Connections

LEO M. CHALUPA AND ANDREW D. HUBERMAN

ABSTRACT Since the pioneering studies of Wiesel and Hubel on the development and plasticity of ocular dominance columns in the visual cortex, it has been widely thought that correlated discharges of neighboring retinal ganglion cells play an instructive role in the formation of segregated eye-specific domains in the mammalian visual system. Here we review the relevant evidence and conclude that while correlated retinal discharges are required for the formation of segregated eye-specific projections in the visual cortex, there is reason to doubt that this is also the case at the level of the dorsal lateral geniculate. More likely, molecular cues play a key role in the stereotypic pattern of segregated retinogeniculate projections that characterize different species. As yet, the role of activity and the identity of the molecular cues involved in this process remain to be firmly established.

Since the latter half of the last century, the formation of eye-specific projections has served as a model system for exploring the development and plasticity of neural circuits. Early in development, retinal ganglion cell (RGC) projections to the dorsal lateral geniculate (dLGN) (Rakic, 1976; Linden, Guillery, & Cucchiaro, 1981; Shatz, 1983; Godement, Salaun, & Imbert, 1984) and dLGN projections to V1 (Hubel, Wiesel, & LeVay, 1977; LeVay, Stryker, & Shatz, 1978; LeVay, Wiesel, & Hubel, 1980; Rakic, 1976) are intermingled. Subsequently, they segregate into non-overlapping eye-specific territories, and this process is believed to require neuronal activity. Indeed, the precise pattern of neural activity, as opposed to the mere presence of action potential, has been hypothesized to “instruct” the segregation process by engaging well-established synaptic plasticity mechanisms (Crair, 1999; Feller, 1999; Stellwagen & Shatz, 2002; Torborg, Hansen, & Feller, 2005).

Here, we provide a brief historical account of the experimental evidence that gave rise to the idea that patterned

neuronal activity plays an instructive role in the formation of eye-specific visual projections. We then review recent studies that tested directly whether patterns of neural activity in fact provide the instructive cues required for the segregation of eye-specific projections to the dLGN. This chapter is an update of a chapter on this topic that we authored for the third edition of *The Cognitive Neurosciences* (Chalupa & Huberman, 2004). We have also offered re-cent reviews of the role of activity in the formation of eye-specific projections in other publications (Chalupa, 2007; Huberman, Feller, & Chapman, 2008).

Formation of ocular dominance columns

That neuronal activity has an influence on the development of visual system connections stems from the pioneering studies of Wiesel and Hubel. Their work showed that closure of one eye during a critical period in postnatal life rendered that eye permanently incapable of driving cortical cells (Wiesel & Hubel, 1965a, 1965b). Subsequently it was shown that this physiological effect was accompanied by a marked reduction in the amount of cortical territory innervated by geniculocortical axons representing the deprived eye and a dramatic expansion of the geniculocortical axons representing the nondeprived eye (Hubel et al., 1977; Shatz & Stryker, 1978). These deprivation studies demonstrated that activity-mediated competition between axons representing the two eyes allocates postsynaptic space in V1.

Transneuronal tracing of retinal-dLGN-V1 connections has been used to assess the formation of ocular dominance columns (ODCs) during early development. Monocular injections of transneuronal tracers indicated that axons representing the two eyes start out overlapped (Hubel et al., 1977; LeVay et al., 1978, 1980; Rakic, 1976) before gradually segregating into ODCs. This finding supported a role for retinal activity in ODC segregation in that abolishing action potentials in both eyes with intraocular injections of tetrodotoxin (TTX) prevented the emergence of ODCs in the visual cortex (Stryker & Harris, 1986). Thus

LEO M. CHALUPA Department of Ophthalmology and Vision Science, School of Medicine and Department of Neurobiology, Physiology and Behavior, College of Biological Sciences, University of California, Davis, California

ANDREW D. HUBERMAN Department of Neurobiology, Stanford University School of Medicine, Stanford, California

the generally accepted model was that, early in development, projections representing the two eyes overlapped in V1, and the formation of separate left- and right-eye ODCs reflected activity-mediated competition between the two eyes.

The notion that activity-mediated events drive the initial formation of ODCs was first challenged by Crowley and Katz (1999). These investigators removed both eyes of postnatal ferrets weeks before geniculocortical axons invade V1, and then after allowing the animals to survive into adulthood, injected anterograde tracers into one or the other putative eye-specific layer in the dLGN. Surprisingly, they found patches of label that resembled normal ODCs in these animals. Obviously, the formation of ODCs could not be due to retinal activity. The authors thus concluded that formation of ODCs “relies primarily on activity-independent cues, rather than on specific patterns of correlated activity” (Crowley & Katz, 1999). In a subsequent study, these investigators used the same tracing method to demonstrate that ODCs are present in the ferret cortex very shortly after geniculocortical axons innervate layer IV and are refractory to early imbalances in retinal activity (Crowley & Katz, 2000). The results of these studies implied that the “overlap” of eye-specific dLGN inputs to V1 seen in the earlier transneuronal experiments was spurious, reflecting leakage of transneuronal tracer into opposite-eye layers in the dLGN. The results of Crowley and Katz therefore raised doubt as to whether activity plays a role in the initial formation of ODCs.

Almost a decade after their publication, the studies of Crowley and Katz (1999, 2000) remain controversial. Some have argued that patches of label they observed in V1 may not represent ODCs because eye removal early in life alters dLGN layering (reviewed in Huberman et al., 2008). Moreover, a recent study has shown that altering spontaneous retinal activity in the first postnatal week permanently disrupts patterning of ODCs and binocular receptive fields in V1 of the ferret (Huberman, Speer, & Chapman, 2006). That study traced ODCs using transneuronal methods in adulthood, when spillover is less of a concern. Now, resolution of whether ODCs form precisely from the outset or through refinement will require developmental studies with tracers not prone to spillover that are capable of demonstrating eye-specific labeling patterns within layer IV of the visual cortex.

Formation of eye-specific inputs to the dLGN

Rakic (1976) pioneered the exploration of the prenatal visual system and was the first to show that in the embryonic macaque monkey the projections of the two eyes are initially overlapped in the dLGN before segregating into eye-specific layers. Subsequently, this was found to be the

case in other species using a variety of tracing methods (mouse: Godement et al., 1984; ferret: Linden et al., 1981; Huberman, Stellwagen, & Chapman, 2002; Huberman et al., 2003; cat: Shatz, 1983). Rakic (1981) also showed that fetal monocular enucleation results in the maintenance of a widespread projection from the remaining eye to the dLGN and the visual cortex, demonstrating the importance of prenatal binocular interactions in this process. Similar results have been obtained following monocular enucleation in the fetal cat (Chalupa & Williams, 1984; Shook & Chalupa, 1986).

The cellular and molecular mechanisms underlying binocular competitive interactions were not directly addressed in these studies, but generalizing from the literature dealing with the plasticity of cortical ODCs, it was reasonable to assume that prenatal binocular competition is also activity mediated. To test this idea, Shatz and Stryker (1988) infused TTX into the brain of fetal cats before retinal segregation of retinogeniculate axons occurred. This procedure caused the projections of the two eyes to remain widespread and overlapping in the dLGN. An obvious implication of this study was that retinal ganglion cells are capable of discharging action potentials even before these cells can be activated by light.

This capability was demonstrated by recording action potentials from retinal ganglion cells in embryonic rats (Galli & Maffei, 1988). These experiments showed that neighboring ganglion cells exhibit correlated discharges (Maffei & Galli-Resta, 1990). Subsequent *in vitro* patch-clamp recordings documented the ontogeny of excitable membrane properties in retinal ganglion cells from the fetal cat (Skaliora, Scobey, & Chalupa, 1993; Skaliora, Robinson, Scobey, & Chalupa, 1995) and rat (Wang, Ratto, Bisti, & Chalupa, 1997). The introduction of *in vitro* multielectrode-array recordings (Meister, Wong, Baylor, & Shatz, 1991) and optical recording of intracellular calcium allowed for simultaneous recording of hundreds of retinal cells (Feller, Wellis, Stellwagen, Werblin, & Shatz, 1996; Wong, Meister, & Shatz, 1993). These studies revealed that the spontaneous bursts of correlated ganglion cell activity propagate across the developing retina in a wavelike manner. Such retinal waves have been now reported in many species, including chick, turtle, mouse, rabbit, rat, ferret, and cat (reviewed in Wong, 1999), suggesting that they are a ubiquitous feature of retinal development. Based on their specific spatial and temporal properties, retinal waves have been hypothesized to play an essential role in the segregation of left- and right-eye inputs to the dLGN (Feller, 1999; Sengpiel & Kind, 2002; Cohen-Corey, 2002), the establishment of retinotopic order in the superior colliculus (Butts & Rokhsar, 2001), and the segregation of On and Off ganglion cell projections to the dLGN (Wong & Oakley, 1996). There is substantial evidence that waves are involved in retinotopic refinement

in the SC (McLaughlin, Torborg, Feller, & O'Leary, 2003), dLGN (Grubb, Rossi, Changeux, & Thompson, 2003), and V1 (Cang et al., 2005), and, as mentioned previously, normal waves are needed for ODC development (Huberman et al., 2006). Whether waves drive eye-specific segregation in the dLGN, however, remains controversial.

How might retinal waves drive eye-specific segregation? Eye-specific segregation is thought to occur because the correlated discharges of spatially adjacent ganglion cells in one eye are better capable of depolarizing neurons in the dLGN than the inputs stemming from the two eyes. In accordance with Hebb's postulate (Hebb, 1949), coactive inputs are preferentially stabilized relative to temporally uncorrelated inputs (Bi & Poo, 2001; Zhang & Poo, 2001).

Three lines of evidence have been invoked in support for this "fire together wire together" idea. First, the occurrence of waves coincides with the segregation of initially overlapping retinal projections (mouse: Muir-Robinson, Hwang, & Feller, 2002; ferret: Penn, Riquelme, Feller, & Shatz, 1998; Huberman et al., 2002, 2003). Second, abolishing all retinal activity prevents the formation of eye-specific projection patterns (Muir-Robinson et al.; Penn et al.; Huberman et al., 2002, 2003). Third, inducing an imbalance in the overall activity levels of the two eyes causes the more active eye to innervate more dLGN territory at the expense of the less active eye (Penn et al.; Stellwagen & Shatz, 2002).

Still, the direct testing of the idea that correlated retinal ganglion cell discharges per se are essential for the formation of eye-specific projections requires that one perturb the correlated activity of adjacent retinal ganglion cells without impacting the overall discharge levels of these neurons. The studies that blocked retinal waves did so by abolishing all ganglion-cell discharges (Penn et al., 1998; Muir-Robinson et al., 2002; Huberman et al., 2002), and the studies that altered the balance of waves in the two eyes either significantly increased or decreased the frequency of ganglion-cell action potentials (Penn et al.; Stellwagen & Shatz, 2002). Thus it has remained an open question whether the changes in eye-specific projections observed in these experiments were due to altering the pattern, as opposed to the level, of spontaneous retinal activity.

The first opportunity to address this issue was provided by the manufacture of a novel immunotoxin designed to selectively target cholinergic neurons (Gunhan, Choudary, Landerholm, & Chalupa, 2002). Although the cellular basis of retinal waves remains unclear, it is known that during the developmental phase when eye-specific segregation is occurring, spontaneous discharges of retinal ganglion cells are caused by acetylcholine released by starburst amacrine cells (Feller et al., 1996; Zhou & Zhou, 2000). Immunotoxin depletion of starburst amacrine cells should thus disrupt the correlated discharges of ganglion cells without completely

blocking the activity of these neurons or significantly changing their overall levels of activity (Huberman et al., 2003).

This strategy was applied to newborn ferrets. In this species retinogeniculate projections are extensively overlapped at birth, segregating gradually to attain their adultlike state by postnatal day 10 (P10) (Linden et al., 1981; Penn et al., 1998; Huberman et al., 2002, 2003). Binocular injections of the immunotoxin were made on the day of birth (P0), and within 48 hours this procedure resulted in elimination of approximately 80% of the starburst amacrine cells. To assess the effects of this manipulation on the firing patterns of these neurons, whole-cell patch-clamp recordings were made from morphologically identified P2–P10 retinal ganglion cells. These recordings showed that ganglion cells were in fact spontaneously active in the cholinergic-cell-depleted retinas. However, their discharge properties were markedly aberrant; some cells fired spikes very infrequently compared to those in normal retinas, while others manifested a firing frequency that was much higher than normal. Importantly, while the discharges of individual cells were abnormal, the overall firing rate of the sample of cells recorded was not statistically different from normal in the immunotoxin treated retinas (see figure 3 in Huberman et al., 2003).

To test directly whether correlated discharges were perturbed by starburst amacrine cell depletion, dual patch-clamp recordings were made from neighboring ganglion cells (less than 25 μm apart). In the normal P2–P10 retinas, all ganglion cells showed highly correlated spiking and membrane potential activity, irrespective of cell class (Huberman et al., 2003; Liets, Olshausen, Wang, & Chalupa, 2003). By contrast, not a single ganglion cell pair in the immunotoxin treated retinas showed any significant correlated activity, and this was the case for every retina examined from P2 to P10. These electrophysiological findings demonstrated unequivocally that depletion of starburst amacrine cells rapidly eliminated the correlated discharges of neighboring retinal ganglion cells, without significantly altering the overall activity levels of these neurons.

Did elimination of correlated ganglion-cell activity disrupt the segregation of left- and right-eye retinogeniculate projections? To answer this question, we examined the pattern of retinogeniculate connections in normal developing ferrets age P2 and P10 and compared these to P10 animals that received intraocular injections of the cholinergic immunotoxin on P0. As mentioned earlier, an injection of immunotoxin on P0 eliminated the correlated firing of neighboring ganglion cells by P2, an age when binocular retinogeniculate inputs are still intermingled extensively. Remarkably, in ferrets injected with immunotoxin, normal eye-specific segregation of retinogeniculate connections still formed. Indeed, quantitative comparison of the extent of overlap for left- and right-eye axons indicated that the degree and pattern of segregation was the same for control and

experimental P10 animals. These results showed for the first time that correlated activity of neighboring ganglion cells is not required for the segregation of eye-specific retinogeniculate projections.

The ongoing quest for understanding the role of retinal waves

Using mutant mice in which the $\beta 2$ subunit of the nicotinic acetylcholine receptor is eliminated, Torborg and colleagues (2005) showed that retinal waves as well as eye-specific dLGN segregation are both perturbed. They concluded that a specific parameter of retinal activity—the amount of RGC bursting > 10 Hz—is the key element that instructs eye-specific segregation. However, a recent study has shown that retinal waves are in fact present in $\beta 2$ mutant mice (Chao, Warland, Ballesteros, van der List, & Chalupa, 2008). Indeed, these mutants manifest robust waves of retinal activity, but eye-specific inputs to the dLGN fail to form normally.

Another approach we employed to test the relevance of retinal waves to the formation of segregated retinogeniculate projections was to assess these two phenomena in the fetal macaque monkey. In the species commonly used for studies of the developing visual system, such as the ferret and even more so the mouse, the time period during which connections in the visual system are made and refined is relatively brief. By contrast, the developmental period when brain connections become established is much more protracted in the macaque monkey, so we reasoned that the salient features of visual system development could be more dispersed, making it more likely that key events could be temporally dissociated from each other.

As a first step we sought to accurately discern the time period during which eye-specific retino-dLGN projections are established in the fetal macaque monkey (Huberman, Dehay, Berland, Chalupa, & Kennedy, 2005). This involved making intraocular injections of different tracers in each eye of fetal monkeys of known gestational ages. Subsequently, the extent of the binocular overlap within the developing dLGN was quantified using confocal microscopy and image analysis software. This study showed that about 100 days before birth at embryonic day 69 (E69), the projections from the two eyes were extensively intermingled in the dLGN. At E84 segregation of left and right eye axons was found to be essentially complete, with the six eye-specific domains that characterize the mature macaque dLGN clearly apparent. Thus the segregation of eye-specific inputs occurs during a remarkably early and relatively brief in utero period in the macaque, taking about 14 days in a 165-day gestation period.

Next, we determined whether the developmental period when eye-specific projections are formed relates to the

presence of retinal waves in the fetal macaque retina. To address this issue, we used multielectrode arrays to record the activity from isolated retinas obtained from fetal monkeys of known gestational age (Warland, Huberman, & Chalupa, 2006). Before E55 the fetal monkey retina was found to be essentially silent, with only a few cells manifesting occasional discharges. This finding means that the specific ingrowth of retinogeniculate axons into regions destined to form magnocellular and parvocellular layers, which occurs prior to E55 (Meissirel, Wikler, Chalupa, & Rakic, 1997), is very unlikely to depend on retinal activity. Retinal waves of activity were found to be prevalent at E60, which is more than a week before segregation of retinogeniculate projections is first observed. Moreover, the incidence of retinal waves decreased progressively during the period when eye-specific projections become established (E69–E76). These findings in the fetal macaque monkey differ from the results obtained in other species where retinal wave activity has been reported to be robust throughout the period when segregated retinogeniculate projections are formed, with such activity declining after this developmental event becomes established (mouse: Demas et al., 2003; Torborg et al., 2005; ferret: Meister et al., 1991; Wong, Meister, & Shatz, 1993; Feller et al., 1996). Thus, while the multiarray recordings from fetal monkey retina do not rule out the possibility that retinal activity plays a role in the formation of segregated retinogeniculate projections, they do indicate that retinal waves are most prominent at a much earlier time in development than the period when eye-specific inputs are being established.

What accounts for the stereotyped pattern of eye-specific layers in the dLGN? Such stereotypy is difficult to reconcile with an activity-based mechanism. Indeed, a purely activity-dependent sorting should result in randomly distributed patterns of right- and left-eye inputs to the dLGN (Huberman et al., 2002; Muir-Robinson et al., 2002). Thus some bias for one or the other layer by the two eyes must exist (Sanes & Yamagata, 1999). Activity-dependent proponents have speculated that the stereotyped pattern of layering in the dLGN reflects the earlier arrival of contralateral-eye versus ipsilateral-eye axons. The use of sensitive anatomical tracers indicates, however, that axons from both eyes are present throughout the dLGN from very early times (Penn et al., 1998; Huberman et al., 2002, 2003).

Two recent studies (one in mouse and one in ferret) have shown that ephrin-As shape the formation of eye-specific zones (Huberman, Murray, Warland, Feldheim, & Chapman, 2005; Pfeiffenberger et al., 2005; Pfeiffenberger, Yamada, & Feldheim, 2006). This makes sense given that ephrin-A receptors, EphAs, are expressed in a gradient across the nasal temporal axis of the retina and that each eye-specific layer receives input from retinal ganglion cells in the nasal or temporal-retina.

Studies aimed at identifying eye-specific molecules in the dLGN and the genes that act downstream of activity to regulate axon refinement are currently under way in several laboratories. A handful of such molecules have been identified, and interestingly, all of these are immune-system factors (Huh et al., 2000; Bjartmar et al., 2006; Stevens et al., 2007). Nevertheless, the issue of how retinal activity contributes to the establishment of eye-specific projections still awaits resolution.

5 Brain Changes Underlying the Development of Cognitive Control and Reasoning

SILVIA A. BUNGE, ALLYSON P. MACKEY, AND KIRSTIE J. WHITAKER

ABSTRACT What precisely is changing over time in a child's brain leading to improved control over his or her thoughts and behavior? This chapter investigates neural mechanisms that develop through childhood and adolescence and underlie changes in working memory, cognitive control, and reasoning. The effects of age and experience on specific cognitive functions are discussed with respect to functional brain imaging studies, highlighting the importance of interactions between prefrontal and parietal cortices in cognitive control and high-level cognition.

What precisely is changing over time in a child's brain, leading to improved control over his or her thoughts and behavior? Throughout childhood and adolescence, we improve at organizing our thoughts, working toward long-term goals, ignoring irrelevant information that could distract us from these goals, and controlling our impulses—in other words, we exhibit improvements in *executive function* or *cognitive control* (Diamond, 2002; Zelazo, Craik, & Booth, 2004; Casey, Tottenham, Liston, & Durston, 2005). By the same token, we exhibit increased facility over this age range in tackling novel problems and reasoning about the world—a capacity referred to as fluid reasoning (Cattell & Bernard, 1971). Both the capacity to consciously control our thoughts and actions and the capacity to reason effectively rely on *working memory*, or the ability to keep relevant information in mind as needed to carry out an immediate goal.

Neuroscientific research is being conducted to better understand the changes in brain structure and function that underlie improved cognitive control and fluid reasoning during child and adolescent development. More specifically, researchers seek to determine how the neural mechanisms underlying specific cognitive functions change with age, how they differ among individuals, and how they are affected by experience.

SILVIA A. BUNGE Helen Wills Neuroscience Institute and Department of Psychology, University of California at Berkeley, Berkeley, California

ALLYSON P. MACKEY and KIRSTIE J. WHITAKER Helen Wills Neuroscience Institute, University of California at Berkeley, Berkeley, California

We begin this chapter with a brief summary of changes in brain structure, focusing primarily on prefrontal and parietal cortices, the brain regions that have been most closely associated with goal-directed behavior. We then provide an overview of functional brain imaging studies focusing on age-related changes in working memory, cognitive control, and fluid reasoning over childhood and adolescence. Because working memory and cognitive control development have been discussed extensively elsewhere (Munakata, Casey, & Diamond, 2004; Rubia & Smith, 2004; Casey et al., 2005; Bunge & Wright, 2007), a relatively greater emphasis is placed on recent studies focusing on the development of fluid reasoning.

Structural brain development

The brain undergoes major structural and functional changes over childhood and adolescence that may, in part, explain changes in behavior and cognition. As explained in chapter 2, by Kostović and Judaš, rapid changes occur at the neuronal level in the prefrontal cortex (PFC) in the first few years of life, followed by slower, protracted changes through adolescence (Petanjek, Judas, Kostovic, & Uylings, 2008). While brain changes at the cellular level can be examined only in postmortem brain tissue, advances in neuroimaging techniques have made it possible to study gross anatomical development in vivo. Structural magnetic resonance imaging (MRI) methods make it possible to quantify age-related changes in cortical thickness (Sowell et al., 2007), in the volume of specific brain structures (Gogtay et al., 2006), and in the thickness and coherence of white matter tracts connecting distant brain regions to one another (Giedd et al., 1999; Klingberg, Vaidya, Gabrieli, Moseley, & Hedehus, 1999).

Cortical thickness follows an inverted U-shaped pattern over development. Up to middle childhood (ages 8 to 12), increased thickness of the gray matter at the surface of the brain reflects increased density of neurons and dendrites. Thereafter, decreased gray matter thickness reflects the pruning of excess dendrites and neurons, as well as increased

myelination of axonal projections to these neurons (Giedd, 2004).

The developmental trajectory of changes in cortical thickness varies across brain structures. In PFC and parietal cortex, gray matter volume peaks around age 10–12 (Giedd, 2004). Thereafter, gray matter loss occurs at different rates in different subregions of the PFC, and it is considered one index of the time course of maturation of a region (Sowell et al., 2003). Within the PFC, gray matter reduction is completed earliest in the orbitofrontal cortex, followed by the ventrolateral PFC (VLPFC) and then by the dorsolateral PFC (DLPFC) and rostralateral PFC (RLPFC) (Gogtay et al., 2004; O'Donnell, Noseworthy, Levine, & Dennis, 2005). Differences in maturational time course between prefrontal subregions could help account for differences in the rate of development of distinct cognitive control processes (Bunge & Zelazo, 2006; Crone et al., 2006).

Developmental changes in interregional connectivity have been studied with an MRI-based method known as diffusion tensor imaging (DTI). Research using DTI has shown that strengthening of frontal-parietal networks is associated with improved performance on working memory tasks (Olesen, Nagy, Westerberg, & Klingberg, 2003; Nagy, Westerberg, & Klingberg, 2004). An age-related increase in frontostriatal tract coherence has also been associated with more efficient recruitment of cognitive control (Liston et al., 2006).

In summary, both cortical pruning within prefrontal and parietal regions and increased neuronal connectivity within and between these and other regions are likely to underlie improvements in cognitive control and fluid reasoning during development. The relationships between behavioral improvements and changes in brain structure and brain function have been explored in recent studies of working memory, as described in the next section.

Working memory development

Working memory is the brain's "mental blackboard," allowing information—either sensory inputs or memories—to be held in mind and manipulated (Miller, Galanter, & Pribram, 1960; Goldman-Rakic, 1992). Considered a central component of human cognition, the maturation of working memory is critical for the development of language comprehension, mental calculation, cognitive control, and fluid reasoning. Although children as young as 5 years do not differ from adults in sensorimotor tasks, performance on tasks that rely on the retention and manipulation of information, such as spatial memory span and Tower of London, improves over childhood (Luciana & Nelson, 1998). Children's performance is critically moderated by task difficulty: their accuracy rapidly declines as the demands of the task become more rigorous and they make more errors. As working

memory improves, children likewise improve on tests of cognitive control and fluid reasoning.

Working memory for different types of information is mediated by interactions between domain-specific brain regions and regions in PFC and parietal cortex (D'Esposito, 2007). It is the integration and refinement of these working memory circuits that underlies age improvements in the maintenance and manipulation of mental representations. In the next subsection, we provide a brief overview of fMRI studies examining age-related changes in working memory.

VISUOSPATIAL WORKING MEMORY Most fMRI studies on working memory development have focused on the ability to keep in mind a series of spatial locations (Casey et al., 1995; Thomas et al., 1999; Klingberg, Forssberg, & Westerberg, 2002a; Kwon, Reiss, & Menon, 2002; Scherf, Sweeney, & Luna, 2006). The superior frontal sulcus (SFS) and the intraparietal sulcus (IPS), which have been strongly implicated in adult visuospatial working memory, are increasingly engaged throughout childhood (Klingberg et al., 2002a; Kwon et al.). Across children, the level of fractional anisotropy in the frontoparietal white matter surrounding the SFS and IPS is positively correlated with visuospatial working memory scores (Nagy et al., 2004). Further, the coherence of these white matter tracts in the left hemisphere is greater among children (age 8–18 years) who exhibit the greatest activation in these regions (Olesen et al., 2003). Thus the brain network underlying effective visuospatial working memory is strengthened over development.

At a microscopic level, the increased engagement of SFS and IPS during a blood-oxygenation-level dependent (BOLD) fMRI visuospatial working memory task could be dependent on one or more cellular changes: neuronal pruning, increased myelination, and/or the strengthening of synaptic connections within or between brain regions. Klingberg and colleagues used computational methods to determine which of these processes are likely to support the development of visuospatial working memory (Edin, Macoveanu, Olesen, Tegner, & Klingberg, 2007). Their computational model of BOLD activation found that strengthened synaptic connectivity within and between brain regions was the most likely candidate for increase in activation in these regions between childhood and adulthood.

Just as core working memory networks are strengthened over childhood and adolescence, supporting networks that are not used by adults for working memory are weakened over this age range. Using a spatial working memory paradigm involving saccadic eye movements, Luna and colleagues showed that increased recruitment of core regions in DLPFC in the left hemisphere and parietal regions was accompanied by a weakening and eventual dismissal of a childhood compensatory circuit involving ventromedial PFC (Scherf et al., 2006). A qualitative shift was observed

in comparing children aged 10–13 and adolescents aged 14–17. Comparing adolescents to adults, the changes were more quantitative, evincing refinement of the visuospatial working memory network. This movement away from the childhood circuit to the more mature adult network is a common theme in developmental cognitive neuroscience, and it is further discussed in this chapter’s section on cognitive control development.

NONSPATIAL WORKING MEMORY In addition to the fMRI studies of visuospatial working memory development, we would like to highlight a study on the development of nonspatial working memory, in which children aged 8–12, adolescents aged 13–17, and young adults were asked to remember a series of three nameable objects (figure 5.1A; Crone, Wendelken, Donohue, van Leijenhorst, & Bunge, 2006). We consider first the pure maintenance condition of this study, in which participants were asked to verbally rehearse the items in the order in which they were presented. All three

groups engaged highly overlapping sets of brain regions, indicating that the core working memory network was already in place by middle childhood. However, there was a positive correlation across participants between task accuracy and level of activation in left ventrolateral PFC (VLPFC), bilateral DLPFC, and bilateral superior parietal cortex.

MANIPULATION OF INFORMATION IN WORKING MEMORY

This study of nonspatial working memory (Crone et al., 2006) also included a manipulation condition, in which participants were asked to reverse the order of the items in their head. Children aged 8–12 were disproportionately impaired relative to adolescents and adults on this manipulation condition relative to the pure maintenance condition. Further, children failed to engage right DLPFC and bilateral superior parietal cortex, regions linked with working memory manipulation, for this purpose. A qualitative shift in the circuitry underlying manipulation was observed from middle childhood onward, such that adolescents and

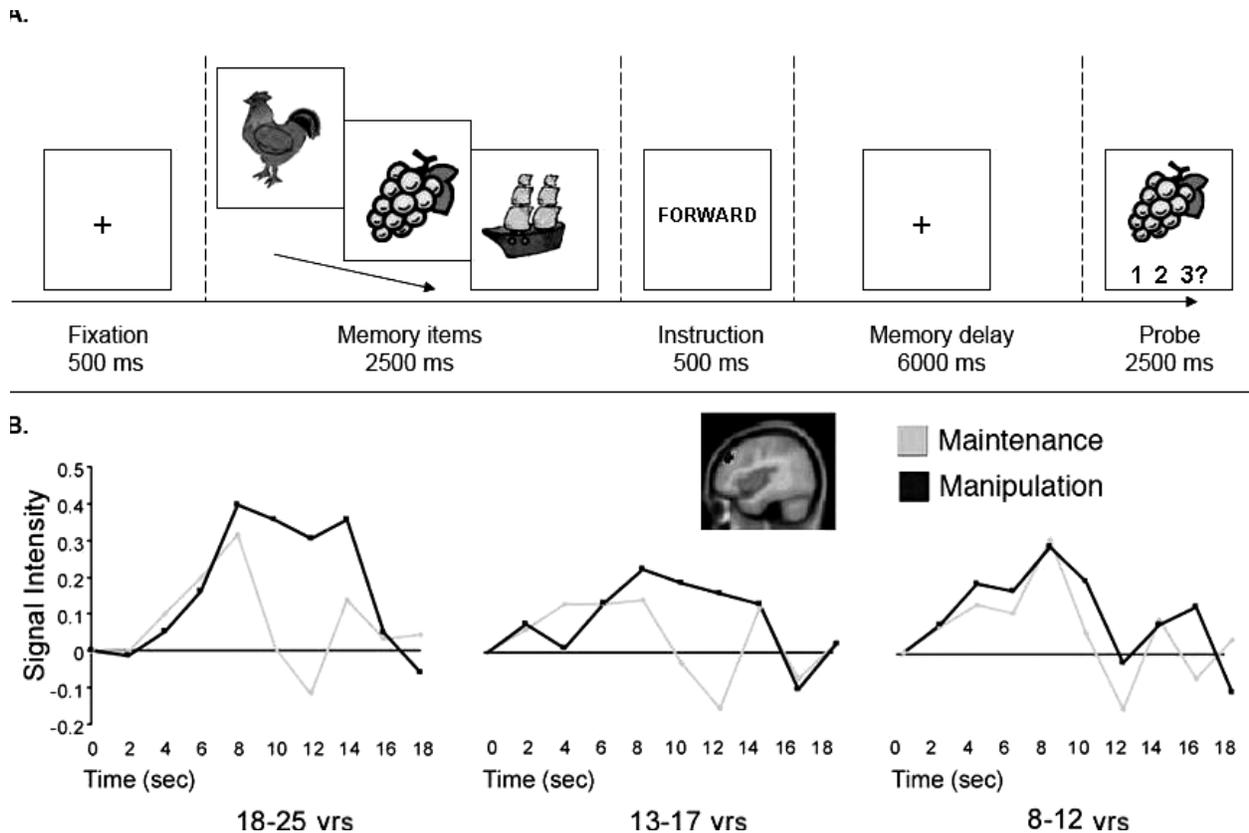

FIGURE 5.1 Development of nonspatial working memory and working memory manipulation. (A) Subjects were asked to remember three nameable objects, presented for 750 ms each and separated by a 250-ms fixation cross. After the last object the instruction “forward” or “backward” directed the participant to either mentally rehearse or reorder these objects during the 6,000-ms delay. Finally a probe object was presented and participants indicated with a button press whether it was first, second, or third object in the memorized sequence. Forward trials required pure maintenance,

whereas backward trials required manipulation in addition to maintenance. (B) Group-averaged time courses for activation in the right DLPFC during the delay period show that adults and adolescents recruited this region more strongly during the harder manipulations trials, whereas children showed the same activation in DLPFC for both “forward” and “backward” tasks. (Reprinted with permission from Crone, Wendelken, Donohue, van Leijenhorst, & Bunge, 2006, copyright © 2006, National Academy of Sciences, USA.)

adults engaged an additional mechanism relative to children aged 8–12. Time-series correlational analyses showed that, for adults, right DLPFC was functionally correlated with bilateral parietal and premotor cortices during manipulation. In children, by contrast, right DLPFC activation during manipulation was correlated with regions that have not been associated previously with this function (unpublished analyses). Thus the brain network underlying manipulation in adults was not yet engaged by children aged 8–12. Importantly, it is not the case that children failed to engage these brain regions during task performance. Indeed, children engaged DLPFC and parietal cortex at encoding and retrieval of items in working memory; they simply failed to sufficiently engage the circuitry that supports manipulation at the time when it was required to reverse the order of objects in working memory (figure 5.1B).

These investigations have shown how the development of PFC and parietal cortex, as well as the connections between them, contributes to increased ability to maintain and manipulate information online. In turn, an increase in working memory capacity contributes to improvements in a variety of cognitive functions, including cognitive control and fluid reasoning.

Cognitive control development

One of the most obvious ways in which children mature behaviorally is that they become increasingly able to ignore irrelevant and distracting information and control their impulses while working toward specific goals. The terms *executive function* and *cognitive control* refer to mental processes associated with the control of thought and action. Thus far, developmental research on cognitive control has been concerned with conscious, deliberate forms of control. Putative cognitive control functions are listed in box 5.1.

Box 5.1 Cognitive Control Functions

1. Selectively attending to relevant information (*selective attention*) and ignoring distracting stimuli or thoughts (*interference suppression/resolution*)
2. Selecting between competing response tendencies (*response selection*) and inhibiting inappropriate response tendencies (*response inhibition*)
3. Using contextual information to identify currently relevant information and appropriate responses (*rule/task-set representation*)
4. Reorganizing information currently held in working memory (*manipulation, updating*)
5. Flexibly switching between tasks and performing two tasks concurrently (*task-switching, dual-task performance*)
6. Monitoring one's own actions and the consequences of these actions (*performance monitoring, error/feedback processing*)

COGNITIVE CONTROL DEVELOPMENT: CHANGES IN ONE OR MORE NEURAL CIRCUITS? A key question in developmental research has been whether age-related changes in cognitive control are associated with the development of a single mechanism, such as the capacity to store or process information (Case, 1992; Dempster, 1993), or with a set of mechanisms (Welsh, Butters, Hughes, Mohs, & Heyman, 1991). Behavioral studies suggest that some of these abilities may mature at different rates. For example, the ability to inhibit a motoric response matures earlier than the ability to inhibit a response when the task additionally requires selective attention (van den Wildenberg & van der Molen, 2004). Likewise, the ability to switch between task rules develops earlier than the ability to keep a difficult rule online (Crone, Wendelken, Donohue, Honomichi, & Bunge, 2004). Recent advances using structural equation modeling indicate that working memory, task switching, and response inhibition are separable latent constructs with distinct developmental trajectories (Brocki & Bohlin, 2004; Huizinga, Dolan, & van der Molen, 2006). Thus behavioral research provides hints that different cognitive control functions may have separable neurodevelopmental trajectories.

In a recent study of cognitive network development, Fair, Dosenbach, and colleagues (2007) show that, initially, the strongest connections between frontoparietal gray matter are anatomically close together. As these regions mature, however, the connections become more functionally relevant and reach further afield, presumably to engage the most effective network for cognitive control (figure 5.2).

The protracted myelination of the white matter tracts connecting the regions necessary for cognitive control over childhood and adolescence (Spear, 2007) may explain the compensatory network required for children to complete these tasks. If long-range projections are not sufficiently insulated by the myelin sheath, they will be unable to communicate with the functionally relevant networks utilized by the adult brain. Eventually, during adolescence, the myelination is sufficient to allow a transition from the local, compensatory mechanism to a more diffuse, adult, effective system.

In the following sections, we highlight a few of the many brain-imaging studies that have examined neurodevelopmental changes in cognitive control.

Response selection and inhibition As noted previously, improvements in working memory manipulation—a form of cognitive control—are associated with an increase in lateral PFC activation with age (Crone et al., 2004). For some cognitive control tasks, however, maturation is instead associated with a decrease in lateral PFC recruitment. For example, a large study involving participants between 8 and 27 years of age by Luna and colleagues (Velanova, Wheeler, & Luna, 2008) examined functional maturational changes associated with

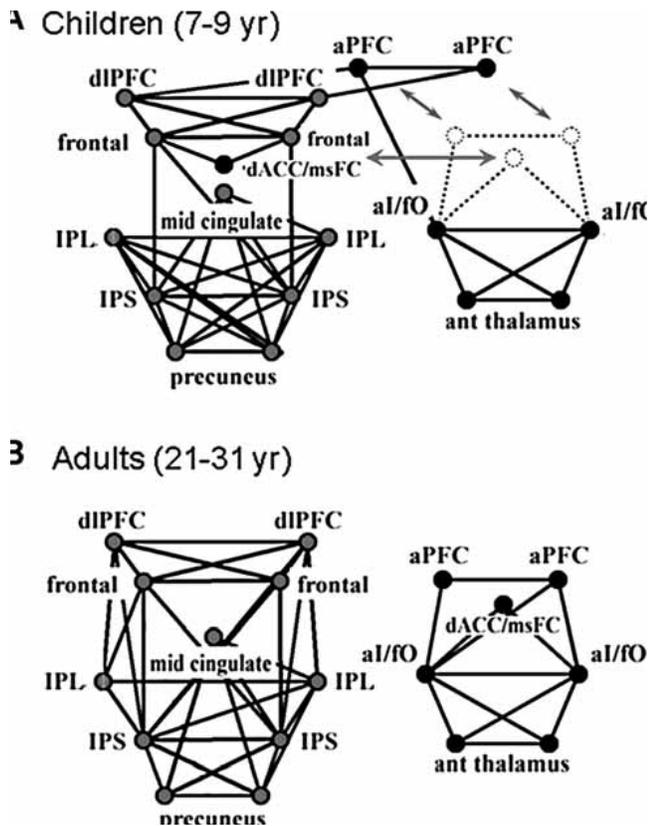

FIGURE 5.2 Development of distinct cognitive control networks through childhood and adolescence. Regions previously identified as pertaining to putative task control were analyzed for pairwise temporal BOLD correlations in (A) children and (B) adults. Right-side ROIs are displayed on the right of each graph and anterior ROIs at the top of each graph. Whereas adults demonstrate two separate control networks, children show a connection between them. Their networks are connected by a bridge between the anterior PFC and DLPFC, and the dACC and medial superior frontal cortex were incorporated into the frontoparietal network. In addition, children lacked connections between the DLPFC and the IPS and inferior parietal lobule. The two separate networks seen in adults are proposed to interpret cues, implement top-down control, and process bottom-up feedback, but use different mechanisms and over different temporal scales. (Reprinted with permission from Fair et al., 2007, copyright © 2007 National Academy of Sciences, USA.)

performance on an antisaccade task. In this response inhibition task, participants must move their eyes away from a visual stimulus that appears suddenly on the screen, resisting the urge to look toward it. The researchers observed an age-related shift away from reliance on DLPFC, toward posterior parietal regions (figure 5.2). Consistent with other work, this finding indicates a shift away from childhood compensatory mechanisms toward the more effective adult networks.

In addition to this antisaccade study, a number of other brain-imaging studies have focused on age-related improvements in the ability to select between competing response

choices and inhibit inappropriate response tendencies (see Munakata, Casey, & Diamond, 2004, and Bunge & Wright, 2007, for reviews). These studies have made use of a variety of paradigms, including the well-known Stroop (Adelman, et al., 2002; Schroeter, Zysset, Wahl, & von Cramon, 2004; Marsh et al., 2006), go-no-go (Rubia, Smith, Taylor, & Brammer, 2007; Rubia et al., 2001; Bunge, Dudukovic, Thomason, Vaidya, & Gabrieli, 2002; Durston et al., 2002; Tamm, Menon, & Reiss, 2002; Booth et al., 2003; Lamm, Zelazo, & Lewis, 2006), and flanker tasks (Bunge et al.; Lamm et al.; Rubia et al., 2006). In task-switching paradigms, the currently relevant task rule changes without warning, and it is necessary to suppress the response to the previous rule and also to retrieve the new rule from memory (Crone et al., 2004). These studies indicate that overlapping but distinct circuits involving regions of PFC, parietal cortex, and basal ganglia are involved in various cognitive control tasks (Rubia, et al., 2001).

Performance monitoring Luna and colleagues used the antisaccade task to examine not only the development of response inhibition, but also the development of performance monitoring (Velanova et al., 2008). The dorsal anterior cingulate cortex (dACC), known to play a central role in performance monitoring (Ford, Goltz, Brown, & Everling, 2005; Polli et al., 2005), was more strongly engaged on error trials in adults than in children or adolescents (figure 5.3). Increased performance monitoring, supported by dACC, is likely to contribute to the observed improvements in inhibitory cognitive control with age.

In summary, cognitive control is considered to comprise a variety of different putative processes, and a few studies have made attempts to compare the developmental time course of specific control processes (e.g., Bunge et al., 2002; Crone et al., 2006; Rubia et al., 2006). However, it remains to be seen if these different behavioral abilities are in fact different underlying neural substrates and if they develop over separable trajectories. Further work must be undertaken to determine the relative independence and interactions of the many cognitive control capabilities throughout development.

Fluid reasoning development

Fluid reasoning is the capacity to think logically and solve problems in novel situations (Cattell & Bernard, 1971). The concept of fluid reasoning is integral to theories of human intelligence (Horn & Cattell, 1967; Cattell, 1987; Horn, 1988; Carroll, 1997; McArdle & Woodcock 1998; Gray, Chabris, & Braver, 2003). Compared to crystallized, or knowledge-based, abilities it is thought to have a stronger neurobiological and genetic component, leading to the belief that it is less dependent on experience. However, some

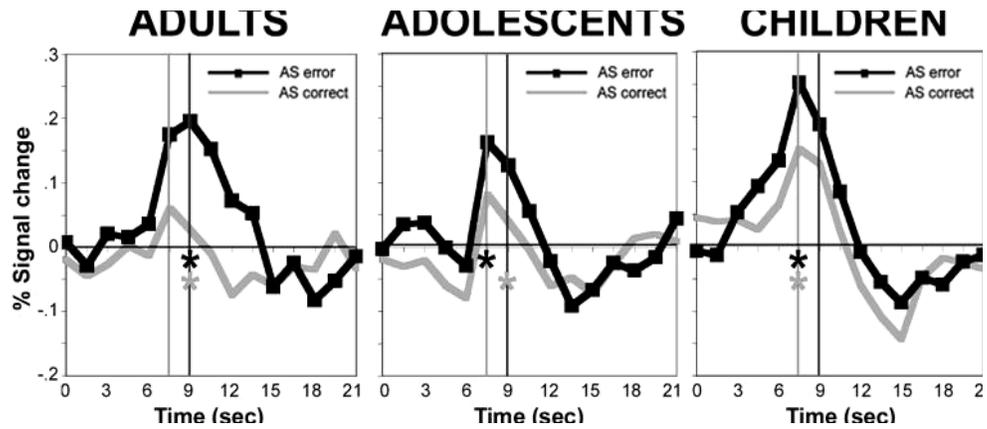

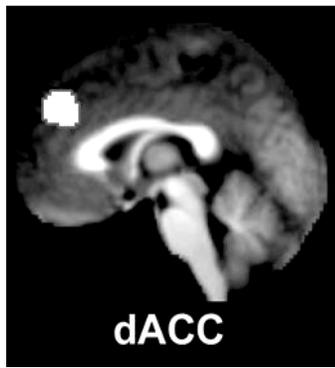

FIGURE 5.3 Development of response inhibition and performance monitoring. Velanova, Wheeler, and colleagues (2008) demonstrated that dACC showed significantly greater modulation during error versus correct trials in an antisaccade task. The task required subjects to inhibit the prepotent tendency to look toward the stimulus and look in the opposite direction. The time course of activation within the dACC, illustrated here, not only shows the difference

between activity during error and correct trials but also that adults exhibit greater differential activity than adolescents and children. For each age group, black asterisks mark the time point showing mean maximal peak activity for error trials, and gray asterisks mark the time point showing mean maximal differences between error and correct trials. (Reprinted with permission from Velanova, Wheeler, & Luna, 2008, copyright Oxford University Press.)

evidence suggests that it is indeed sensitive to cultural and environmental influences (Flynn, 2007).

The development of reasoning ability is central to understanding cognitive development as a whole, because it serves as scaffolding for many other cognitive functions (Cattell, 1987; Blair, 2006). Fluid reasoning has been identified as a leading indicator of changes in crystallized abilities (McArdle, 2001). It strongly predicts changes in quantitative ability (Ferrer & McArdle, 2004) and reading (Ferrer et al., 2007) among children aged 5 to 10. Fluid reasoning ability even predicts performance through college and in cognitively demanding occupations (Gottfredson, 1997).

One form of fluid reasoning is relational reasoning: the ability to consider relationships between multiple distinct mental representations (Gentner, 1983; Hummel & Holyoak, 1997). Analogical reasoning, more specifically, involves abstracting a relationship between familiar items and applying it to novel representations (Gentner, 1988; Goswami, 1989). In other words, forming analogies allows us to determine general principles from specific examples and to establish connections between previously unrelated pieces of information. Analogical thought is an important means by which cognition develops (Goswami, 1989; R. Brown & Marsden, 1990). For example, children use analogies to learn new words and concepts by association with previously learned information (Gentner, 1983).

WHEN DOES REASONING ABILITY DEVELOP? Historically, theories of reasoning development focused on children's limitations. Piaget claimed that, before the stage of formal operations around age 11, children are not capable of mentally representing the relations necessary to solve analogies (Inhelder & Piaget, 1958). When Piaget and

his colleagues showed children pictorial problems of the form "A is to B as C is to . . . ?" and asked them to find the D term among a set of pictures, he found that children often chose items that were perceptually or semantically related to the C item (Piaget, Montangero, & Billeter, 1977). Sternberg and colleagues found similar limitations in young children's analogical reasoning, observing an overreliance on lower-order relations during analogical problem solving (Sternberg & Nigro, 1980; Sternberg & Downing, 1982). It has been argued that children as young as 3 years old can solve simple analogies as long as they are familiar with the objects involved and understand the relevant relations (Goswami, 1989), but improvements in analogical reasoning are observed throughout childhood and adolescence (Sternberg & Rifkin, 1979; Richland, Morrison, & Holyoak, 2006).

Fluid reasoning ability seems to be a distinct cognitive function, rising and falling at its own rate across the life span (Cattell, 1987). It follows a different developmental trajectory than crystallized abilities, supporting the idea that these are separable cognitive functions (Horn, 1991; Schaie, 1996; McGrew, 1997). Fluid reasoning capacity increases very rapidly until late adolescence and early adulthood, peaking at around age 22 and declining thereafter (McArdle, Ferrer-Caja, Hamagami, & Woodcock, 2002).

ASSESSING REASONING ABILITY One of the most commonly used measures of fluid reasoning ability is the Raven's Progressive Matrices test (RPM), a classic visuospatial task that can be administered to both children and adults (Raven, 1941). This test is considered an excellent measure of fluid reasoning ability (Kline, 1993) and of intellectual ability overall (Wechsler & Stone, 1945).

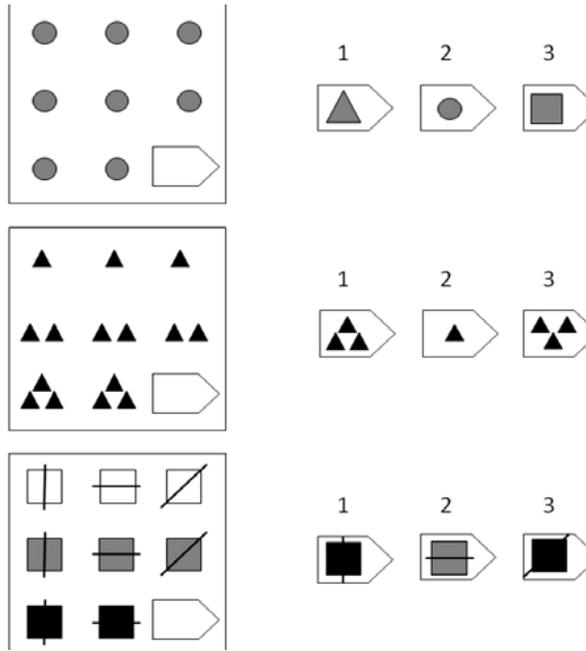

FIGURE 5.4 Sample problem similar to Raven's Progressive Matrices. (A) Zero-relational problem (REL-0) that requires only perceptual matching (Answer: 2). (B) One-relational problem (REL-1) that involves consideration of change in either the vertical or horizontal direction (Answer: 1). (C) Two-relational problem (REL-2) that requires attention to change in both the vertical and horizontal directions (Answer: 3).

As illustrated in figure 5.4, the RPM includes zero-relational (REL-0), one-relational (REL-1), and two-relational (REL-2) problems. REL-0 problems require only perceptual matching. REL-1 problems require subjects to consider either vertical or horizontal changes (or spatial relations) across figures in a 3×3 grid to infer the missing piece in the bottom right corner. REL-2 problems require subjects to process changes in both the horizontal and vertical directions simultaneously in order to choose the missing piece. These problems are the most difficult because they require the integration of two visuospatial relations.

Analogical reasoning can be assessed behaviorally and in an MRI scanner with propositional analogy problems involving either words or pictures of nameable objects. The visual analogy task used in a recent fMRI study from our laboratory (Wright, Matlen, Baym, Ferrer, & Bunge, 2008) requires children to select which of four pictures completes an analogy. The answer choices for these problems include perceptual and semantic lures (figure 5.5).

NEURAL CORRELATES OF FLUID REASONING Brain regions important for fluid reasoning have been identified through studies of patients with impaired reasoning ability and neuroimaging studies of healthy adults. Research on patients in the early stages of frontotemporal dementia (FTD) has shown that reasoning is differentially affected based on the

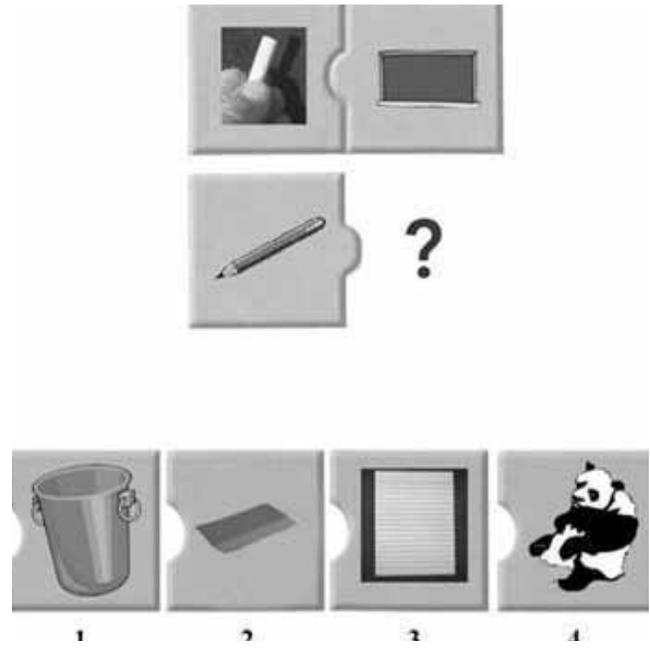

FIGURE 5.5 Sample visual analogy problem. On this type of problem, subjects must consider the relationship between the top two images and choose the image that completes the bottom analogy (Answer: 3; 2 is the semantic lure).

brain areas most compromised by the disease. Patients with frontal-variant FTD make errors on analogical reasoning problems related to limited working memory and trouble inhibiting inappropriate responses. In contrast, patients with temporal-variant FTD are profoundly impaired on analogical reasoning problems as a result of semantic memory loss (Morrison et al., 2004). Another study of patients with prefrontal damage revealed that these patients have a specific deficit in relational integration as compared to patients with anterior temporal lobe damage, who are more impaired on tests of episodic and semantic memory (Waltz et al., 1999).

Imaging research has narrowed down the region in PFC responsible for relational integration to the most anterior part of lateral PFC (RLPFC). Functional MRI studies of reasoning, including the RPM task (Prabhakaran, Smith, Desmond, Glover, & Gabrieli, 1997; Christoff et al., 2001; Kroger et al., 2002) and a verbal propositional analogy task (Bunge, Wendelken, Badre, & Wagner, 2005), have implicated RLPFC in problems that require joint consideration of multiple relations. The other lateral PFC regions play roles in reasoning that are not specifically associated with relational complexity. DLPFC may support reasoning by organizing representations in working memory, selecting between competing response alternatives, and monitoring performance (Christoff et al.). Depending on the nature of the task, different brain regions contribute to fluid reasoning. Left VLPFC (Broca's area) supports reasoning by retrieving

semantic relations on propositional analogy problems (Bunge et al.; Wright et al., 2008). Likewise, hippocampus and parietal cortex may play a role in reasoning by representing individual relations in visuospatial tasks involving relational integration, including Raven's Progressive Matrices (Crone et al., 2009) and transitive inference problems (Wendelken & Bunge, under review).

Parietal cortex is consistently engaged in high-level cognitive tasks like the RPM (Gray et al., 2003) and shares strong connections with PFC (Petrides & Pandya, 1984; Fuster, 2002). A study of individual differences in reasoning ability in adults showed that stronger prefrontal and parietal recruitment on a difficult working memory task is associated with better fluid reasoning, as measured by an RPM-type task (Gray et al.). The level of activation in left lateral PFC and bilateral parietal cortex accounted for more than 99.9% of the relationship between fluid intelligence and working memory performance in these adults.

Taken together, the preceding studies suggest that maturation of RLPFC should lead to improvements in relational processing, while maturation of Broca's area, hippocampus, and parietal cortex should lead to better reasoning through improved representation of individual verbal and visuospatial relations.

HOW DOES THE BRAIN CHANGE TO ALLOW FOR IMPROVEMENTS IN REASONING ABILITY? The neuroimaging research described thus far has identified brain regions that contribute to reasoning in adults. However, researchers are just now beginning to track how these regions develop during childhood and how this development leads to improved fluid reasoning ability. As noted earlier in this chapter, in the section on structural brain development, DLPFC, RLPFC, and parietal cortex develop relatively slowly: cortical gray matter loss continues through the early twenties (Giedd, 2004). A study by Shaw and colleagues showed that the trajectory of changes in cortical thickness in several prefrontal regions differed across children with superior, high, and average intelligence (Shaw et al., 2006). Surprisingly, children with superior intelligence exhibited a delayed peak of cortical thickness in anterior PFC relative to the other groups, around age 11 as opposed to age 7–8 in children of average intelligence. The precise significance of this intriguing finding is as yet unclear. In particular, the role of environmental factors has not been explored; in this study sample, IQ was correlated with socioeconomic factors. However, this finding indicates that cognitive ability is related to the particular time course of cortical maturation in frontal regions, rather than the size of a given region at a specific age. This finding speaks to the unique insights that can be gained from longitudinal studies of brain development.

While structural imaging has provided critical insight into the neural changes that underlie reasoning development,

functional neuroimaging is essential to understand how changes in brain function lead to changes in behavior. This section highlights the first two fMRI studies of reasoning ability in children.

Visual analogies In the first study, our laboratory (Wright et al., 2008) presented children aged 6–13 and young adults with visual analogy problems (figure 5.5). Children were capable of identifying analogous relationships between pairs of images, but made disproportionately more mistakes than adults on the analogy problems relative to 1-relational problems that required them to select from several images the one that was most semantically related to a cue image (figure 5.5A).

In left VLPFC, a region involved in the effortful retrieval of individual semantic relations between items (see, for example, Badre & Wagner, 2007), no consistent differences were observed between children and adults (Wright et al., 2008). However, older children did engage this region more strongly than younger children, indicating that left VLPFC contributes increasingly to controlled semantic retrieval between the ages of 6 and 13.

In bilateral RLPFC, the time-course analyses provided strong evidence for an immature activation profile in children (figure 5.6). The peak of activation in RLPFC occurred at least 4 seconds later for children than for adults, despite minimal differences in response times between the groups. In fact, for children, RLPFC activation peaked after the motor cortex activation associated with the behavioral response. Overall, consistent with a model whereby relatively more rostral PFC matures later than caudal PFC (Bunge & Zelazo, 2006), larger differences between children and adults were observed in RLPFC than in VLPFC. Changes in the function of RLPFC over childhood and adolescence may contribute to improvements in reasoning ability, and individual differences in RLPFC functioning may explain, at least in part, why some people have a greater capacity for fluid reasoning than others.

Raven's Progressive Matrices In the second study, our laboratory (Crone et al., 2009) presented children aged 8–12 and young adults with problems adapted from the Raven's Progressive Matrices (figure 5.4). Behaviorally, children made a disproportionate number of errors on the REL-2 problems relative to REL-1 problems, and their response times on the REL-2 problems did not differ from those of adults. This finding suggests that children selected responses for these difficult problems before adequately considering both dimensions of relational change.

In adults, RLPFC activation was greater for REL-2 problems than for REL-1 problems. While children also recruited RLPFC, they did not exhibit sustained preferential recruitment of RLPFC for REL-2 problems as compared with

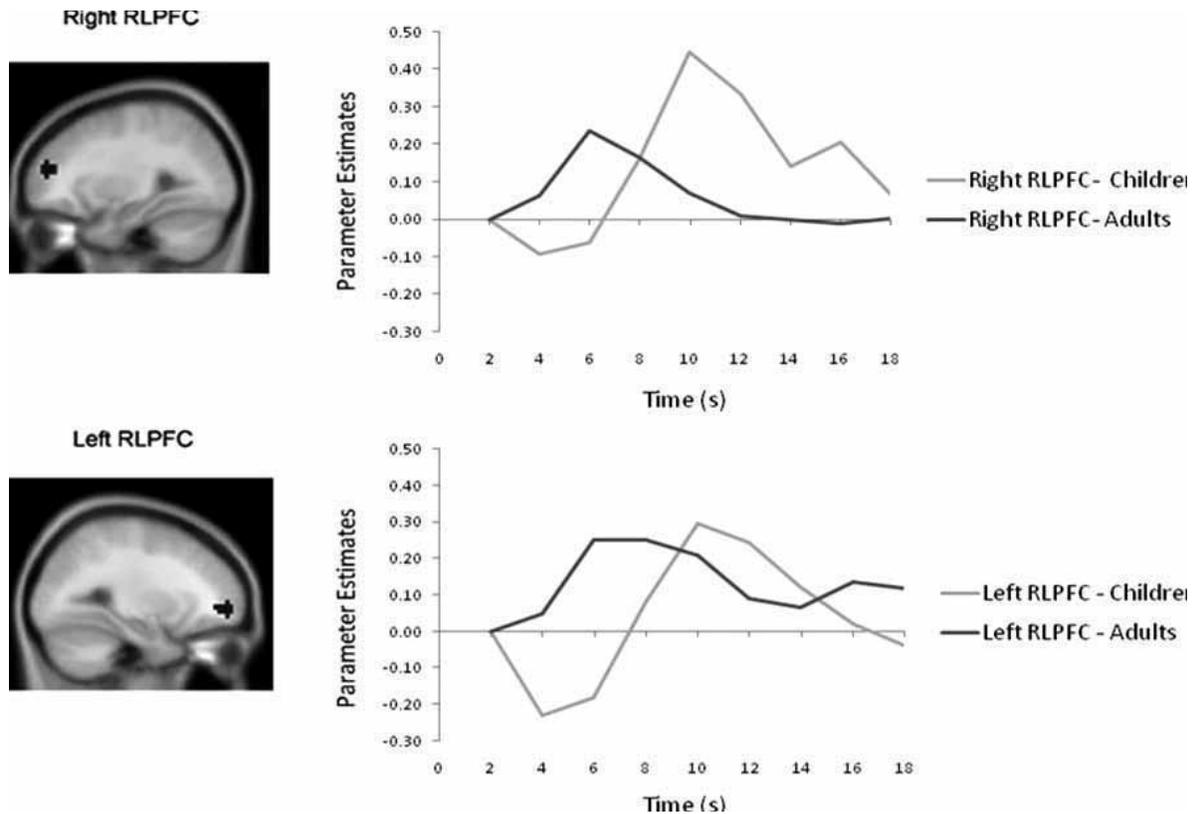

FIGURE 5.6 RLPFC regions of interest and time courses. On the left side of this image, the right and left RLPFC regions of interest are shown in a sagittal view. The right side displays time courses from these regions from baseline at 2 seconds through 18 seconds

REL-1 problems. Together with the response time data, this finding suggests that the children were more likely to treat the REL-2 problems similarly to REL-1 problems, considering only a single dimension of change. Activation of RLPFC associated with the REL-2 problems increases with age, indicating that development of RLPFC integration mechanism occurs, at least in part, over the age range (8–12 years) that was studied. Unlike RLPFC, the inferior parietal lobule was sensitive to the number of relations in adults and showed an immature pattern of activation in children. In summary, this study provides evidence that the development of reasoning is associated with functional changes in RLPFC in response to relational integration.

In summary, fluid reasoning ability comes online early in childhood but continues to develop through adolescence and even into adulthood. Intelligence in adults is related to connectivity between PFC and parietal cortex (Shaw et al., 2006). Structural neuroimaging studies (Giedd, 2004) have shown that development of these regions, PFC and parietal cortex, follows a prolonged developmental time course that matches behavioral data on reasoning in childhood (Richland et al., 2006). Initial functional neuroimaging studies have shown that children recruit brain regions similar to those that adults use to solve analogy problems, but with

after trial onset for both children and adults. Bilaterally, the peak of activation occurs about 4 seconds later in children than in adults, and these regions even appear deactivated during the first few seconds of stimulus presentation.

different patterns of activation suggesting functional immaturity (Wright et al., 2008; Crone et al., 2009).

Conclusions

A growing literature indicates that the increased recruitment of task-related regions in prefrontal and parietal regions contribute to improvements in goal-directed behavior over middle childhood and adolescence. The pattern of developmental changes in brain activation has been generally characterized as a shift from diffuse to focal activation (Durstun, Davidson, et al., 2006) and from posterior to anterior activation (Rubia et al., 2007; T. Brown et al., 2005). Differences can be either quantitative, with one age group engaging a region more strongly or extensively than another, or qualitative, with a shift in reliance on one set of brain regions to another, or both (T. Brown et al., 2005; T. Brown, Petersen, & Schlagger, 2006; Rubia et al., 2007; Scherf et al., 2006; Badre & Wagner, 2007). Importantly, the precise pattern of change observed depends on the task, the ages being examined, and the brain region in question. By further characterizing neurodevelopmental changes in cognitive control processes within subjects and across a range of tasks, we hope to better understand the development of the human mind.

CURRENT AND FUTURE DIRECTIONS By around age 12, the ability to hold goal-relevant information in mind and use it to select appropriate actions is already adequate, although not fully mature. It is of great interest to track brain function associated with working memory and cognitive control earlier in childhood, when these abilities are first acquired. Optical imaging studies can be conducted from infancy onward, although the spatiotemporal resolution of this method is suboptimal. It is now possible to acquire fMRI data in children as young as four years of age (Cantlon et al., 2006), although not without challenges like head motion, low accuracy, and poor attention span.

An important future direction is to determine the extent to which observed age differences in brain activation reflect hard developmental constraints (e.g., the required anatomical network is simply not yet in place at a given age) as opposed to lack of experience with a given type of task or cognitive strategy. Training studies involving several age groups would allow us to investigate effects of age and effects of practice independently and to test whether inherent age differences in performance and brain activation are still present after substantial practice (Luna & Sweeney, 2004; Qin et al., 2004).

Thus far, all but one (Durstun, Davidson, et al., 2006) of the published developmental fMRI studies on working memory or cognitive control have compared groups of individuals at different ages. While these cross-sectional studies are valuable, they provide only a coarse indicator of developmental change. It is also important to conduct longitudinal studies to characterize intra-individual changes in brain function with age.

To understand how goal-directed behavior is achieved, it will be necessary to know how PFC and parietal cortices interact with other brain regions. It is the maturation of a specific network, rather than a particular brain region, that determines how effectively a given brain process is carried out. Some information about these interactions can be gleaned from functional connectivity analyses of fMRI data. Another approach is to acquire fMRI and EEG data in the same group of participants, either in separate sessions or simultaneously (Debener et al., 2005). An important current and future direction for developmental neuroimaging studies is to examine developmental changes in interactions between brain regions, furthering the work of Fair and colleagues (2007) demonstrated in figure 5.2.

The examination of the normal developmental pathways of distinct control functions will be important for understanding sensitive periods in brain development. For example, damage to PFC in childhood has a much greater impact than does damage in adulthood, likely because this region is important for acquiring skills and knowledge during childhood (Eslinger, Flaherty-Craig, & Benton, 2004).

Finally, a better understanding of neurodevelopmental changes in healthy children will lead to insights into the reasons for impoverished goal-directed behavior in a number of neurodevelopmental disorders, such as attention-deficit/hyperactivity disorder (Vaidya et al., 2005; Durstun, Mulder, et al., 2006) and Tourette syndrome (Peterson, Pine, Cohen, & Brook, 2001; Baym, Corbett, Wright, & Bunge, 2008).

Introduction

HELEN NEVILLE AND MRIGANKA SUR

PLASTICITY—THE ABILITY of the brain to change adaptively during learning and memory or in response to changes in the environment—is one of the most remarkable features of higher brain function. Five years ago, in the third edition of *The Cognitive Neurosciences*, researchers described many new mechanisms at multiple levels of the neuraxis that produce and regulate neuroplasticity. These included the genesis of new neurons and glia throughout life, and the role of adult stem cells in plasticity. The papers comprising the plasticity section in 2004 were all conducted in non-human animals. Over the last five years animal studies of neuroplasticity have continued apace. Additionally, a burgeoning literature on human neuroplasticity has emerged. The papers in the current section on plasticity describe both animal and human research and have several themes in common. Several point to the key role of attention in neuroplasticity and also to the malleable nature of attention itself. Several also describe the two sides of plasticity: the systems that are most changeable by environmental input are both more enhanceable and more vulnerable to deficit. Another theme that was repeated and that is important to reiterate is that different functions and related brain systems display different degrees and time periods of maximal plasticity, whereas others display equivalent plasticity throughout life. An exciting new development is the recognition of the key role that genes and molecules play in neuroplasticity. Allelic variation within several specific genes is a major determinant of the degree to which neuroplasticity is evident in both animals and humans. Furthermore, plasticity is manifested through molecular mechanisms that transduce electrical activity in the brain into changes in the weights of synapses or into patterns of synaptic contact and network connections. While these mechanisms have been studied extensively in animal models of developmental or adult

plasticity, they have clear implications for understanding neuroplasticity in the human brain.

Topographic projections, or maps, are fundamental for representing and analyzing sensory information in the brain. In chapter 6, Horng and Sur describe guidance and patterning molecules that underlie the formation of retinotopic maps in the visual pathway. Such maps form a scaffold of connections that is subsequently refined by activity-dependent plasticity. Target molecules themselves can be altered to induce “rewiring” of inputs from the retina to the auditory pathway in ferrets and mice. The auditory cortex, when driven by vision, develops key features of the visual cortex such as visual-orientation-selective cells and maps, demonstrating that the nature of input activity during development is crucial for creating networks that process the input. Finally, the projection from the two eyes to primary visual cortex forms another model system in which molecular mechanisms that refine cortical connections are being rapidly discovered.

In chapter 7, Whitlock and Moser describe mechanisms of plasticity in a brain region that is critical for the formation of episodic memory and that has been studied extensively in the adult animal brain: the CA1 region of the rat hippocampus. They describe the link between long-term synaptic potentiation and behavior, and show how synaptic plasticity supports the formation of place cells in the rat’s hippocampus. More generally, place cells are part of neural networks which have different states that can aid in the storage or recall of representations or memories.

In chapter 8, Li and Gilbert describe plasticity in the primary visual cortex of adult primates as a correlate of perceptual learning. Even early sensory cortical areas retain the capacity for synaptic and network changes, so that repeated perceptual experiences and familiarity elicit enhanced sensitivity to specific stimulus features. Such plas-

ticity often involves an interplay between top-down and bottom-up processing, such that neuronal responses are often dynamically influenced by the nature of the task being performed or the context in which a stimulus appears. The efficient encoding of behaviorally relevant stimuli within a dynamic cortical network is a manifestation of the plasticity seen in perceptual learning.

In chapter 9, Pasqual-Leone describes neuroplasticity in studies of sighted and blind individuals and those who have sustained brain damage. Employing transcranial magnetic stimulation of different frequencies, he can enhance and decrease neuroplasticity. Furthermore these studies can differentiate the neural changes that are necessary for improvement in behavior from those changes that are not, and from changes that instead are harmful. He also describes several genetic polymorphisms that constrain the neuroplasticity in these populations.

In chapter 10, Bavelier, Green, and Dye describe the remarkable enhancements in several cognitive functions in individuals who engage in fast-action video games. They propose that such activity results in Bayesian learning—that is, enhanced learning in the course of optimizing the rewards associated with success in video gaming. They discuss the different ways that harnessing the factors that are important in these effects could benefit educational programs and performance in the workplace.

In chapter 11, Stevens and Neville describe the different profiles of neuroplasticity and the two sides of neuroplasticity in the human visual, auditory, language, and attentional systems. These studies have been conducted on individuals with visual or auditory deprivation and of children of different ages. They also describe their recent studies of interventions that target the most plastic and vulnerable brain systems in children with or at risk for neurocognitive deficits.

6 Patterning and Plasticity of Maps in the Mammalian Visual Pathway

SAM HORNG AND MRIGANKA SUR

ABSTRACT Maps at successive stages of the visual system, and in particular visual cortex, organize salient stimulus features into complex cortical networks. Retinotopic maps and ocular dominance domains arise during development using a molecular program that specifies the rough topographic order of projections. Genetic mutations in mice have identified guidance and patterning cues that mediate this organization of maps and may lead to the creation of new maps. Spontaneous activity produced in the retina refines the precision of the maps before eye opening, and patterned activity after eye opening drives further refinement and maintenance. For ocular dominance, the cortex has a critical period for synaptic plasticity during which it is especially responsive to changes in input. During this time, changes in eye-specific drive lead to Hebbian and homeostatic changes in the cortical network. This potential for plasticity represents a functional reorganization in response to changing demands from the outside world and allows the organism to adapt to its environment.

A critical function of the brain is to provide an orderly and efficient neural representation of salient sensory stimuli from the outside world. In the mammalian visual pathway, representations of light reflectance in visual space are relayed from the retina as a topographic map to the thalamus and superior colliculus. Along this pathway, projections from the two eyes are kept in parallel. Retinotopic and eye-specific information from the thalamus are transferred to the primary visual cortex, where additional stimulus features are extracted. The mechanisms by which visual stimulus feature maps are established and modified in response to experience are an active area of research, as these mechanisms are central to specifying the organizational details of the visual pathway and the functional characteristics of vision.

In this chapter, we will review the processes of retinotopic mapping and cortical plasticity in the mammalian brain. Molecular mechanisms of these phenomena have been studied most extensively in the mouse, a model for which genetic manipulations are available. What we currently know of these mechanisms illustrates how circuits are shaped

by genetic programs, electrical activity, and experience-dependent modulation of stimulus input.

During development, the formation of a retinotopic map requires that axons responsive to neighboring positions in visual space maintain their relative positions as they innervate their target. This process involves graded patterns of guidance receptors expressed across the population of axons and matched to a complementary gradient of ligands on the target cells. The genetic patterning of guidance cues confers a rough order and spatial efficiency to the retinotopic map. However, further retinotopic precision and ocular dominance segregation depend upon patterns of spontaneous activity in the retina and experience-driven input. Changes in the level or pattern of activity can alter the structure and function of the retinotopic map in early development and of ocular dominance regions in later development and adulthood. Ocular dominance plasticity occurs in response to changes in competitive input between the eyes, and a variety of molecular pathways, many of which reflect the maturational state of the circuit, have been implicated in this process. Thus the developmental context shapes the extent to which changes induced by competitive input between the eyes occur. Here, genetic programs of development interact with activity- and experience-dependent input to mediate map refinement and plasticity.

The formation of the visual pathway during early development

REGIONALIZATION OF VISUAL PATHWAY CENTERS
Functional pathways of the brain arise out of genetic programs of early development, which establish structural regions and wire them together (Rakic, 1988; O'Leary, 1989; Job & Tan, 2003; Sur & Rubenstein, 2005). During embryogenesis, sources of diffusible molecules, called signaling centers, induce regional and graded patterns of gene expression in the anterior neural tube. These patterns translate into structurally parcellated and functionally differentiated brain regions, including those devoted to processing incoming visual stimuli (Figdor & Stern, 1993; Rubenstein, Martinez, Shimamura, & Puelles, 1994; Rubenstein, Shimamura, Martinez, & Puelles, 1998;

SAM HORNG and MRIGANKA SUR Department of Brain and Cognitive Sciences, The Picower Institute for Learning and Memory, MIT, Cambridge, Massachusetts

Ragsdale & Grove, 2001; Nakagawa & O'Leary, 2002; Grove & Fukuchi-Shimogori, 2003; Shimogori, Banuchi, Ng, Strauss, & Grove, 2004).

In the mouse, centers of the visual pathway are established in this way: neuromeres P2 and P3 of the diencephalon differentiate into the dorsal and ventral thalamus, respectively, and around E13.5, lateral nuclei cluster to form the dorsal and ventral subdivisions of the lateral geniculate nucleus (LGN) (Jones, 1985; Tuttle, Braisted, Richards, & O'Leary, 1998). From E11 to E19, area 17 of posterior cortex differentiates in response to cortical gradients of FGF8, Wnts, BMP, and Shh to form the primary visual cortex (V1) (Dehay & Kennedy, 2007). How continuous gradients of gene expression throughout the neural tube are translated into boundary-delimited regions of functionally specific identities is not yet known; moreover, region-specific gene expression has not yet been reported (Nakagawa & O'Leary, 2001; Jones & Rubenstein, 2004).

TARGETING AND RETINOTOPIC WIRING The visual pathway is wired (figure 6.1A) when roughly one-third of the ganglion cell axons from the retina project to the dorsal and ventral subdivisions (LGNd, LGNv) of the LGN while the remaining two-thirds target the superior colliculus (SC) in the brain stem (Jones, 1985; Tuttle et al., 1998). Axonal pathfinding to fugal (i.e., thalamic) and collicular targets begins around E15–16 and peaks at E19 (Colello & Guillery, 1990; Figdor & Stern, 1993; Tuttle et al., 1998; Inoue et al., 2000; Gurung & Fritsch, 2004; Guido, 2008). In the mouse, axons from the ventrotemporal retina project ipsilaterally while the rest of the axons project contralaterally, with contralateral innervation to the thalamus occurring earlier (E15–16) than ipsilateral targeting (P0–2) (Dräger & Olsen, 1980; Godement, Salaun, & Imbert, 1984). Connections between the LGN (in this review, LGN is used to denote LGNd) and V1, both in the feedforward geniculocortical direction and in the feedback corticogeniculate pathway, emerge around E14 (Zhou et al., 2003).

Elucidating the mechanisms of retinotopic targeting and mapping has become a comprehensive field of study (figure 6.1B). Molecular mechanisms of retinal ganglion cell (RGC) guidance have been extensively studied in *Xenopus*, zebrafish, chick, and mouse models. Much of this work has focused on guidance to the optic disk, decussation at the optic chiasm, and topographic map formation at the optic tectum, or SC (Inatani, 2005; Mann, Harris, & Holt, 2004). In the retina, laminin and netrin repulse DCC receptor-expressing RGC axons out of the optic head and into the optic nerve (Hopker, Shewan, Tessier-Lavigne, Poo, & Holt, 1999). Along the optic nerve, a repulsive semaphorin 5a sheath maintains the integrity of an interior axon pathway (Shewan, Dwivedy, Anderson, & Holt, 2002; Oster, Bodecker, He, & Sretavan, 2003). Slit1- and slit2-expressing cells guide repulsed robo-

expressing axons to the proper decussation site for optic chiasm formation (Erskine et al., 2000; Ringstedt et al., 2000; Plump et al., 2002), and ephrin-B2 expression at the optic chiasm steers EphB1-receptor-expressing ventrotemporal axons ipsilaterally (Williams et al., 2003; Lee, Petros, & Mason, 2008). Matrix metalloproteinases (MMP) have been implicated in optic chiasm crossing and tectal targeting (Hehr, Hocking, & McFarlane, 2005). Additionally, traditional morphogens influence retinal ganglion cell pathfinding (Charron & Tessier-Lavigne, 2005): FGF-2 repels RGC growth cones along the optic tract (Webber, Hyakutake, & McFarlane, 2003), BMP7 promotes axonal outgrowth at the optic disk (Carri, Bengtsson, Charette, & Ebendal, 1998; Bovolenta, 2005), and Shh exhibits concentration-dependent attractive or repulsive effects in the retina and optic chiasm, respectively (Trousse, Marti, Gruss, Torres, & Bovolenta, 2001; Kolpak, Zhang, & Bao, 2005). Less is known about the specific cues mediating ganglion cell ingrowth to the LGN and geniculocortical targeting to area 17, or V1.

However, molecules that contribute to the topographic ordering of projections have been investigated in the LGN and V1, as well as the SC. The spatial position of visual stimuli is inverted through the lens and encoded on a sheet of retinal ganglion cells. This topographic map gets projected into the LGN and V1, as well as the SC. Because axon guidance cues must not only flag targets but also confer information about the relative topography of neighboring axons, positional cues are needed to maintain the retinotopic order of the projecting pathway. To avoid employing an infinitely large number of distinct positional cues, a gradient of one molecule along the sheet of axons may be matched to a complementary gradient of its binding partner in the target (Sperry, 1963). This “chemoaffinity” model has been confirmed with the discovery of a number of different receptor-ligand gradients expressed in projecting axons and target cells along the visual pathway.

The most comprehensively studied of these graded mapping molecules are the ephrin ligands and Eph family of tyrosine kinase receptors (figure 6.1B). The contribution of ephrinA-EphA receptor interactions to topographic mapping was first described in the optic tectum, where low-to-high ephrin-A2/A5 expression along the anterior-posterior axis was found to interact with a complimentary high-to-low EphA3 receptor gradient in terminals of the temporal-nasal axis of retina (Nakamoto et al., 1996; Feldheim et al., 1998, 2000; Hansen, Dallal, & Flanagan, 2004; Bolz et al., 2004). Interactions between ephrin-A and EphA receptors were initially thought to be repulsive, though subsequent studies revealed a concentration-dependent transition from attraction to repulsion: with low ephrin-A concentrations causing axonal attraction and high levels causing repulsion (Hansen et al., 2004). The ability of one ligand-receptor system to both attract and repel allows for

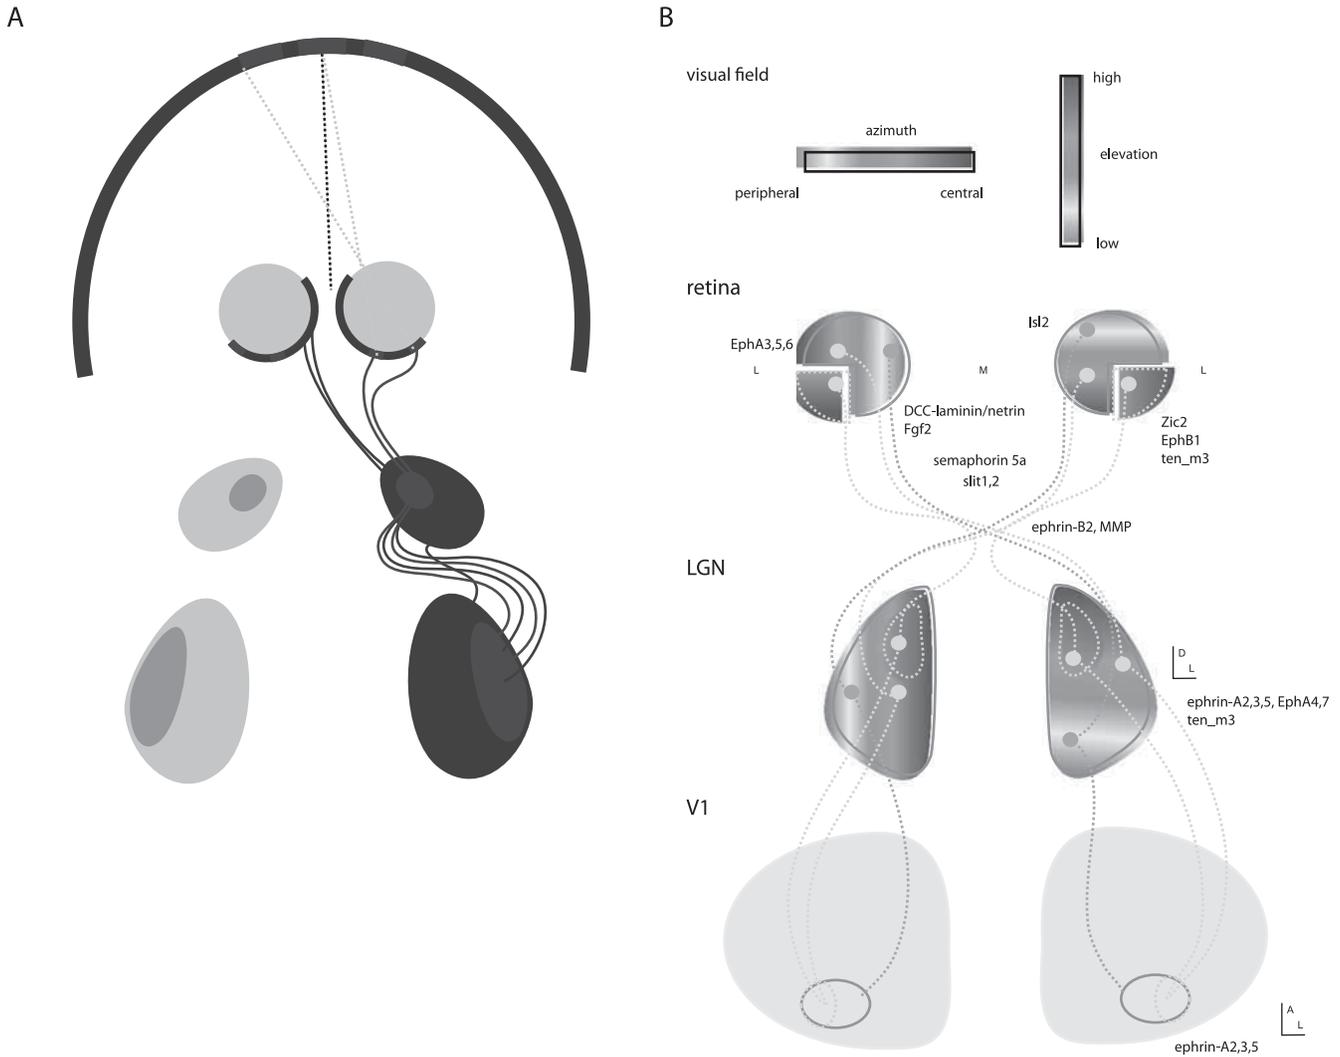

FIGURE 6.1 (A) Representation of the rodent visual pathway. Retinal ganglion cells project to the LGN, which in turn projects to the primary visual cortex (V1). A central region of the visual field is represented by both eyes along the pathway (ipsilateral, red; contralateral, blue). Contralateral and ipsilateral retinal ganglion cell terminals representing this binocular region are segregated in the LGN (red, ipsilateral zone; blue, contralateral zone). Geniculocortical fibers representing this region converge onto a binocular zone located in the lateral half of V1 (red, binocular zone; blue, monocular zone). (B) Schematic representation illustrating retinotopic map organization at each stage of the visual pathway and known guidance cues contributing to patterning. The visual field can be divided into two Cartesian axes, azimuth and elevation. For clarity, the azimuthal map on the left is diagrammed onto the visual pathway of the right hemisphere. The elevation map on the right is diagrammed onto the pathway of the left hemisphere. In reality, both axes of visual space are represented concurrently in both hemispheres. The ganglion cell sheet of the retina is divided into a contralaterally projecting region and an ipsilaterally projecting region. The ipsilateral retina originates from the ventrotemporal quadrant and is characterized in late

embryogenesis by *Zic2* and *EphB1* expression. Conversely, the contralateral retina is characterized by *Isl2* expression. Retinal ganglion cells express *DCC* and are repulsed out of the optic head by laminin and netrin. Factors, such as semaphoring-5a, keep retinal axons on course in the optic tract, where ipsilateral axons are repulsed by ephrin-B2 while contralateral axons decussate. High temporal to low nasal gradients of EphA receptor and *ten_m3* expression in retinal axons likely influence terminal zones onto gradients of ephrin-A in the LGN. Ipsilateral axons terminate in a dorsomedial core of the LGN, segregated from surrounding contralateral axons. Activity-dependent refinement is necessary for proper eye-specific segregation. While ephrin-A gradients shape retinotopic termination zones, *ten_m3* specifically influences ipsilateral targeting. Geniculocortical axons innervate V1. Ipsilateral inputs and corresponding contralateral fibers converge in the lateral binocular zone, while contralateral inputs representing regions not detected by the ipsilateral eye terminate in the medial monocular zone. Loss of ephrin-As leads to the disorganization of cortical maps only on the azimuthal axis, suggesting that other, unidentified factors contribute to the mapping of elevation. (See color plate 2.)

the target to be filled more parsimoniously than with separate attractant and repulsant molecules.

High lateral-to-medial gradients of ephrin-A2/A5 are also present in the mouse and ferret LGN and direct topography of high levels of EphA5/A6 expression from the contralateral nasal projections and low levels in the ipsilateral temporal projections (Huberman, Murray, Warland, Feldheim, & Chapman, 2005). Loss and ectopic gain of ephrin-A2, 3 and 5 lead to disruptions of the topographic map in both the LGN and V1: loss produces a medial shift in V1, in addition to internal disorganization, while lateral overexpression leads to a compression of V1, suggesting that EphA-expressing geniculocortical axons respond to a high medial to low lateral gradient of ephrinA (Cang et al., 2005). High dorsal EphB receptor expression in retina responds to low ventral ephrin-B expression in the tectum, and EphB-ephrinB gradients are speculated to similarly organize distinct axes in the LGN and V1 (Hindges, McLaughlin, Genoud, Henkemeyer, & O'Leary, 2002; McLaughlin, Hindges, Yates, & O'Leary 2003). The role of potential cis and trans mediated interactions among ephrin and Eph receptors from countergradients expressed on axons of the same area have yet to be explored (Luo & Flanagan, 2007). Finally, additional graded positional cues have been identified in the retinotectal map. Repulsive guidance molecule (RGM), a novel membrane-associated glycoprotein expressed in the posterior tectum, repulses temporal axons in vitro (Monnier et al., 2002), while engrailed-2 (En-2), a homeodomain transcription factor, is secreted by the posterior tectum, is endocytosed into axons, and attracts nasal axons while repelling temporal axons (Brunet et al., 2005). A high-to-low gradient of Wnt3 in the medial-lateral axis of the optic tectum mediates patterning via ventral-dorsal differences in Ryk receptor expression (Schmitt et al., 2006), and a Wnt signaling inhibitor, SFRP1, interacts with RGC receptor Fz2, to steer axons along the optic tract en route to the tectum (Rodriguez et al., 2005).

Experiments in which half of retinal ganglion cells are ablated or a disordered set of cells gain EphA expression reveal that retinotectal axons persistently fill their target (Brown et al., 2000; Feldheim et al., 2000). Thus it is the relative level of positional information rather than absolute signaling that determines the topography of retinal axons. Some limiting factor, whether from the axon-axon interaction or target-derived cues, may ensure that target filling occurs (Luo & Flanagan, 2007). Loss of L1CAM leads to incomplete filling of the tectum, and this molecule may have such a role (Demyanenko & Maness, 2003).

EYE-SPECIFIC DOMAINS A second fundamental organizational feature of the visual pathway is its segregation into eye-specific domains. Maintaining parallel channels for eye-specific input allows for stereoscopic vision, or depth

perception. In mice, ipsilateral projections form a dorsal core in the LGN (LGNd) and are flanked laterally by contralateral terminals representing matched areas of visual space. These axons intermix when projecting to layer IV cells of the binocular zone, a V1 subregion bounded medially by a monocular zone of contralateral input (figure 6.1A,B). In mammals with more complex visual systems, such as the ferret, cat, primate, and human, eye-specific domains form a map of ocular dominance stripes in V1 (figure 6.3). Whether eye-specific domains are influenced by positional cues in addition to activity dependent processes of terminal segregation has only recently begun to be explored. Developmental time course studies in the mouse show that early (P0–P5) ipsilateral axons are diffusely targeted to the dorsal-medial portion of the LGN and progressively become more strictly confined to a central core by P28 (Jaubert-Miazza et al., 2005). Although activity-dependent processes to be discussed later contribute to the refinement of ocular domains in the LGN (Shatz, 1983; Shatz & Stryker, 1988; Pfeiffenberger et al., 2005), the initial ingrowth of ipsilateral axons shows a bias toward the binocular region in the central part of the dorsal half of the LGN, and eye-specific guidance cues likely instruct this initial positioning (Godement et al., 1984). The presence of functional markers, *Isl2* and *Zic2*, during late embryogenesis (E13–E17), for contralaterally and ipsilaterally projecting retinal ganglion cells, respectively, suggests that the two populations have distinct differentiation programs and potentially respond to unique cues in their target (Herrera et al., 2003; Pak, Hindges, Lim, Pfaff, & O'Leary, 2004). Loss of *ten_m3*, a homophilic binding protein expressed strongly on ipsilaterally projecting axons, leads to the selective ventral expansion of ipsilateral axons and no disruption in contralateral axons in the LGN (Leamey, Glendinning, et al., 2007; Leamey, Merlin, et al., 2007). Therefore, *ten_m3* and potentially other unknown cues may contribute to the formation of eye-specific domains. Mechanisms of how corresponding ipsilateral and contralateral axons are coordinated and aligned to form binocular maps are poorly understood.

OTHER FEATURE MAPS AND THE FORMATION OF NEW MAPS In mice and other mammals, additional stimulus features are encoded in the visual pathway at the cortical level. Cells in V1 are selective for orientation, spatial frequency, and the direction of visual stimuli. In carnivores and primates, these cells are organized into selectivity maps of their own. For example, multiple stripes converging around a pinwheel center on the cortical surface represent graded regions of different orientation selectivity. Within these orientation-selective regions, directionally selective subregions are present. Using a layout that maximizes map continuity and cortical coverage (Swindale, Shoham, Grinvald, Bonhoeffer, & Hübener, 2000), multiple feature

maps are superimposed and organized in systematic fashion, with regions of high gradients from different maps spatially segregated from one another (Yu, Farley, Jin, & Sur, 2005). That is, while individual, adjacent neurons respond best to different values of the same feature, the way in which these features are mapped varies systematically. The critical parameter is the rate of change of each feature across the same set of neurons: at locations where one feature changes rapidly, other features change little.

Mechanisms of map formation for these additional stimulus features are not well understood, although the role of intrinsic genetic programs of patterning and activity-dependent input may differ depending on the specific feature map (White & Fitzpatrick, 2007). Whereas the retinotopic and eye-specific maps are patterned roughly before birth and eye opening, the orientation map is detectable only by the time of eye opening in the ferret (Chapman, Stryker, & Bonhoeffer, 1996; White, Coppola, & Fitzpatrick, 2001; Coppola & White, 2004), and the direction-selective map appears 1–2 weeks later (Li, Fitzpatrick, & White, 2006). Therefore, the formation of these maps likely depends critically on developmental processes coincident with patterned input into the cortex.

The formation of orientation maps coincides with a period during which axonal connections in V1, especially long-range horizontal inhibitory projections in layer 2/3, proliferate (Bosking et al., 2002). Orientation tuning has been hypothesized to arise from feedforward patterns of thalamo-cortical connectivity (Ferster & Miller, 2000) and to be shaped by intracortical connections (Somers, Nelson, & Sur, 1995) and balanced inhibition (Marino et al., 2005). The maturation of this supragranular inhibitory network may contribute to the appearance of orientation tuning and organization of tuned cells into selective domains. Mice deficient in Arc, an activity-dependent cytoskeletal-associated protein implicated in the synapse-specific modulation of AMPA receptor number, show weaknesses in orientation tuning in V1 (Wang et al., 2006). Dark-reared animals exhibit a delay in the formation of the orientation map, while binocularly lid-sutured animals have a near complete degradation of the map (White et al., 2001), suggesting that low levels of non-patterned activity have a greater disruptive effect than the absence of input. Therefore, unknown intrinsic properties of the cortex instruct the formation of the orientation map in the weeks after eye opening and induce the map even in the absence of vision. However, the orientation map is susceptible to disruption in response to disorganized activity.

In contrast to orientation maps, a 2-week period following eye opening is both necessary and sufficient for the formation of direction-selective maps (Li et al., 2006). Thus the direction-selective map is induced by changes in either the cortex or LGN that are driven by activity. Sharpening of retinotopic tuning and decreases in the response latency of

LGN cells may play a role (Tavazoie & Reid, 2000). Different feature maps in V1 appear to be guided by independent mechanisms. Loss of the direction-selective map leaves the orientation map intact, and monocular enucleation to eliminate the ocular dominance map does not interfere with the formation of the remaining V1 feature maps (Farley, Yu, Jin, & Sur, 2007). However, the relative positioning of different maps in V1 is responsive to alterations in a given map, as monocular enucleation leads to the coordinated reorganization of the remaining map dimensions (Farley et al., 2007). Therefore, while the formation of stimulus-specific maps or networks likely relies on unique developmental mechanisms, whether they be genetically determined or instructed by activity, the detailed organization of each map and its structural and spatial coordination with other maps is a key feature of activity-dependent cortical organization.

Because of the independent origin of individual maps (and response features), the appearance of new maps in evolution may have depended on unique events and developmental processes for a given map. However, there may be general properties in neural circuits that allow for the introduction of a novel map. Novel maps may arise potentially through the duplication and subsequent functional divergence of an existing map, or the addition of a novel input into an existing region and subsequent reorganization of cortical circuitry into a new map. An example of the former is the induction of duplicate barrel cortices by ectopic posterior cortical FGF8 expression (Fukuchi-Shimogori & Grove, 2001). An example of novel input leading to the introduction of a new map includes the implantation of a third eye leading to triple ocular dominance stripes in the tectum of the frog (Constantine-Paton & Law, 1978), rewired retinal input to the MGN driving retinotopic maps to form in primary auditory cortex (A1) (Sur, Garraghty, & Roe, 1988), and *ten_m3* mutation in mouse leading to a medial expansion of ipsilateral input to V1 and the de novo formation of cortical ocular dominance stripes (C. Leamey, personal communication).

Rewiring vision into the auditory pathway

After neonatal surgical ablation of the inferior colliculus (IC), retinal ganglion cells are rerouted to target the auditory thalamus and subsequently induce the auditory pathway to process visual information (figure 6.2). This experimental paradigm allows us to investigate the role of novel input in producing retinotopic and feature maps, and to screen for unknown guidance cues involved in wiring together sensory pathways. The normal auditory pathway comprises cochlear afferents projecting to the inferior colliculus (IC), which sends fibers along the brachium of the IC (BIC) to the medial geniculate nucleus (MGN) in the thalamus, which then innervates the primary auditory cortex (A1; figure 6.2A). Using hamsters, Schneider discovered that retinal afferents form

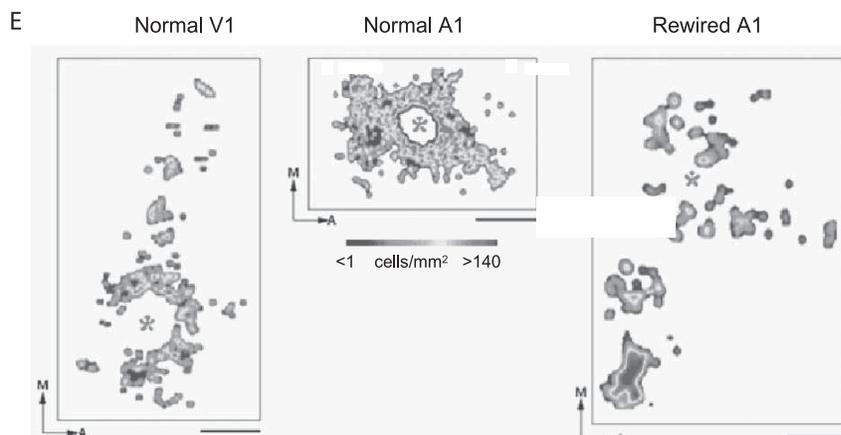

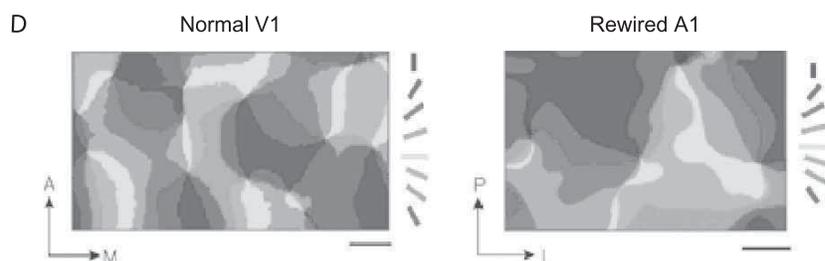

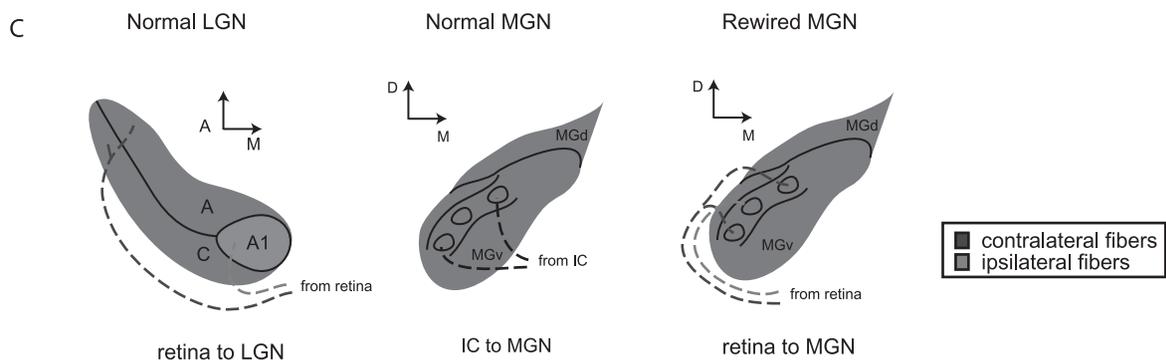

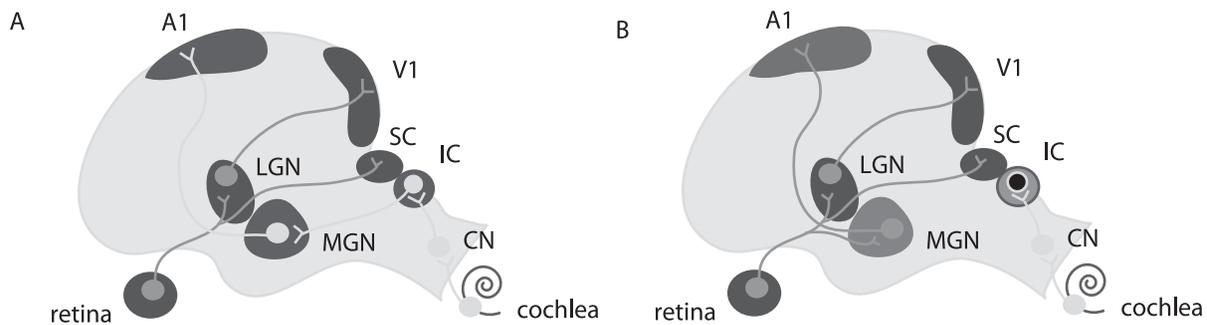

FIGURE 6.2 Primary visual and auditory pathways in normal and rewired mice: anatomical and physiological consequences of rewiring. (A) The visual pathway in ferrets and mice begins with retinal projections to the lateral geniculate nucleus (LGN) and superior colliculus (SC). The LGN projects in turn to the primary visual cortex (V1). The auditory pathway traces from the cochlea to the cochlear nucleus (CN) and then to the inferior colliculus (IC). From IC, connections are made with the medial geniculate nucleus (MGN), which projects to the primary auditory cortex (A1). (B) Ablation of the IC in neonatal animals induces retinal afferents to innervate the MGN and drive the auditory cortex to process visual information. (C) Retinogeniculate axons of normal ferrets project to eye-specific regions of the LGN (horizontal plane), while IC afferents project to the ventral subdivision (MGv) of the MGN (coronal plane) and innervate lamellae parallel to the lateral-medial axis. Rewired auditory fibers innervate the MGv along adjacent, nonoverlapping eye-

specific terminals within MGv lamellae. (Adapted from Sur & Leamey, 2001.) (D) Orientation maps are present in normal V1 and rewired A1 of ferrets using optical imaging of intrinsic signals. The animal is stimulated with gratings of different orientations, while hemodynamic changes in red wavelength light reflectance caused by increases in oxygen consumption are detected from the cortex with a digital camera. The orientation preference map is calculated by computing a vector average of the response signal at each pixel. Color bar: color coding representing different orientations. Scale bar: 0.5 mm. (E) Retrograde tracers reveal the pattern of horizontal connections in superficial layers of normal V1, normal A1, and rewired A1 of ferrets. Distribution of horizontal connections in rewired A1 more closely resembles that of normal V1 than normal A1 and potentially contributes to the refinement of orientation mapping in rewired A1. Scale bars: 500 μm . (Adapted from Sharma, Angelucci, & Sur, 2000.) (See color plate 3.)

novel connections to the ventral MGN (MGv) when the IC is ablated after birth (figure 6.2B; Schneider, 1973; Kalil & Schneider, 1975; Frost, 1982; Frost & Metin, 1985). This “rewiring” paradigm has subsequently been demonstrated and studied in the ferret and mouse models (Sur et al., 1988; Roe, Pallas, Hahm, & Sur, 1990; Roe, Pallas, Kwon, & Sur, 1992; Lyckman et al., 2001; Newton, Ellsworth, Miyakawa, Tonegawa, & Sur, 2004; Ellsworth, Lyckman, Feldheim, Flanagan, & Sur, 2005).

On receiving retinal ganglion cell input, the MGN adopts some of the anatomic and physiologic features of the normal LGN (figure 6.2C). Rewired MGN neurons of the ferret exhibit center-surround visual receptive fields (Roe, Garraghty, Esguerra, & Sur, 1993), topographic ordering (Roe, Hahm, & Sur, 1991), and eye-specific segregation (Angelucci, Clasca, Bricolo, Cramer, & Sur, 1997). The potential to form ordered retinotopic and ocular dominance regions in MGN indicates that common patterning cues exist between the LGN and MGN. Experiments in ephrin A2/A5 double knockout mice reveal that surgically induced rewiring is enhanced (Lyckman et al., 2001), with ipsilateral projections especially increased, as they originate from the temporal retina and express the highest levels of EphA receptor (Ellsworth et al., 2005). Loss of innervation to the MGN somehow makes this nucleus permissive to retinal axon ingrowth, and a gene-screening process between the normal and rewired MGN may facilitate the discovery of tropic or repulsive agents regulating retinal axon affinity for different sensory nuclei of the thalamus.

Nonetheless, certain morphological aspects of rewired MGN are resistant to change (figure 6.2C). In ferrets, retinal axon terminations are elongated along the typical isofrequency axis, or lamellae, of the MGN as opposed to more focal, isotropic distributions in the LGN (Pallas, Hahm, & Sur, 1994). In addition, eye-specific clusters are smaller and cruder than the eye-specific layers of LGN (Angelucci et al., 1997).

In the cortex of rewired ferrets, cells in A1 respond to visual field stimulation and form a functional retinotopic map of visual space (Roe et al., 1990). However, the thalamocortical axons transmitting this information retain their pattern of elongated projections along the anteroposterior axis of A1, which typically correspond to isofrequency bands (Pallas, Roe, & Sur, 1990). In order to create the functional map of focal retinotopic representations, either a refinement of these elongated inputs by a reorganized intracortical inhibitory network or a difference in drive along the projection itself is required (Sur, Pallas, & Roe, 1990). Consistent with the first possibility, calbindin-immunoreactive GABAergic neurons of rewired A1 have more elongated axonal arbors (Gao, Wormington, Newman, & Pallas, 2000). Thus, despite persistent structural features of A1 and thalamocortical input, functional retinotopy can be driven by novel patterns of activity.

In the ferret, rewired A1 acquires novel maps of orientation selectivity with pinwheels and orientation domains (figure 6.2D), similar in general to maps in normal V1 (Sharma et al., 2000; Rao, Toth, & Sur, 1997). In rewired A1, orientation maps are less organized, although intrinsic horizontal connections of superficial layer pyramidal neurons are clustered and bridge distantly located domains of the same orientation preference, as in V1 (figure 6.2E; Sharma et al., 2000). This pattern of intracortical connectivity is in contrast to horizontal connections in normal A1, where horizontal connections are limited to isofrequency domains of the tonotopic map and stretch along these bands. Such reorganization of horizontal connections driven by visual activity is likely related to changes in the inhibitory circuits of rewired A1, and it suggests that coordinated activity-dependent changes in inhibitory and excitatory networks of at least the superficial cortical layers are a prominent feature of cortical map organization and plasticity.

Finally, the rewired auditory pathway is sufficient to instruct visually mediated behavior. After training to

distinguish a left visual hemifield stimulus from an auditory stimulus, ferrets with a unilaterally rewired left hemisphere are able to accurately perceive a right visual hemifield stimulus as visual even after left LGN ablation (von Melchner, Pallas, & Sur, 2000). After left LGN ablation, the ferrets also possess diminished yet intact spatial acuity in the right hemifield. Subsequent ablation of the rewired A1 abolishes the animals' ability to distinguish a right hemifield stimulus presented as visual. Thus rewired A1 is sufficient and necessary in the absence of ipsilateral visual pathway input to detect a visual percept in trained ferrets. In mice, direct subcortical projections from the MGN to the amygdala are involved in rapid fear conditioning to an auditory cue (Rogan & LeDoux, 1995; Doran & LeDoux, 1999; Newton et al., 2004). Because of an indirect pathway from the LGN through V1 and the perirhinal cortex to the amygdala, a fear conditioning to a visual cue requires many more training sessions (Heldt, Sudin, Willott, & Falls, 2000). In rewired mice, the acquisition time of a fear conditioning to a visual cue is accelerated and resembles that of a normal mouse in response to an auditory cue (Newton et al., 2004).

Activity-dependent refinement of visual maps

Although topography of the retinotopic map and eye-specific domains are roughly established by programmed guidance and patterning cues, activity plays a critical role in the refinement and maturation of these maps. Single cells in the mouse LGN receive weak input from one to two dozen retinal ganglion cells, which occupy 30% of the cell surface, in the first postnatal week, and then begin to prune these connections down to one to three strong monocular inputs that occupy 1–5% of the cell surface (Chen & Regher, 2000; Jaubert-Miazza et al., 2005; Guido, 2008). Ipsilateral projections to the LGN are also diffuse and widespread during this first week, occupying nearly 60% of the nucleus area. By the time of eye opening (P12–P14), the ipsilateral zone occupies only 10% of the LGN (Jaubert-Miazza et al., 2005; Guido, 2008).

Both the retinotopic and eye-specific pruning of synapses is affected by altering spontaneous activity caused by cholinergic waves that sweep across the retina (Meister, Wong, Baylor, & Shatz, 1991; Wong, Meister, & Shatz, 1993). Blockade of retinal electrical activity with TTX (Harris, 1980) or loss of retinal waves by genetic loss of the $\beta 2$ nAChR (Rossi et al., 2001; McLaughlin, Torborg, Feller, & O'Leary, 2003; Grubb, Rossi, Changeux, & Thompson, 2003; Chandrasekaran, Plas, Gonzalez, & Crair, 2005) causes terminals to remain desegregated and diffuse. Combined ephrinA and $\beta 2$ nAChR mutants lead to additive defects in retinotopic organization in the LGN and V1 along the elevation axis in visual space, demonstrating that activity-dependent refine-

ments form a strong contribution to the integrity of the retinotopic and eye-specific maps (Pfeiffenberger et al., 2005; Pfeiffenberger, Yamada, & Feldheim, 2006; Cang et al., 2008). The nob mutant mouse, which acquires an abnormal onset of high-frequency waves after eye opening, develops normal eye-specific segregation before eye opening, because early spontaneous waves are intact. After the onset of abnormal high-frequency waves, eye-specific inputs desegregate because of potentially synchronized firing between the eyes (Demas et al., 2006). Similarly, fish exposed to the synchronized stimuli of strobe illumination lose eye-specific segregation (Schmidt & Eisele, 1985). The most straightforward mechanism for these data involves the strengthening of correlated inputs and weakening and subsequent pruning of noncorrelated inputs (Hebb, 1949; Zhang & Poo, 2001). In retinogeniculate synapses, bidirectional changes in synaptic strength depend on the relative timing between optic tract stimulation and LGN depolarization (Butts, Kanold, & Shatz, 2007).

Specifically how decorrelated axon terminals are eliminated and persisting synapses strengthened is not well understood, though canonical immunologic signaling molecules may be involved in synaptic pruning. Loss of Class I MHC proteins, neuronal pentraxins, and the C1qb component of the complement cascade leads to persistently enlarged and desegregated ipsilateral zones in the LGN (Huh et al., 2000; Bjartmar et al., 2006; Stevens et al., 2007). These molecules are hypothesized to tag weak synapses for pruning during activity-dependent refinement. Notably, these manipulations do not affect the basic topographic organization of the retinotopic map and eye-specific domains. Conversely, ephrin-A mutants alone contain topographically disorganized, yet tightly refined, retinotectal terminals (Frisen et al., 1998; Feldheim et al., 2000).

In the mouse, retinotopic maps in V1 require patterned input for normal maturation. During the first 10 days after eye opening (P13–P23), normal activity brings eye-specific maps to adult levels of responsiveness and precision in receptive field organization (Smith & Tractenberg, 2007). The contralateral eye develops more precociously in map precision and magnitude, while the ipsilateral eye lags behind by roughly 5 days. When the contralateral eye is deprived, both contralateral and ipsilateral maps are delayed in retinotopic precision; when the contralateral eye is removed or silenced, precision of the ipsilateral maps is accelerated; when the contralateral eye is removed and ipsilateral eye deprived, the ipsilateral map precision is delayed. These data suggest that competing patterned inputs from both eyes is necessary for normal map refinement. Isolated patterned input accelerates map refinement, perhaps because of a lack of noise from the contralateral eye. The effects of binocular deprivation, or ipsilateral

removal plus contralateral deprivation, were not examined in this study.

In addition to Hebbian pruning and strengthening of feedforward inputs, changes due to activity that contribute to map refinement potentially involve additional developmental processes, including the remodeling of excitatory connections, the maturation of inhibitory circuits, and the timed expression of L-type Ca^{2+} channels. Excitatory synapses in the LGN initially contain NMDA receptors but increase their proportion of AMPA receptors as synaptic elimination proceeds (Chen & Regehr, 2000; X. Liu & Chen, 2008). Networks of GABAergic interneurons in the LGN also appear at P5 and mature by P14 (Ziburkus, Lo, & Guido, 2003; Jaubert-Miazza et al., 2005). L-type Ca^{2+} channels are expressed in excitatory LGN synapses before eye opening and are necessary for eye-specific segregation and CRE-mediated gene transcription (Cork, Namkung, Shin, & Mize, 2001; Pham, Rubenstein, Silva, Storm, & Stryker, 2001; Jaubert-Miazza et al., 2005).

In sum, mechanisms of map refinement in response to activity likely involve a number of different processes that contribute to the functional maturation of the circuit, including the selection and elimination of synapses, the modulation of synaptic strength, and the structural formation of inhibitory networks. Activity may also in turn influence the actions of guidance cues; activity blockade prevents ephrinA-mediated repulsion because of disruptions in cAMP signaling (Nicol et al., 2007).

Ocular dominance plasticity

Once a functional map is refined, ongoing patterns of activity contribute to the maintenance and alteration of this map in response to experience. The potential for plasticity is of particular interest for understanding how neural circuits adapt their structure and function to accommodate changing demands in the environment. Plasticity in the V1

ocular dominance map has become a paradigmatic model of activity-driven reorganization in network structure and function (figure 6.3A).

STRUCTURAL AND FUNCTIONAL CHANGES IN RESPONSE TO LID SUTURE Within the binocular zone of V1 in mammals, neurons particularly in the superficial and deep

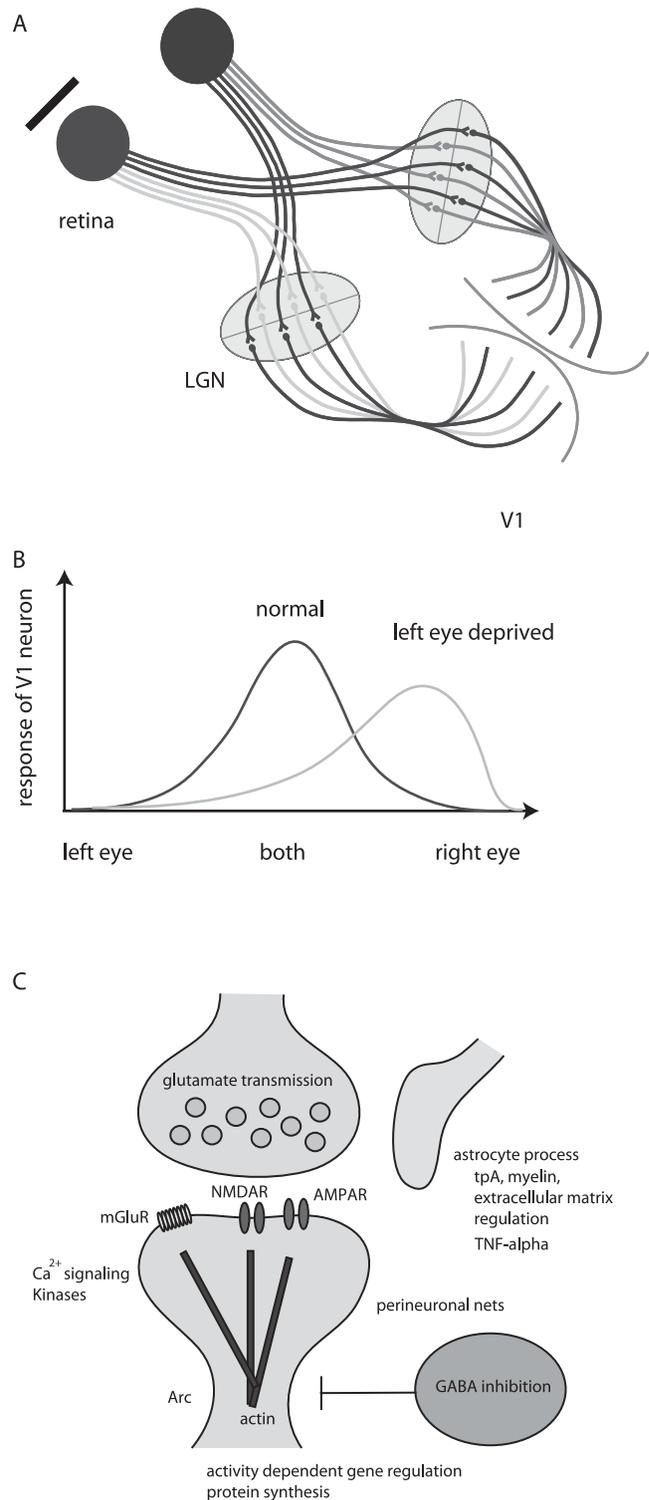

FIGURE 6.3 Ocular dominance anatomy and plasticity in V1. (A) Contralateral and ipsilateral fibers are segregated in the LGN but converge onto binocular cells in V1. (B) When one eye is deprived of input for a brief period during the critical period, or for a longer period during adulthood, binocular cells in V1 become more strongly driven by the nondeprived eye. Ocular dominance plasticity reflects both structural and functional changes of synapses. (C) The cellular and molecular mechanisms of ocular dominance plasticity are an active area of investigation. Processes known to play a critical role include signal transduction pathways downstream of the mGluR and NMDARs, and activity-dependent changes in AMPAR content at synapses, mRNA transcription, and protein translation. GABAergic inhibition is involved in inducing the critical period of ocular dominance plasticity, and extracellular matrix factors and perineuronal nets surrounding inhibitory interneurons have been implicated in constraining plasticity. (See color plate 4.)

layers of cortex are driven by both eyes, though neurons in layer 4 of carnivores and primates are primarily driven by one eye (Hubel & Wiesel, 1963; Stryker & Harris, 1986). When an imbalance of input occurs after lid suturing one eye for several days (monocular deprivation, or MD), a series of structural and functional changes leads to the weakening of the deprived eye input and the strengthening of nondeprived eye input (figure 6.3B). The mechanisms underlying these changes (figure 6.3C) shed light on core principles of plasticity in the developing brain in response to experience. Before functional shifts are apparent, spine motility increases (Majewska & Sur, 2003; Oray, Majewska, & Sur, 2004), followed by transient pruning of spines (Mataga, Mizuguchi, & Hensch, 2004; Oray et al.). Electrophysiological and optical imaging techniques reveal that deprived-eye connections are weakened first, while supragranular horizontal connections are remodeled (Trachtenberg, Trepel, & Stryker, 2000; Trachtenberg & Stryker, 2001; W. Lee et al., 2006). Strengthening of nondeprived eye connections follows (Frenkel & Bear, 2004), and finally, layer IV geniculocortical axons representing the nondeprived eye grow and expand their terminals at the expense of shrinking deprived-eye terminals (Antonioni & Stryker, 1996; Antonioni, Fagiolini, & Stryker, 1999). The chronology of these events has been best characterized for the developmental “critical period” in mouse, though differences in structural and physiological response may exist for MD during adulthood or under different paradigms of development, such as dark rearing (Jiang, Treviño, & Kirkwood, 2007). The developmental context under which MD is applied can make a qualitative and quantitative difference in the ocular dominance plasticity observed and likely involves different cellular and network mechanisms.

CRITICAL PERIODS AND THE DEVELOPMENTAL CONTEXT OF PLASTICITY The ability to induce and reverse ocular dominance plasticity was initially thought to exist only during a “critical period” in development, a time approximately 10 days after eye opening during which short MD (a few days in the mouse) leads to a robust shift in ocular dominance toward the nondeprived eye (Hubel & Wiesel, 1970; Gordon & Stryker, 1996). This “critical period” is delayed by roughly three weeks in dark-reared animals (Cynader, Berman, & Hein, 1976; Fagiolini, Pizzorusso, Berardi, Domenici, & Maffei, 1994; G. Mower, 1991), suggesting that the cortex must reach a maturational state that is facilitated by a period of patterned vision. This maturational state has been shown to involve the development of an inhibitory network that depends on BDNF produced in response to neural drive (Hensch, 2005). Overexpression of BDNF leads to a precocious start of the critical period and premature development of inhibitory cells in the cortex (Huang et al., 1999; Hanover, Huang, Tonegawa, & Stryker, 1999), while

administration of BDNF to dark-reared animals leads to the induction of a critical period (Gianfranceschi et al., 2003). Mice lacking polysialic acid also experience premature maturation of inhibitory networks and a precocious critical period (Di Cristo et al., 2007). GAD65 knockout mice, which lack axonal GABA synthesis and subsequent inhibitory transmission, do not experience a critical period unless induced with benzodiazepine drug infusion at any age (Hensch et al., 1998; Fagiolini & Hensch, 2000). Therefore, tonic GABA release is sufficient to mature an intracortical inhibitory network and induce critical period plasticity. The process by which the critical period closes and why critical period induction is a one-time event are not understood.

Although the critical period occurs once during development, longer periods of MD (7 to 10 days in the mouse) are able to trigger ocular dominance plasticity in adulthood (Sawtell et al., 2003; Hofer, Mrsic-Flogel, Bonhoeffer, & Hübener, 2006; Fischer, Aleem, Zhou, & Pham, 2007). This form of plasticity is thought to differ mechanistically from that experienced during the critical period, as nondeprived-eye connections are strengthened more rapidly and deprived-eye connections remain stable (Kaneko, Stellwagen, Malenka, & Stryker, 2008). Previous experiences with MD, either in the critical period or in adulthood, facilitate plasticity in response to short MD later in life (Hofer et al.; Frenkel & Bear, 2004), suggesting that a functionally suppressed anatomical trace has been laid. Ocular dominance plasticity may also be induced in adulthood after a 10-day period of visual deprivation, and this process mimics the time course of plasticity present during the critical period (He, Hodos, & Quinlan, 2006; Frenkel & Bear, 2004). Therefore, even the apparent closure of critical period plasticity may be reactivated by a brief loss of visual input.

HEBBIAN AND HOMEOSTATIC MECHANISMS OF PLASTICITY Spike-timing-dependent activity has been demonstrated to lead to strengthening or weakening of geniculocortical and intracortical synapses in V1 (Frégnac & Shulz, 1999; Meliza & Dan, 2006). Long-term depression (LTD) of deprived-eye inputs occurs *in vivo* after MD and has been proposed to precipitate the eventual reduction in deprived-eye synapses (Heynen et al., 2003; Frenkel & Bear, 2004). Decreases in the threshold for LTD after dark rearing (as a result of decreases in NR2A/NR2B ratio of subunit composition in NMDA receptors) are posited to mediate the reactivation of plasticity (He et al., 2006). In hippocampal neurons, AMPA receptors are added to synapses during long-term potentiation (LTP) and removed during LTD (Manilow & Malenka, 2002), a mechanism that may act as the substrate for altering synaptic strength in visual cortex due to altered visual experience. Group I metabotropic glutamate receptors have been identified as inducers of LTD, and loss of mGlu5 blocks ocular dominance plasticity

(Dölen et al., 2007). Gene transcription and protein synthesis downstream of synaptic events is necessary for ocular dominance plasticity. Blocking cortical protein synthesis while preserving LTD effectively prevents ocular dominance shifts (Taha & Stryker, 2002). Loss of the cAMP responsive element, CREB, a protein that promotes CRE-mediated gene transcription, prevents ocular dominance shifts (A. Mower, Liao, Nestler, Neve, & Ramoa, 2002). Upstream Ca²⁺-sensitive signaling kinases, including ERK, PKA, and CamKII α , are also necessary for OD plasticity, and these likely activate a number of functional cascades that lead to gene transcription and structural modifications to the synapse (Di Cristo et al., 2001; Taha & Stryker, 2002; Berardi, Pizzorusso, Ratto, & Maffei, 2003; Suzuki, al-Noori, Butt, & Pham, 2004; Gomez, Alam, Smith, Horne, & Dell'Acqua, 2002; Chierzi, Ratto, Verma, & Fawcett 2005; Taha & Stryker, 2005). The extent to which LTD and LTP are necessary for ocular dominance shifts is uncertain, however. In mice lacking the protein phosphatase, calcineurin, LTD is blocked, but ocular dominance plasticity remains intact (Yang et al., 2005).

Although Hebbian mechanisms are likely to contribute to ocular dominance plasticity in which poorly driven synapses from the deprived eye are pruned and synapses from the nondeprived eye are strengthened (Katz & Shatz, 1996), additional cellular and network mechanisms likely affect the response of the cortex to MD. Homeostatic processes that work to preserve a certain level of cortical drive are known to operate in neuronal development (Turrigiano & Nelson, 2004) and may contribute to the ability of binocular neurons to undergo ocular dominance plasticity after deprivation (Desai, Cudmore, Nelson, & Turrigiano, 2002; Mrsic-Flogel et al., 2007). Nondeprived inputs strengthen only after deprived inputs are weakened (Frenkel & Bear, 2004), and pathways of synaptic scaling, the global (or cellwide) modulation of synapses, may be operating. TNF α , a glial secreted cytokine which acts as a positive scaling factor by increasing synaptic GluR1 and mEPSC amplitudes, is necessary for scaling up synaptic strength in vitro (Stellwagen, Beattie, Seo, & Malenka, 2005; Stellwagen & Malenka, 2006) and for the increase in amplitude of nondeprived inputs after MD (Kaneko et al., 2008). Arc, a negative scaling factor that increases AMPAR endocytosis (Chowdhury et al., 2006; Rial Verde, Lee-Osbourne, Worley, Malinow, & Cline, 2006), may also influence ocular dominance plasticity (McCurry, Tropea, Wang, & Sur, 2007).

Inhibitory networks may provide an additional circuit mechanism for modulating input strength during MD. Somatic inhibition on excitatory pyramidal cells would allow for instructive gating of precisely correlated inputs by preventing the backpropagation, as well as subsequent strengthening, of imprecisely timed inputs (Bi & Poo, 2001; Song, Miller, & Abbott, 2000; Pouille & Scanziani, 2001;

Hensch, 2005). Gap junctions between parvalbumin-expressing inhibitory cells would also allow for tightly coupled inputs to drive networks of inhibitory cells more strongly and facilitate discriminative responsiveness of pyramidal cells (Galarreta & Hestrin, 2001; Hensch, 2005). Endocannabinoid signaling on presynaptic terminals of layer 2/3 are necessary for plasticity, and these synapses may modulate the drive from the supragranular inhibitory network (C. Liu, Heynen, Shuler, & Bear, 2008).

STRUCTURAL PLASTICITY AND PERMISSIVE CHANGES IN EXTRACELLULAR MATRIX Increasing evidence supports the role of proteases and perineuronal nets (PNN) of extracellular matrix in regulating the ability of cortex to respond to MD. Degradation of chondroitin-sulfate proteoglycans (CSPGs) leads to the reactivation of ocular dominance plasticity in adult cortex (Pizzorusso et al., 2002, 2006). The protease tissue plasminogen activator (tPA), which cleaves extracellular matrix and other molecules, is expressed during juvenile MD and is necessary for functional plasticity in the adult (Mataga, Nagai, & Hensch, 2002; Müller & Greisinger, 1998). Application of tPA enhances spine motility, and loss of tPA prevents the loss of superficial spines after 4 days of MD (Oray et al., 2004; Mataga et al., 2004). Extracellular matrix could have a restrictive effect on ocular dominance plasticity by constraining spine motility and axonal growth or by imposing structurally mature functional elements onto intracortical inhibitory cells. Parvalbumin-expressing GABAergic cells become ensheathed in PNNs as the cortex matures (Härtig et al., 2001); degradation of PNNs may reduce the efficacy of inhibitory input by altering the ionic or chemical milieu and allow for plasticity. Mice lacking myelination factors Nogo-66 receptor and Nogo-A/B exhibit ocular dominance plasticity after brief MD in adulthood as well as a prolonged critical period (McGee, Yang, Fischer, Daw, & Strittmatter, 2005), suggesting that extracellular factors strongly constrain plasticity.

GENE SCREENS FOR NOVEL PLASTICITY FACTORS The use of gene microarrays to screen for differences in cortical gene expression under different conditions has facilitated the discovery of novel pathways and functional molecules involved in ocular dominance plasticity. A screen comparing the expression of normal and MD cortex at different ages revealed common and age-specific pathways modulated by MD (Madjan & Shatz, 2006). A comparison of V1 at different ages and with MD cortex showed an upregulation of actin-stabilizing genes, including the calcium sensor, cardiac troponin C, and myelinating factors, which were reversed with MD (Lyckman et al., 2008). Comparisons of dark-reared with normal V1 found a reduction in genes with a role in functional inhibition, reflecting a maturational delay,

while MD and normal V1 comparisons identified a number of growth factor and immunomodulatory factors that were upregulated in response to MD (Tropea et al., 2006).

Summary and conclusion

Retinotopic and feature selective maps constitute key organizational principles of the visual pathway. Intrinsic genetic programs and activity-dependent processes both play a role in setting up the structure and function of these maps. In addition, patterns of activity interact with programs of gene expression as they modulate signaling pathways within the cell. Understanding specific mechanisms of how visual stimulus feature maps are assembled and modified in response to experience is central to identifying fundamental processes of neural circuit development and plasticity.

7 Synaptic Plasticity and Spatial Representations in the Hippocampus

JONATHAN R. WHITLOCK AND EDVARD I. MOSER

ABSTRACT How does the brain acquire and remember new experiences? It is believed that synaptic plasticity, the process by which synaptic connections are strengthened or weakened, is a key mechanism for information storage in the central nervous system. Long-term potentiation (LTP), the long-lasting enhancement of excitatory synaptic transmission, and long-term depression (LTD), the persistent depression of synaptic responsiveness, are experimental models of synaptic plasticity thought to reveal how synapses are modified during learning. In this chapter we focus on the properties of LTP and LTD that make them attractive functional models for memory and review key findings from studies that demonstrate a link between LTP and behavior. We then discuss how synaptic modifications can affect spatial representations expressed by hippocampal place cells, which have been used as tools for understanding how synaptic changes are implemented in neural networks. We conclude the chapter by discussing how attractor states in neural networks can aid in the storage and recall of many representations involving more than just space, and how LTP may help fine-tune shifts between attractor states during behavior.

Synaptic modifications as a means for memory: The realization of an idea

The idea that memory traces are stored as changes in synaptic efficacy is anything but new. Since the late 19th century, when the Spanish neuroanatomist Santiago Ramón y Cajal first observed spinelike structures lining the dendrites of cortical pyramidal cells, the idea has existed that the connections between nerve cells provide an anatomical substrate for memory. This idea was formalized by Donald Hebb in his 1949 work *The Organization of Behavior*, in which he formulated his famous postulate that is still one of the most quoted phrases in neuroscience: “When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A’s efficiency, as one of the cells firing B, is increased” (Hebb, 1949). Hebb recognized

that there must be a mechanism by which a postsynaptic neuron (cell “B”) can stabilize its connections with a nearby presynaptic neuron (cell “A”) when it activates the postsynaptic cell strongly enough.

It was not until approximately 20 years after Hebb’s seminal work that the first efforts were made that would successfully demonstrate the physical reality of long-lasting, activity-dependent modifications at synapses. Prior to the discovery of *long-term potentiation* (LTP), researchers had sought and failed to elicit long-term synaptic modifications in spinal pathways, where the observed enhancements were very short-lived (Eccles & McIntyre, 1953), and in the neocortex, whose extensively intricate neuroanatomy proved too complex to isolate responses from single synapses. It was in the hippocampus, whose straightforward laminar architecture made easy the study of monosynaptic responses (figure 7.1A), where LTP was discovered by Terje Lømo and Tim Bliss (Bliss & Lømo, 1973). The initial characterization was made in the dentate gyrus, the first of the three major subfields in the trisynaptic circuit of the hippocampus (figure 7.1A). Bliss and Lømo used a stimulating electrode to deliver brief pulses of minute electrical current to the *perforant path* (PP, figure 7.1A), the largest direct input from the neocortex to the hippocampus. A recording electrode was placed in the dentate gyrus (DG), the subregion of the hippocampus that receives the largest perforant path input, to record *field excitatory postsynaptic potentials* (fEPSPs) evoked in response to electrical stimulation. A fEPSP is a transient voltage deflection recorded at the tip of an extracellular recording electrode when ions flow into or out of the dendrites of large populations of cells (see traces at top of figure 7.1B; the responses are negative-going in this case because positive current is flowing away from the electrode). It was found that the amplitude of dentate fEPSPs, taken as a measure of synaptic strength, showed substantial increases lasting for several hours in response to brief (10-second) episodes of tetanic (15 Hz) stimulation applied to the perforant path, and that the enhancements were only expressed in the pathways that received the tetanus (figure 7.1B). The fact that a brief stimulus could induce changes that were (1) long lasting and (2) input specific in a structure that was known to be involved in memory formation (Scoville & Milner, 1957) immediately

JONATHAN R. WHITLOCK and EDVARD I. MOSER Kavli Institute for Systems Neuroscience and Centre for the Biology of Memory, Norwegian University of Science and Technology, Trondheim, Norway

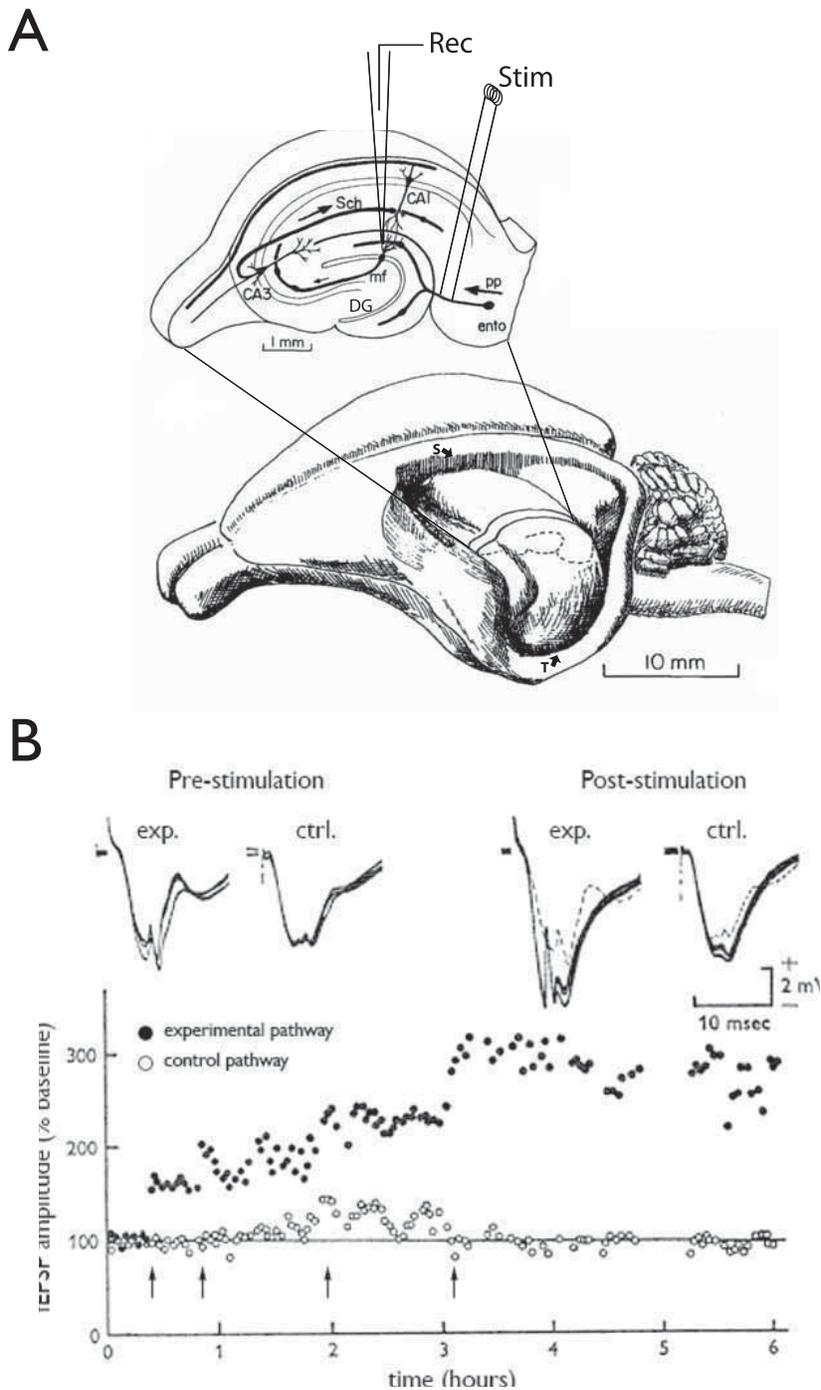

FIGURE 7.1 Anatomy of the hippocampal formation and a demonstration of hippocampal LTP. (A) A drawing of the rabbit brain (below) demonstrating the location of the hippocampus, oriented so that the anterior is facing left, and posterior is facing right. The long axis of the hippocampus extends from the septum (S) to the temporal cortex (T). Shown above is an enlarged cross section of the hippocampus detailing the trisynaptic connectivity between the different subregions and the placement of stimulating (Stim) and recording (Rec) electrodes by Bliss and Lomo. Abbreviations: ento, entorhinal cortex; pp, perforant path; DG, dentate gyrus; mf, mossy fiber pathway; CA3, CA1, cornu ammonis fields of the hippocampus; Sch, Schaffer collateral pathway. (Modified with kind permission of Springer Science+Business Media and from P. Andersen et al., Lamellar organization of hippocampal excit-

atory pathways, *Experimental Brain Research*, 13, 222–238, © 1971.) (B) Example of an LTP experiment in the anaesthetized rabbit in which fEPSP amplitude served as the measure of synaptic strength (traces shown at top). The responses were obtained (left) before conditioning and (right) 2.5 hr after the 4th stimulating train. On the graph (below), fEPSP response amplitude is plotted on the y-axis; values are expressed as a percentage of the prestimulation baseline; enhancements were specific to the pathway that received the conditioning stimulation (“experimental pathway,” black dots). Arrows indicate time of tetanization. (Modified with permission from T. Bliss & T. Lomo, Long-lasting potentiation of synaptic transmission in the dentate area of the anaesthetized rabbit following stimulation of the perforant path. *Journal of Physiology*, 232[2], 331–356, © 1973, Blackwell Publishing.)

suggested LTP as a possible model for understanding memory at the neural level.

Some years after the discovery of LTP, other labs managed to reproduce the effect, and LTP was reliably induced in hippocampal slices (Andersen, Sundberg, Sveen, & Wigstrom, 1977), paving the way for detailed studies of the underlying cellular mechanisms. Long-term potentiation was found to exist in a number of forms and in a number of brain areas, and the complementary phenomenon of *long-term depression* (LTD) was discovered. Input-specific LTD was first characterized in area CA1 of the hippocampus, where it was found that longer (15-minute) periods of more modest stimulation (1 Hz) produced a long-lasting, nonpathological decrease in the slope of fEPSPs (Dudek & Bear, 1992; Mulkey & Malenka, 1992). The possible involvement of LTP and LTD in memory formation has made *synaptic plasticity* one of the most studied phenomena in the brain, with thousands of studies over the years aimed at elucidating the cellular mechanisms for the induction, expression, and maintenance of LTP and LTD.

LTP and LTD: A short overview of cellular mechanisms

Because of its anatomical simplicity and accessibility, the vast majority of studies exploring the biological mechanisms of LTP and LTD have been performed in the hippocampus, particularly at the synapses where axons from cornu ammonis 3 (CA3) pyramidal cells contact the dendrites of pyramidal cells in CA1 via the Schaffer collateral pathway (figure 7.1A). In these experiments, commonly performed in hippocampal slices, Schaffer collaterals are stimulated and fEPSPs are recorded from the apical dendrites of CA1 pyramidal cells. A common protocol for inducing LTP in CA1 is the application of multiple trains of high-frequency stimulation (HFS), typically 100 Hz, while low-frequency stimulation (LFS), consisting of 1 Hz stimulation, is commonly used to elicit NMDA receptor-dependent LTD. The existing data suggest that many of the properties of Schaffer collateral-CA1 synapses are common to synapses throughout the neocortex, so in the following paragraphs we will describe the mechanisms for the best characterized and most common forms of LTP and LTD at synapses in area CA1.

The key requirement for Hebb-like synaptic modifications is the *coincident* activation of pre- and postsynaptic neurons; that is, cells must fire together to wire together. How, then, does one cell know when another cell is driving it to fire? Fast excitatory synaptic transmission at Schaffer collateral-CA1 synapses, along with most synapses in the central nervous system, is mediated primarily by glutamate-gated ion channels (i.e., glutamate receptors) embedded in the postsynaptic cell membrane. Glutamate receptors

contribute to the fast excitatory postsynaptic response by allowing positively charged ions to flow into the postsynaptic compartment upon binding glutamate. Different classes of receptors are named for their most potent chemical agonists; in this chapter we will focus on AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazole propionate) receptors and NMDA (*N*-methyl-D-aspartate) receptors (figure 7.2A). In the mature brain, AMPA receptors primarily conduct Na^+ ions and mediate the initial and largest component of fEPSPs, while NMDA receptors have the unique property of allowing Ca^{2+} to flow into the postsynaptic cell in addition to Na^+ . The contribution of NMDA receptors to basal synaptic transmission is highly variable because, under resting physiological conditions, their ion pores are blocked by Mg^{2+} ions which prevent current flow. However, during periods of heightened stimulation, the amount of positive charge flowing in through AMPA receptors depolarizes the postsynaptic spine sufficiently to remove the Mg^{2+} block and allow Ca^{2+} to enter the postsynaptic terminal through the NMDA receptor (middle panel, figure 7.2A) (Mayer, Westbrook, & Guthrie, 1984; Nowak, Bregestovski, Ascher, Herbet, & Prochiantz, 1984). The NMDA receptor thus satisfies the requirement of Hebb's coincidence detector, with its activation requiring *concurrent* presynaptic glutamate release and postsynaptic depolarization. The amount of Ca^{2+} passing through the NMDA receptor varies depending on the magnitude of pre- and postsynaptic coactivation and ultimately determines whether synaptic connections will be strengthened or weakened (Cummings, Mulkey, Nicoll, & Malenka, 1996; for review, see Lisman, 1985; Madison, Malenka, & Nicoll, 1991; Malenka & Nicoll, 1999). The most commonly studied forms of LTP and LTD are NMDA receptor dependent.

What are the physical and chemical changes that bring about the strengthening and weakening of synapses? The induction of LTP requires large influxes of Ca^{2+} in the postsynaptic terminal that trigger the activation of *protein kinases*, enzymes that add a phosphate group to specific proteins and modify their function, and whose enzymatic activity can long outlast the changes in Ca^{2+} concentration that triggered them (figure 7.2A right panel, figure 7.2B). The phosphorylation of synaptic and structural substrates, such as AMPA receptors and synaptic scaffolding proteins, plays a critical role in the induction and expression of LTP (see Browning, Huganir, & Greengard, 1985; Soderling & Derkach, 2000, for review). In addition to the phosphorylation of AMPA receptors already at synapses, new AMPA receptors are also inserted in the postsynaptic membrane (figure 7.2A, right panel) (Hayashi et al., 2000; Heynen, Quinlan, Bae, & Bear, 2000; Shi et al., 1999; see Malinow, Mainen, & Hayashi, 2000, for review), leading to larger amplitude fEPSPs with faster onsets, while on the presynaptic side more glutamate is released

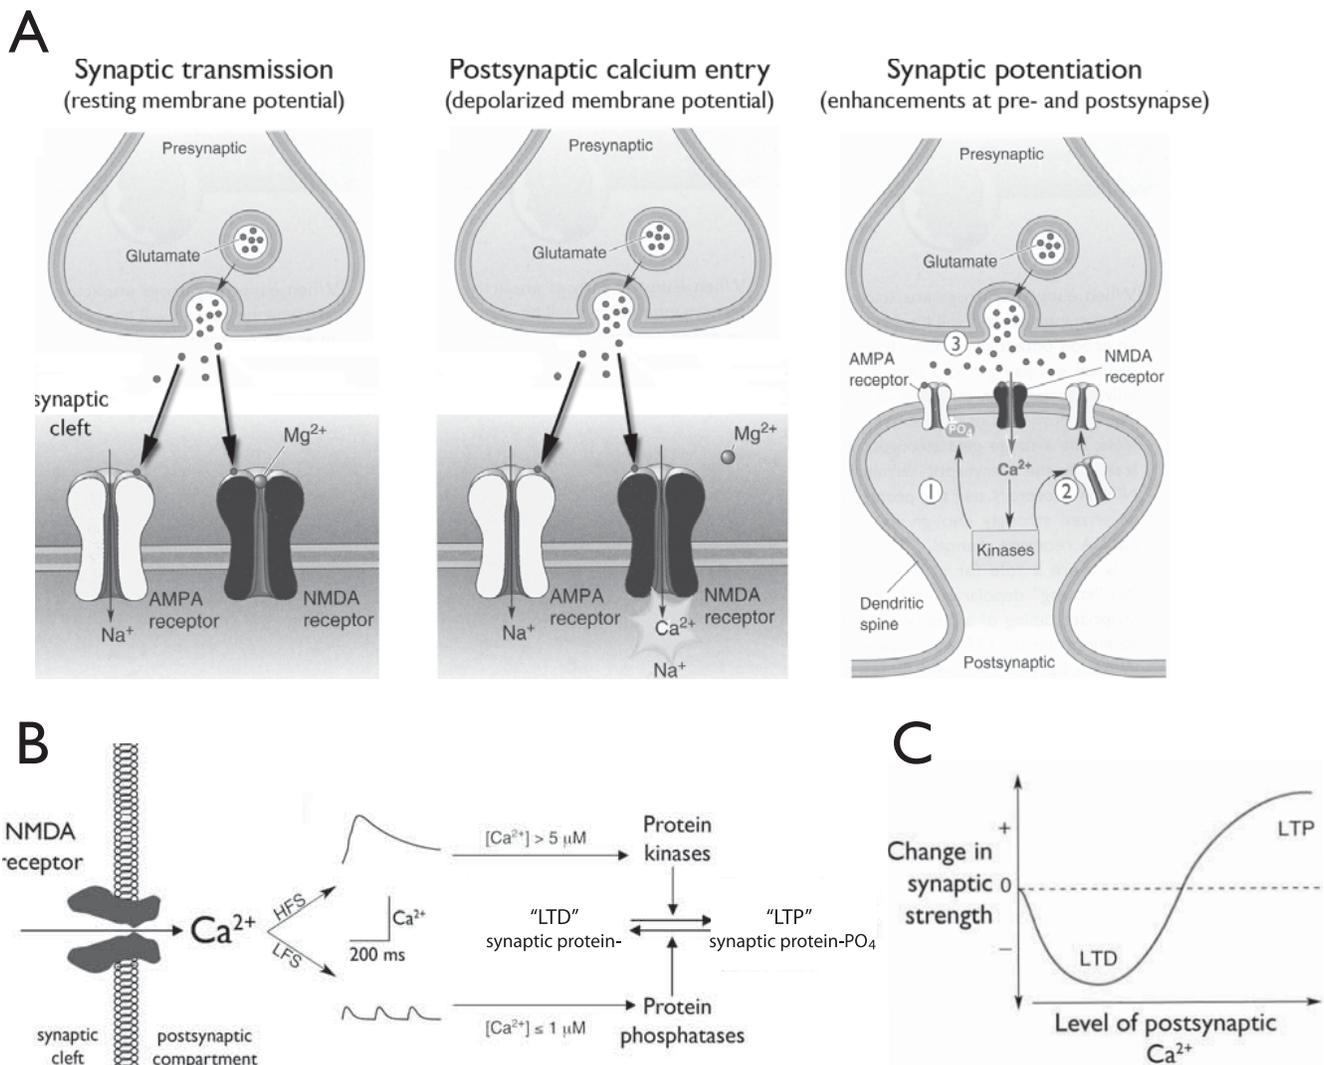

FIGURE 7.2 Postsynaptic calcium entry is the key for inducing LTP and LTD. (A) The NMDA receptor is activated by coincident pre- and postsynaptic activity. (left) During synaptic transmission, glutamate is released into the synaptic cleft and acts on AMPA and NMDA receptors, though NMDA receptors are blocked by Mg^{2+} ions at negative (resting) membrane potentials; (middle) if glutamate release coincides with sufficient postsynaptic depolarization, the Mg^{2+} block is removed and Ca^{2+} enters the postsynaptic neuron through NMDA receptors; (right) postsynaptic kinases initiate synaptic potentiation by (1) phosphorylating AMPA receptors already at the synapse, and (2) driving additional AMPA receptors.

Glutamate release into the synaptic cleft (3) is also enhanced. (B) A large, brief increase in postsynaptic calcium, induced here by high-frequency stimulation (HFS), favors the activation of protein kinases and results in LTP, while small, sustained Ca^{2+} elevations during low-frequency stimulation (LFS) favor the activation of protein phosphatases, resulting in the dephosphorylation of synaptic proteins and LTD. (C) Long-term changes in synaptic strength can be explained as a function of the amount of calcium flowing into the postsynaptic neuron via NMDA receptors. (Modified with permission from M. Bear, B. Connors, & M. Paradiso, *Neuroscience: Exploring the brain*, 3rd edition, © 2007, Lippincott Williams & Wilkins.)

into the synaptic cleft (Bliss, Errington, & Lynch, 1990; Bliss, Errington, Lynch, & Williams, 1990; Dolphin, Errington, & Bliss, 1982). Structural changes, such as the growth of new spines and the enlargement or splitting of synapses in two, have also been observed following LTP induction (Abraham & Williams, 2003; Chen, Rex, Casale, Gall, & Lynch, 2007; Nagerl, Eberhorn, Cambridge, & Bonhoeffer, 2004; see Yuste & Bonhoeffer, 2001, for review). LTP lasting several hours or days (sometimes referred to as L-LTP) requires the synthesis of new proteins, and will gradually decay back to

baseline if protein synthesis inhibitors are applied within the first couple of hours following conditioning stimulation (Frey, Krug, Reymann, & Matthies, 1988; Krug, Lossner, & Ott, 1984; Stanton & Sarvey, 1984; see Kelleher, Govindarajan, & Tonegawa, 2004, for review).

In the case of LTD, small increases in Ca^{2+} arising from weak synaptic stimulation favor the activation of *protein phosphatases* that dephosphorylate synaptic proteins including glutamate receptors (figure 7.2B) (Mulkey, Endo, Shenolikar, & Malenka, 1994; Mulkey, Herron, & Malenka,

1993). Contrary to LTP, LTD results in the removal and eventual degradation of AMPA receptors, NMDA receptors, and structural synaptic proteins (Ehlers, 2000; Heynen et al., 2000; Colledge et al., 2003), as well as the retraction of existing spines (Nagerl et al., 2004; Zhou, Homma, & Poo, 2004). Despite the fact that LTD involves the destruction of some preexisting proteins, long-lasting LTD (i.e., L-LTD), like L-LTP, also depends on the synthesis of new proteins—in fact, recent experiments have shown that proteins synthesized in response to L-LTP induction at one set of synapses can also be used to sustain L-LTD at nearby synapses on the same cell (Sajikumar & Frey, 2004). For a lengthier description of the mechanisms of LTP and LTD we recommend reviews by Bliss and Collingridge (1993), Malenka and Bear (2004), and Malinow and Malenka (2002).

Properties of LTP and LTD that are relevant for memory formation

Many of the physiological properties of LTP and LTD are homologous to the characteristics of behavioral memory expressed at the level of the whole animal, such as rapid induction (enabling fast learning) and longevity (allowing some memories to last a lifetime). While LTP and LTD are generally accepted as the leading cellular mechanisms for learning and memory, it should be noted that certain aspects of memory do not necessarily translate directly from changes at synapses, but more likely emerge at the level of the neural network in which the synaptic modifications are embedded (Hebb, 1949; Marr, 1971). The functional features exhibited by LTP and LTD are exactly the type that would be useful in enabling neural networks to rapidly acquire and store large amounts of information during behavior.

First, induction is rapid and long lasting. Changes in synaptic strength can be induced following very brief trains of high-frequency stimulation (Douglas & Goddard, 1975), and the resulting potentiation can last anywhere from several minutes to perhaps the entire lifetime of an animal (Abraham, Logan, Greenwood, & Dragunow, 2002; Barnes, 1979). These properties allow information learned from very brief episodes to be remembered for a lifetime, such as to not stick one's finger in a light socket.

Second, LTP provides a cellular mechanism for association of inputs to different synapses of a cell. This is indirectly apparent from the fact that the probability of inducing LTP increases with the number of stimulated afferents, a phenomenon referred to as *cooperativity* (McNaughton, Douglas, & Goddard, 1978). Weak stimulation will only affect a small proportion of synapses and is less likely to induce a postsynaptic change, whereas a strong stimulus will affect more synapses and increase the likelihood of inducing a long-lasting change in the postsynaptic response (figure 7.3, left). Transiently increasing the stimulation intensity during the delivery of a tetanus will lead to the recruitment of additional afferents and cause potentiation of synapses that would not have been coactivated during a weaker stimulation. In this sense, “cooperativity” is a form of associative synaptic potentiation (discussed in the next paragraph).

A more direct illustration of *associativity* involves the observation that when both weak and strong inputs are stimulated together, the weak input will show LTP, whereas if the weak input is stimulated alone, no LTP will be seen (figure 7.3, middle) (Barrionuevo & Brown, 1983; Levy & Steward, 1979). Associativity is relevant to learning and memory because it allows neurons to associate arbitrary patterns of activity from distinct neural pathways that may relay information regarding distinct but related events. This

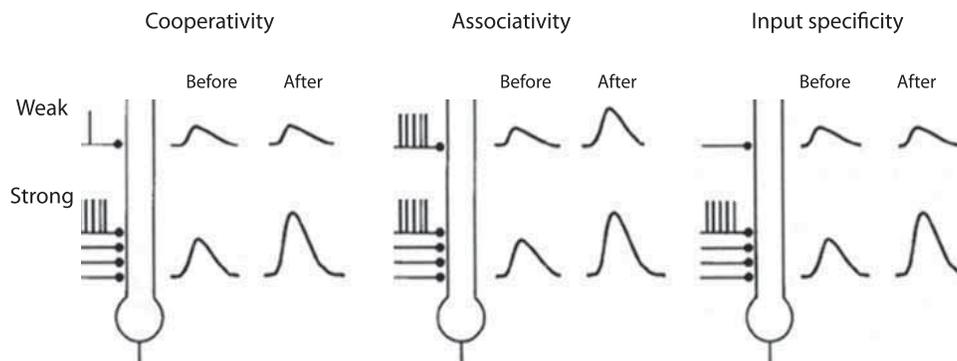

FIGURE 7.3 LTP exhibits physiological properties that make it a tenable cellular substrate for memory. Cooperativity (*left*) describes the property whereby a weak tetanus that activates relatively few afferents will not induce a change in the synaptic response, whereas coactivating many inputs with sufficiently strong stimulation will induce a change. Associativity (*middle*) describes the property whereby the concurrent simulation of weak and strong convergent

pathways results in the long-term strengthening of the weak pathway. (*right*) LTP is input specific because only those synapses active at the time of the tetanus express potentiation; inactive inputs do not share in the potentiation. Cooperativity, associativity, and input specificity apply similarly to LTD. (Modified with permission from R. Nicoll, J. Kauer, & R. Malenka, The current excitement in long-term potentiation, *Neuron*, 1, 97–103, © 1988, Cell Press.)

phenomenon is epitomized by recent experiments showing that two populations of synapses given either weak or strong stimulation both express a biochemical “plasticity tag” that allows them to capture “plasticity-related proteins” synthesized specifically in response to the strong stimulation (Frey & Morris, 1997). This process, known as *synaptic tagging*, allows weakly stimulated synapses to sequester and utilize the same proteins as strongly stimulated synapses and express long-lasting LTP as though they had received strong stimulation.

The property of NMDA receptor-dependent LTP and LTD perhaps most relevant to memory formation is input specificity, where only the synaptic pathways that receive conditioning stimulation show a change in synaptic strength; other synapses on the same postsynaptic cell that do not receive stimulation do not express plasticity (figure 7.3, right) (Andersen et al., 1977; Bliss & Lømo, 1973; Dudek & Bear, 1992). This property is relevant to learning and memory for two reasons: (1) because it ensures that only the particular synapses that were activated by an experience will store information relevant to that experience (of what use is LTP as a memory mechanism if one event results in the nonspecific potentiation of all the synapses in your brain?), and (2) because the information storage capacity of a neuron is much greater when information is encoded at individual synapses rather than as a change in a property of the entire cell (such as whole-cell excitability).

Studies of LTP and LTD in behaving animals

The functional properties of LTP and LTD are suggestive of an involvement in memory processes, but how can this be tested in behaving animals? Over the years, researchers have proposed different strategies for testing a necessary and sufficient role for synaptic modification in behavioral learning (Martin, Grimwood, & Morris, 2000; Neves, Cooke, & Bliss, 2008; Stevens, 1998). *Anterograde alteration* and *retrograde alteration* approaches, historically the most common, seek to describe correlations between synaptic plasticity and behavioral memory by manipulating various mechanisms of LTP or LTD before or after learning and characterizing the ensuing changes in learning or memory maintenance; the goal of the *detection* strategy is to determine whether LTP- or LTD-like changes are induced naturally as a consequence of learning; and *mimicry*, the most technically challenging and hitherto unrealized approach, would seek to engineer a memory of an experience that never actually occurred by tweaking just the relevant synaptic weights (Neves et al., 2008). Successfully installing an “artificial” memory in this manner would provide the ultimate proof that changes in synaptic weight are sufficient for memory storage, but because this has not yet happened we shall focus instead on the first three strategies.

ANTEROGRADE ALTERATION Studies in recent years have demonstrated unequivocally that many of the mechanisms necessary for the induction and maintenance of LTP are also necessary for the acquisition and maintenance of memory (though there are arguments rebutting the notion that LTP is involved in memory; see Shors & Matzel, 1997, for review). The basic assumption of the anterograde alteration strategy holds that, if learning new information requires the induction of LTP, then blocking LTP prior to learning should prevent memory formation. One of the first pharmacological studies linking LTP induction to spatial learning involved infusing the selective NMDA receptor antagonist APV into the lateral ventricles of rats prior to learning the *Morris water maze* task, in which animals learn to swim through opaque water to find a submerged escape platform using visual cues outside the water tank as guides (figure 7.4A) (Morris, Anderson, Lynch, & Baudry, 1986). At first the animals swim randomly through the maze until they happen to find the platform, but they eventually learn to swim directly to the correct location. In the study by Morris and colleagues, rats treated with a dose of APV sufficient to block LTP induction in vivo were impaired at learning the water maze task and showed no preference for the target quadrant after the platform was removed, whereas animals treated with the inactive isoform of the drug performed the same as saline-treated controls (figure 7.4B). Furthermore, subsequent work showed that the extent of the spatial learning deficit correlated with the degree of LTP impairment as the dose of APV was increased (Butcher, Davis, & Morris, 1990). Some criticisms raised against these pharmacological studies, however, were that APV infusions caused sensory and motor deficits unrelated to learning (Abraham & Kairiss, 1988; Caramanos & Shapiro, 1994; Shors & Matzel, 1997) and that animals given pretraining in different mazes were able to learn new platform locations even when NMDA receptors were blocked (Bannerman, Good, Butcher, Ramsay, & Morris, 1995; Saucier & Cain, 1995). These concerns were addressed by a follow-up study demonstrating that direct hippocampal infusions of APV caused a delay-dependent impairment in rapidly acquired spatial learning that could not be explained by interference from drug side effects (Steele & Morris, 1999).

An essential role for NMDA receptor-dependent synaptic plasticity in spatial memory was further demonstrated through the use of mice with a regionally restricted, postnatal genetic deletion of the obligatory NMDA receptor subunit NR1 (Tsien, Huerta, & Tonegawa, 1996). This study represented an important technological advance over previous studies using knockout mice because the spatial and temporal restrictions of the genetic deletion ruled out compensatory side effects during development as a possible explanation for any learning deficits. It was found that deleting the NR1 gene exclusively in CA1 pyramidal cells led to the specific

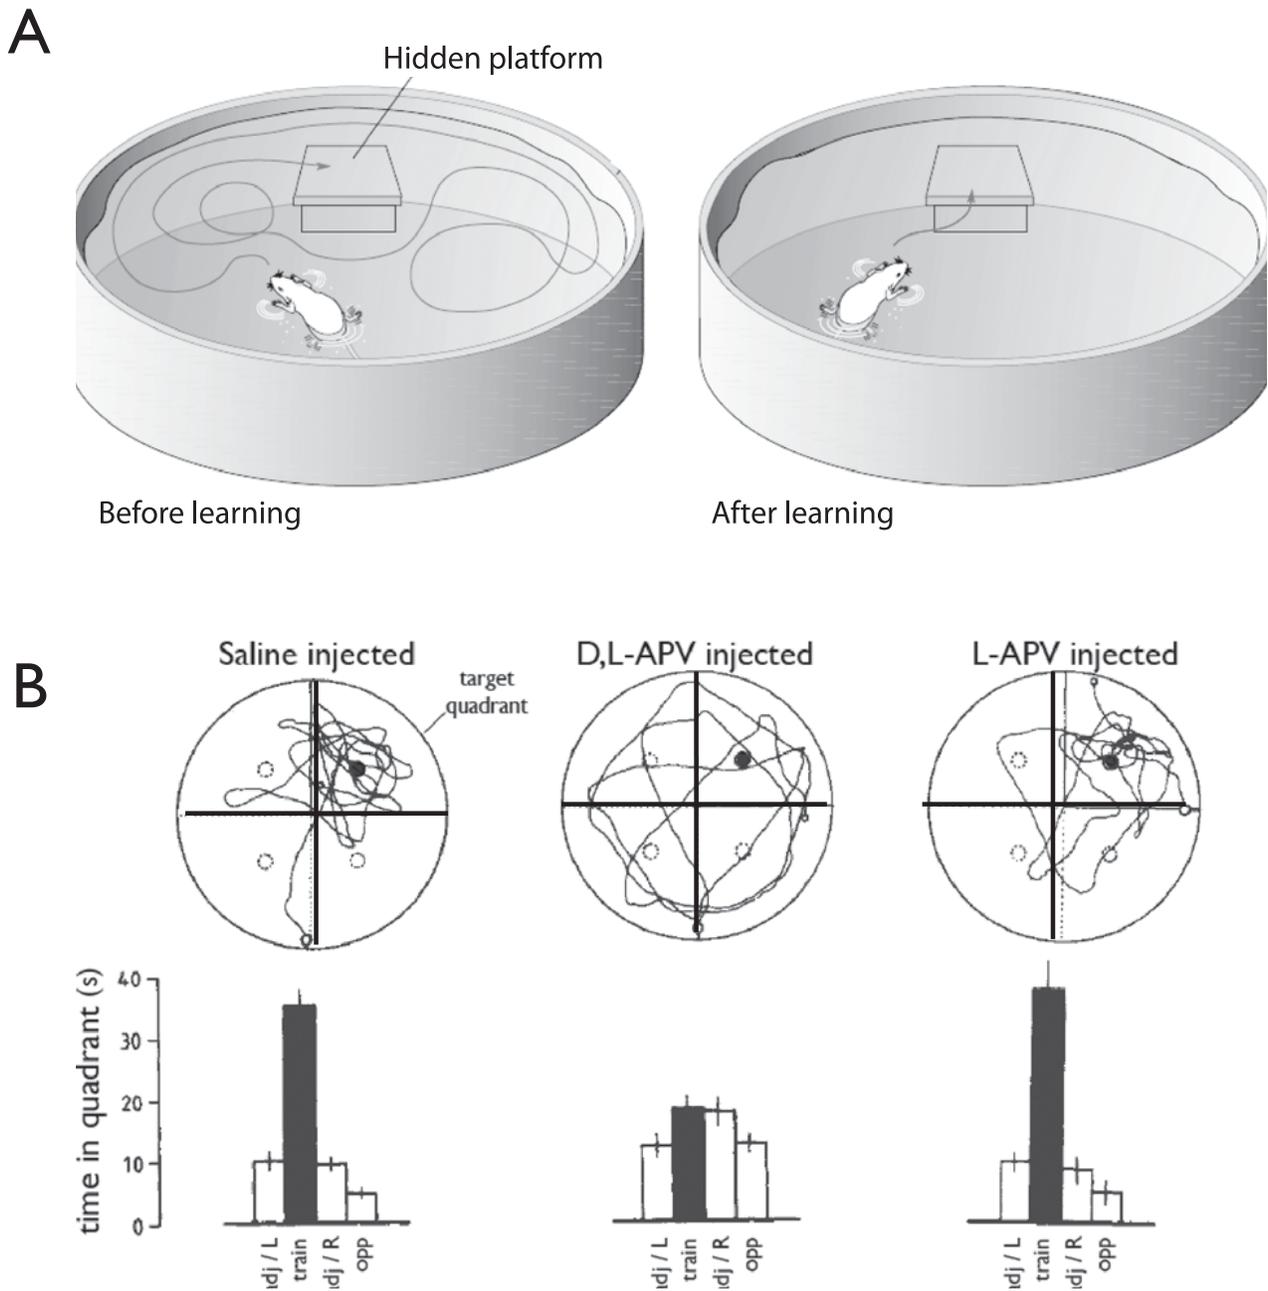

FIGURE 7.4 The Morris water maze is one of the most common behavioral tests of spatial learning and memory. (A) In the task, an animal is placed in a pool filled with opaque water and must locate a submerged escape platform. At the start of training the animal's swim path is typically long and circuitous. After several training trials the rat learns the platform location and will swim straight to it during a test trial. (Modified with permission from M. Bear, B. Connors, & M. Paradiso, *Neuroscience: Exploring the brain*, 3rd edition, © 2007, Lippincott Williams & Wilkins.) (B) Shown at top are the swim trajectories of animals tested in the Morris water maze after having been given different drug treatments prior to training.

Animals injected with saline (left) spent the greatest amount of time in the target quadrant (which earlier had the escape platform), whereas animals treated with the NMDA receptor antagonist D,L-APV (middle) showed no preference for the target quadrant. Animals injected with the inactive L-isomer of APV (right) showed normal spatial memory similar to the saline-injected group. (Modified with permission from Morris, Anderson, Lynch, & Baudry, Selective impairment of learning and blockade of long-term potentiation by an *N*-methyl-D-aspartate receptor antagonist, AP5, *Nature*, 319, 774–776, © 1986, Nature [Nature Publishing Group].)

ablation of LTP in CA1, while LTP in the dentate gyrus was unaffected. Furthermore, CA1-knockout mice showed no place preference for the target quadrant in the test phase of the Morris water maze task. Subsequent studies have refined the temporal resolution of genetic manipulations even more through the use of genetically modified transcription factors that can be reversibly activated or inactivated over the course of a few days by interacting with innocuous drugs administered in the animals' food (Mansuy et al., 1998; Mayford & Kandel, 1999).

NMDA receptor activation is also necessary for the acquisition of associative Pavlovian learning tasks, such as contextual fear conditioning, where animals learn to associate a particular context with a foot shock, and cued fear conditioning, in which animals learn that the presentation of an auditory tone predicts an imminent foot shock (see Maren, 2001, for review). Similarly, inhibitory avoidance training, a single-trial learning paradigm in which animals learn to avoid the shock-associated compartment of a conditioning apparatus, depends on NMDA receptor activation (Izquierdo et al., 1992; Jerusalinsky et al., 1992). A totally different approach to assess the role of LTP in learning and memory is to drive LTP in a hippocampal pathway to saturation prior to learning (McNaughton, Barnes, Rao, Baldwin, & Rasmussen, 1986; Moser, Krobot, Moser, & Morris, 1998). The hypothesis is that, if information is stored as increases in synaptic weights, then saturating LTP at hippocampal synapses should impair subsequent learning. To achieve this purpose, the investigators implanted multiple stimulating electrodes into the perforant path and applied several trains of HFS to drive LTP in the dentate gyrus to asymptote. Animals in which LTP was truly saturated were impaired at learning the Morris water maze, whereas other animals in which as little as 10% residual LTP could be induced were able to learn normally (Moser et al.). This observation suggests that even a very small capacity for LTP is sufficient for the hippocampus to store spatial information.

RETROGRADE ALTERATION Another strategy for assessing the involvement of LTP in memory is to compromise the expression or maintenance of LTP after learning. This strategy is predicated on the assumption that, if information is stored as distributed modifications in synaptic connections, then memory should be susceptible to disruption by manipulations that alter or erase the pattern of synaptic weights (figure 7.5A). A successful example comes from a follow-up study to the 1998 work by Moser and colleagues, where the approach was to induce LTP in the dentate gyrus *after* animals were trained in the Morris water maze to compromise the learning-induced pattern of synaptic weights (Brun, Ytterbo, Morris, Moser, & Moser, 2001). Indeed, posttraining LTP induction impaired the rats' memory of the platform location. A separate group of animals given an

NMDA receptor antagonist after learning but before LTP induction expressed normal spatial memory, suggesting that the memory impairments were generated specifically as a consequence of the artificial manipulation of synaptic weights.

In addition to the electrophysiological approach, researchers have used pharmacological agents to block specific kinases necessary for LTP induction and maintenance to disrupt memory. For example, infusing inhibitors of calcium/calmodulin-dependent kinase II (CaMKII) or protein kinase C (PKC), enzymes critical for the establishment of LTP, into the hippocampus of rats soon after inhibitory avoidance training was found to cause full retrograde amnesia in animals tested 24 hours later (Paratcha et al., 2000; Wolfman et al., 1994). It is not known whether the amnesia was caused by a reversal of LTP in these studies, but more recent work has reported a parallel erasure of LTP and hippocampus-dependent spatial memory. Pastalkova and colleagues infused an inhibitor of the zeta isoform of protein kinase M (PKM ζ), an enzyme whose constitutive activity is necessary for the maintenance of long-term hippocampal LTP *in vivo* (figure 7.5B) (Pastalkova et al., 2006). The fact that the drug simply reversed preexisting LTP without apparently affecting synaptic transmission or subsequent LTP induction in any other way made it ideal for testing the importance of LTP in long-term memory maintenance. In the study, rats learned to associate a particular area on a rotating platform with a mild foot shock, and acquired a robust avoidance response after just a few training trials. Infusing the PKM ζ inhibitor into the hippocampus 24 hours after training eradicated the avoidance response (figure 7.5C), and, shockingly, had the same effect when rats were treated *1 month* after learning. The results challenged the view that protein kinases play only a time-limited role in LTP and memory formation, and that lifelong memories are eventually stored independently of the hippocampus.

DETECTION Before it can be accepted that learning and LTP modify synapses in the same way, it must be demonstrated that learning causes detectable changes in synaptic strength that (1) resemble and (2) occlude LTP. There are a growing number of studies which report learning-related enhancements in synaptic responses in areas of the brain appropriate to the type of information learned. We will briefly elaborate on a few of the studies demonstrating long-lasting synaptic modifications occurring as a result of learning.

Some of the clearest electrophysiological evidence linking neocortical LTP and learning has come from studies using skill learning in rats, where the animals were trained to reach through a small window and retrieve a food pellet with their forepaw. When recordings were later conducted on brain slices prepared from trained animals, it was found that fEPSPs

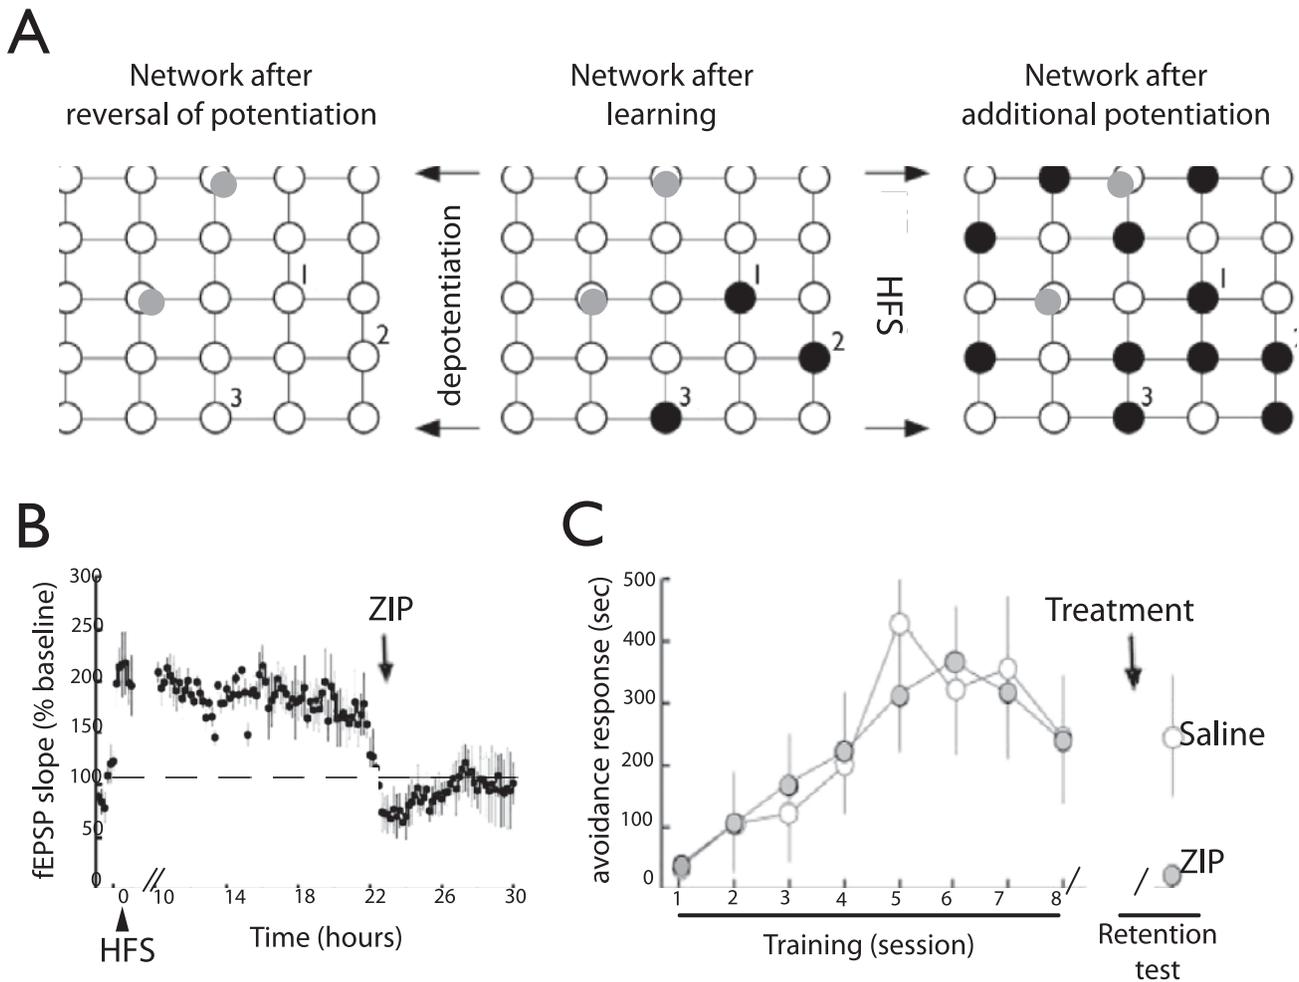

FIGURE 7.5 Disrupting the pattern of synaptic weights in a network results in a loss of the information stored across the synapses. (A) A hypothetical distribution of synaptic enhancements induced in a network by learning; lines are neuronal processes which intersect at synapses represented as circles; black circles are synapses potentiated by recent learning, gray circles are synapses already potentiated from an unrelated event; white circles are unpotentiated synapses. (top right) Randomly potentiating irrelevant synapses with high-frequency stimulation (HFS) after learning scrambles the pattern of learning-induced synaptic weights and disrupts memory storage; this is the experimental strategy used by Brun, Ytterbo, Morris, Moser, and Moser (2001). (top left) The reversal of learning-related synaptic enhancements should erase the information stored across the connections and cause retrograde

amnesia. (Modified with permission from Brun et al., Retrograde amnesia for spatial memory induced by NMDA receptor-mediated long-term potentiation, *Journal of Neuroscience*, 21(1), 356–362, © 2001, Society for Neuroscience.) (B) Robust LTP induced in the dentate gyrus in vivo can be rapidly reversed 22 hours later by intrahippocampal infusion of the selective PKM ζ antagonist “zeta inhibitory peptide,” or ZIP. (C) In parallel with the reversal of LTP, intrahippocampal infusions of ZIP caused abrupt and complete amnesia in a place-avoidance task in rats tested either 24 hours or 1 month after training. The avoidance memory of saline-infused animals remained intact. (Modified with permission from Pastalkova et al., Storage of spatial information by the maintenance mechanism of LTP, *Science*, 313, 1141–1144, © 2006, American Association for the Advancement of Science.)

in the primary motor cortex (M1) corresponding to the preferred reaching paw were substantially larger than fEPSPs from the hemisphere for the untrained paw (i.e., the “untrained” hemisphere) (figure 7.6A) (Rioult-Pedotti, Friedman, Hess, & Donoghue, 1998). Follow-up studies investigated the impact of skill learning on subsequent LTP and LTD and revealed a marked reduction in the amount of LTP and an enhancement in the magnitude of LTD in the “trained” portion of cortex (figure 7.6B) (Monfils & Teskey, 2004; Rioult-Pedotti, Friedman, & Donoghue, 2000), sug-

gesting that learning had elevated the synapses in motor cortex closer to their ceiling for LTP expression and, concurrently, left more space for synaptic depression. The partial reduction, or “occlusion,” of LTP by learning suggests that skill learning and LTP engage a common neural mechanism. More recent work has shown that the synaptic modification range shifts upward to accommodate the synaptic enhancements a few weeks after learning, thereby restoring the capacity of the connections to express their previous levels of LTP and LTD (Rioult-Pedotti, Donoghue, & Dunaevsky, 2007).

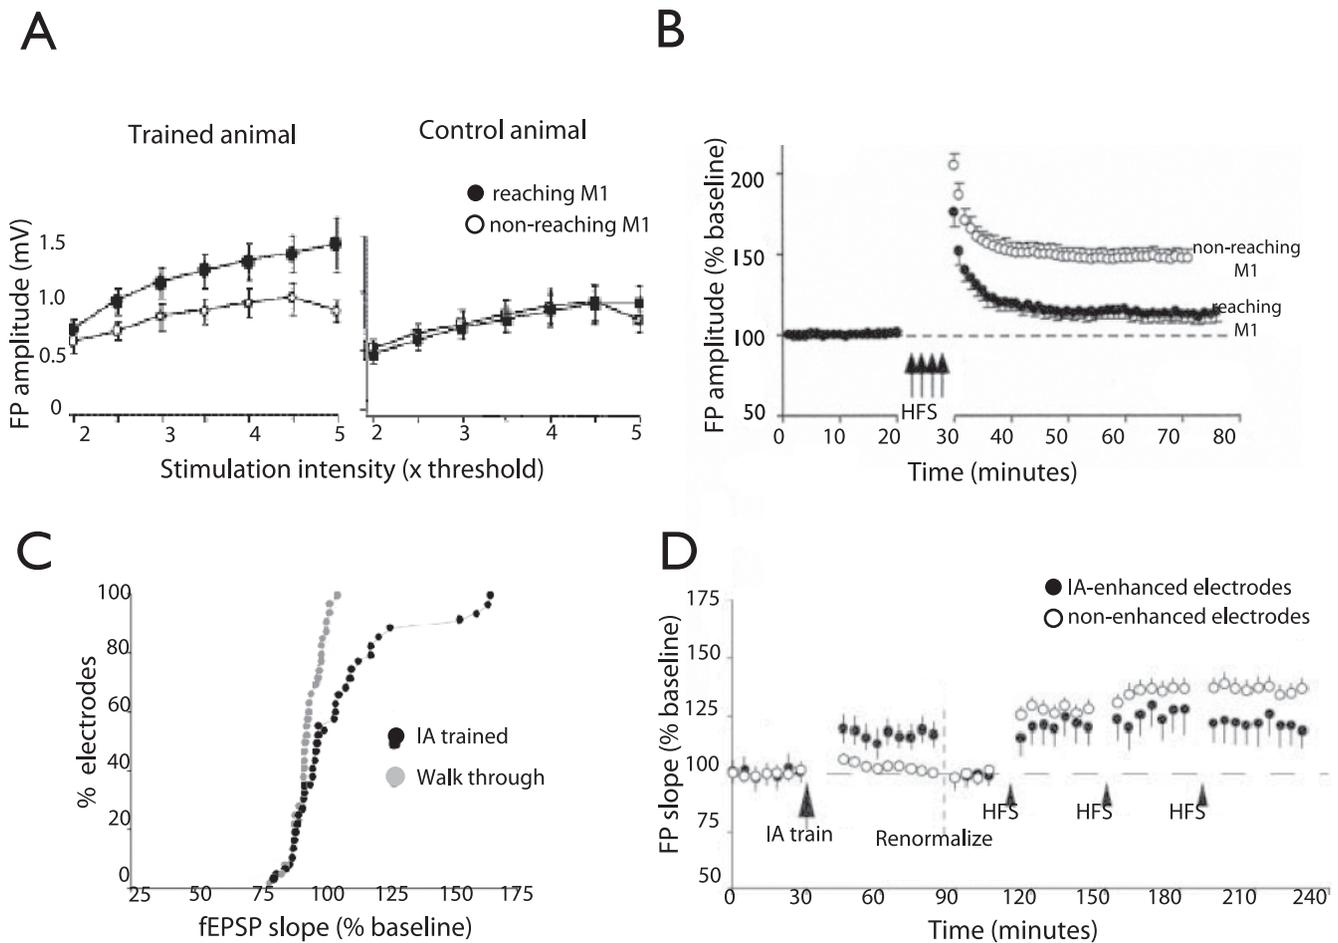

FIGURE 7.6 Learning induces synaptic enhancements that occlude LTP in brain areas relevant to the type of information learned. (A) Learning a new motor skill enhanced fEPSP amplitude specifically in the forelimb region of primary motor cortex (M1) corresponding to the preferred reaching paw in trained rats; no enhancements were observed in the same area of M1 in untrained control animals. (Modified with permission from Rioult-Pedotti, Friedman, Hess, & Donoghue, Strengthening of horizontal cortical connections following skill learning, *Nature Neuroscience*, 1(3), 230–234, © 1998, Nature [Nature Publishing Group].) (B) The fEPSP enhancements associated with skill learning resulted in the partial occlusion of LTP in M1 in the “reaching” hemisphere compared to the “nonreaching” hemisphere in trained rats. (Modified with permission from Rioult-Pedotti, Friedman, & Donoghue, Learning-induced LTP in neocortex, *Science*, 290, 533–536, © 2000,

American Association for the Advancement of Science.) (C) In vivo recording experiments in rats revealed that single-trial inhibitory avoidance (IA) training led to fEPSP enhancements in a subpopulation of recording electrodes in the hippocampus of trained animals relative to controls (who walked through the training apparatus without receiving a foot shock, i.e., the “Walk through” group). Data were collected 2 hours after conditioning. (D) Electrodes showing fEPSP enhancements upon IA training reached LTP saturation more rapidly and showed less LTP in response to repeated trains of HFS, demonstrating that this form of learning mimicked and occluded hippocampal LTP in vivo. (Modified with permission from Whitlock, Heynen, Shuler, & Bear, Learning induces long-term potentiation in the hippocampus, *Science*, 313, 1093–1097, © 2006, American Association for the Advancement of Science.)

Studies in the amygdala have also yielded strong evidence linking LTP and memory formation. Because of its well-characterized anatomical connectivity, the amygdala has allowed neuroscientists the opportunity to directly investigate associative synaptic plasticity between distinct inputs following associative learning. One of the most common experimental approaches has been to use Pavlovian fear-conditioning paradigms in which the aversive, fear-evoking stimulus of a foot shock (the US) is paired with a novel environmental cue, such as a tone (the CS). Research in the

1990s showed that repeatedly pairing a tone with a foot shock resulted in the strengthening of auditory thalamic inputs to the amygdala and increases in the amplitude of auditory-evoked responses when animals were replayed the tone after conditioning (McKernan & Shinnick-Gallagher, 1997; Rogan, Staubli, & LeDoux, 1997). Thus the initially weak tone representation became potentiated through its association with the foot shock. Similar to LTP, it was found that this form of learning resulted in the delivery of AMPA receptors to amygdalar synapses and that blocking

the synaptic delivery of AMPA receptors prevented the formation of the fear memory (Rumpel, LeDoux, Zador, & Malinow, 2005).

In addition to the amygdala, several studies have demonstrated learning-specific, LTP-like changes in the synaptic expression and phosphorylation of AMPA receptors in the hippocampus following tasks such as contextual fear conditioning, where animals learn to fear a context as opposed to a discrete tone, and inhibitory avoidance training (Shukla, Kim, Blundell, & Powell, 2007; Matsuo, Reijmers, & Mayford, 2008; Cammarota, Bernabeu, Levi De Stein, Izquierdo, & Medina, 1998; Bevilaqua, Medina, Izquierdo, & Cammarota, 2005; Whitlock, Heynen, Shuler, & Bear, 2006). Many of the downstream biochemical cascades initiated by inhibitory avoidance training are the same as those seen following LTP induction in the hippocampus (for review, see Izquierdo et al., 2006). Electrophysiological experiments have further confirmed the occurrence of LTP-like modification of hippocampal synapses following various learning tasks. In one such study, Sacchetti and colleagues showed that hippocampal slices obtained from rats after contextual fear conditioning showed fEPSP enhancements that partially occluded subsequent LTP, suggesting that contextual learning and LTP shared a common expression mechanism (Sacchetti et al., 2001, 2002). LTP-like enhancements in synaptic transmission have also been recorded in area CA1 following trace eyeblink conditioning, a form of hippocampal-dependent associative learning. Enhanced fEPSP responses were reported following this task in hippocampal slices prepared from trained rabbits (Power, Thompson, Moyer, & Disterhoft, 1997), as well as in the intact hippocampus of freely behaving mice (Gruart, Munoz, & Delgado-Garcia, 2006). Some of the most conclusive evidence demonstrating learning-induced LTP in the hippocampus comes from recent *in vivo* recording experiments in rats that were given inhibitory avoidance training (Whitlock et al., 2006). Multielectrode arrays were chronically implanted to record fEPSPs at several sites in the hippocampus of awake, behaving animals before and after inhibitory avoidance training. The training caused abrupt and long-lasting (>3 hr) enhancements of evoked fEPSPs in a subpopulation of the recording electrodes in trained animals relative to controls (figure 7.6C). Additional experiments demonstrated that electrodes showing training-related fEPSP enhancements expressed less subsequent LTP in response to HFS than neighboring electrodes that were not enhanced by training—that is, the learning-related enhancements partially occluded subsequent LTP (figure 7.6D). This demonstration of learning-induced fEPSP enhancements that occlude LTP *in vivo* provided long-awaited evidence that the strengthening of hippocampal synapses is a natural physiological occurrence following some forms of associative learning.

How does LTP influence hippocampal receptive fields?

If changes in synaptic transmission ultimately result in modified behavior, then they must change the way in which the brain structures that mediate those behaviors communicate with one another. A mechanistic understanding of how LTP contributes to behavior therefore requires a description of how changes in synaptic strength affect representations in neural networks. A well-studied experimental tool for understanding neural representations has been hippocampal place cells, first characterized in area CA1, which discharge only when an animal occupies a particular spatial location, the “place field” (O’Keefe & Dostrovsky, 1971). Neighboring place cells express distinct but overlapping place fields such that the entire surface of a recording environment is completely represented by a group of cells (O’Keefe, 1976). The spatial representations of place cells are extremely specific, with the cells firing at entirely unrelated locations from one recording environment to the next (O’Keefe & Conway, 1978), and can be incredibly stable, maintaining the same firing field locations for as long as the cells are identifiable (Thompson & Best, 1990). More recent advances in recording technology have enabled researchers to simultaneously record the activity of large ensembles of place cells (>100) as new map representations emerged during exploration of a novel environment (Wilson & McNaughton, 1993). Because the concerted activity of large groups of cells in the hippocampus will completely cover any environment encountered by an animal, it has been hypothesized that the hippocampus provides the neural substrate for an integrative “cognitive map,” which provides “an objective spatial framework within which the items and events of an organism’s experience are located and interrelated” (O’Keefe & Nadel, 1978). The remarkable spatial specificity and stability of place cells make them ideal candidates for contributing to a spatial memory system. Long-term potentiation is thought to fit into this framework by providing a synapse-specific mechanism enabling the long-lasting storage of spatial representations for a potentially very large number of environments. In this section we review studies that have begun to establish a link between LTP and place cell representations.

One of the earliest studies demonstrating a mechanistic relationship between LTP and place fields used mice carrying a CA1-specific deletion of the gene encoding the NMDA receptor subunit NR1 (McHugh, Blum, Tsien, Tonegawa, & Wilson, 1996). In parallel with the previously mentioned impairments in LTP and spatial learning in these mice, the authors found that the firing fields of CA1 place cells exhibited somewhat reduced spatial specificity, although the place fields did not disappear entirely (i.e., they were broader and had less well-defined boundaries than control animals; figure 7.7A). Place cells with overlapping place fields also showed reduced covariance of firing, implying a reduced capacity

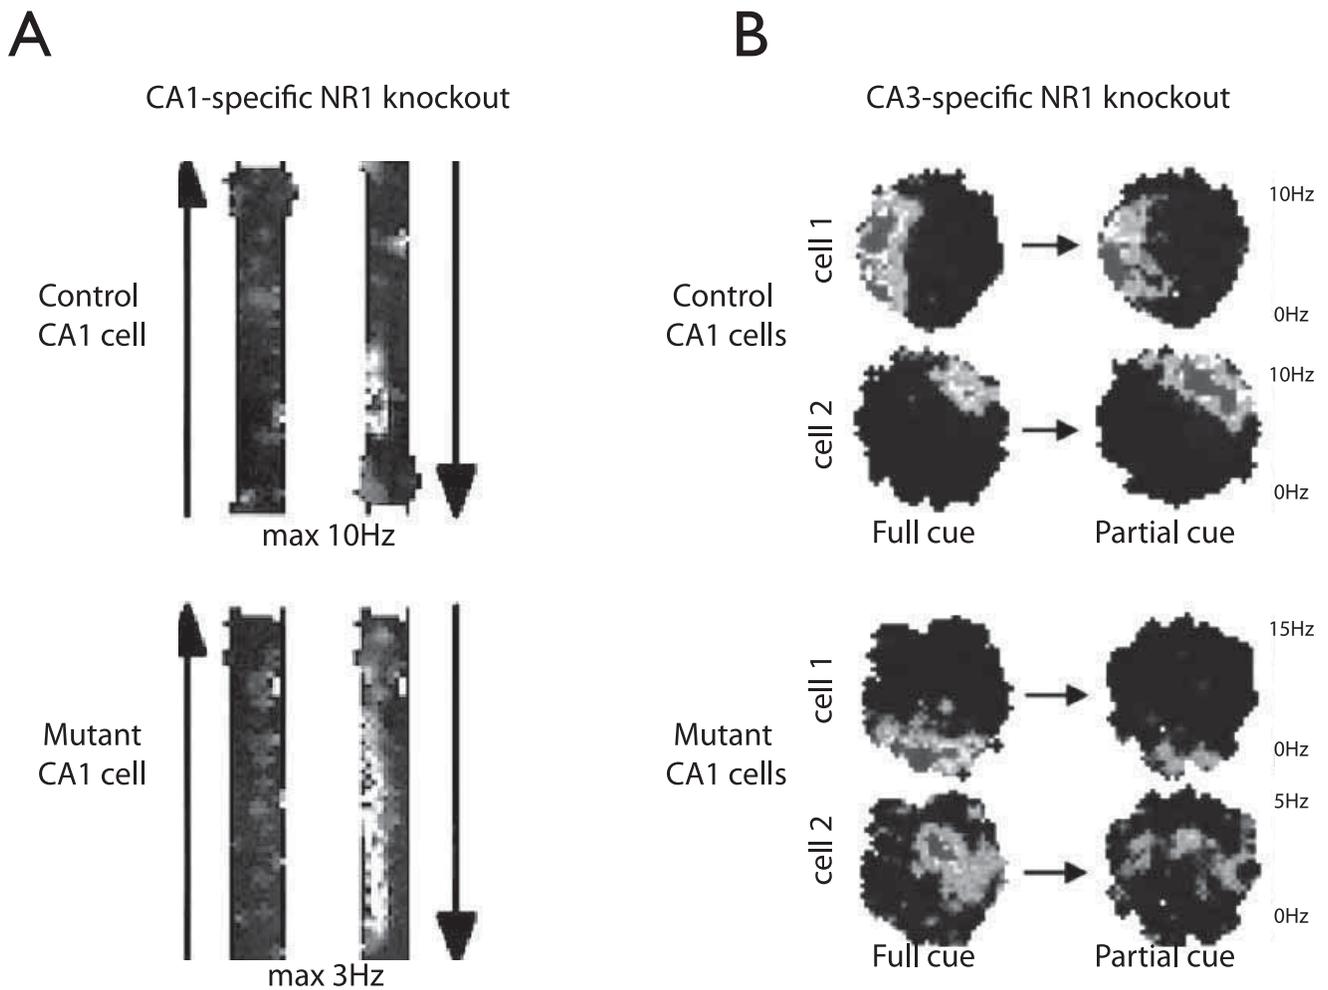

FIGURE 7.7 Genetic deletion of the obligatory NR1 subunit of the NMDA receptor alters place cell properties without preventing the expression of place fields per se. (A) Examples of direction-specific CA1 place cell activity from CA1-specific NR1 knockout mice and control mice running on a one-dimensional linear track; the panels show the firing rates of cells as a function of the location of the animals on the track. In this example, the cells were virtually silent when the animals traversed the track in the upward direction, but fired in a spatially restricted manner as the animals ran back down. Place fields in CA1 knockout mice were stable but significantly larger than in controls. (Modified with permission from McHugh, Blum, Tsien, Tonegawa, & Wilson, Impaired hippocampal representation of space in CA1-specific NMDAR1 knockout

mice, *Cell*, 87, 1339–1349, © 1996, Cell Press.) (B) The firing fields of CA1 place cells in CA3-specific NR1 knockout mice differed from controls only during specific environmental manipulations. There were no differences in place field properties when four out of four distal cues were present in the recording arena (“full cue” condition); however, when mice were returned to the arena with only one of four cues present (“partial cue”), CA3 knockout mice expressed significantly smaller CA1 place fields and had lower firing rates than controls. These experiments suggested a functional role for CA3 in pattern completion. (Modified with permission from Nakazawa et al., Requirement for hippocampal CA3 NMDA receptors in associative memory recall, *Science*, 297, 211–218, © 2002, American Association for the Advancement of Science.)

for coordinating ensemble codes for spatial location across cells. Considerable sparing of place-specific firing was also seen in mice with a specific deletion of the NR1 subunit in the CA3 subfield (Nakazawa et al., 2002). In these animals, the sharpness of firing fields in CA1 was not reduced at all. Impaired spatial firing appeared only under conditions where a substantial fraction of the landmarks in the environment were removed (figure 7.7B). Further insight was obtained in a study by Kentros and colleagues, where the authors used a pharmacological approach to compare the

role of NMDA receptors in induction and maintenance of spatial representations (Kentros et al., 1998). They found that injecting rats with a selective NMDA-receptor antagonist prevented the maintenance of new place fields acquired in novel environments when animals were reexposed to the environments a day later. The drug treatment did not affect preexisting place fields in a familiar environment, and new place fields were expressed instantaneously as animals explored a novel environment. These observations, together with the spared spatial firing observed in the NR1 knockout

mice, suggest that the mechanism for the expression of place fields per se is NMDA-receptor independent. NMDA receptors may instead be necessary for maintaining place fields in fixed locations across different experiences in the environment.

NMDA receptor activation is also necessary for experience-dependent changes in place cell discharge properties, as revealed by experiments in which rats repeatedly traversed the length of a linear track. This behavior was associated with the asymmetric, backward expansion of CA1 place fields relative to the rat's direction of motion, which was hypothesized to aid in predicting elements of upcoming spatial sequences before they actually occurred (Mehta, Barnes, & McNaughton, 1997; Mehta, Quirk, & Wilson, 2000). This form of behaviorally driven receptive field plasticity was hypothesized to arise from LTP-like synaptic enhancements between cells in CA3 and CA1 and, indeed, the effect was blocked in animals injected with NMDA receptor antagonists (Ekstrom, Meltzer, McNaughton, & Barnes, 2001). In addition to studies demonstrating a permissive role for NMDA-receptor activation in place cell plasticity, evidence supporting an instructive role for LTP in driving changes in place representations comes from a study by Dragoi and colleagues. It was found that inducing LTP in the hippocampus caused remapping of place cell firing fields in familiar environments, including the creation of new fields, the disappearance of others, and changes in the directional preferences of others (Dragoi, Harris, & Buzsaki, 2003). Additional work revealed that contextual fear conditioning, which itself induces LTP-like enhancements of hippocampal fEPSPs (Sacchetti et al., 2001, 2002), also results in the partial remapping of place fields in CA1 (Moita, Rosis, Zhou, LeDoux, & Blair, 2004), suggesting that synaptic plasticity and place field plasticity are merely different aspects of a common mechanism engaged by the hippocampus during associative contextual learning.

Synaptic plasticity and attractor dynamics in neural networks

Place cells are thought to be part of a hippocampal system for storage of episodic memories with a spatial component (S. Leutgeb et al., 2005; S. Leutgeb, J. K. Leutgeb, Moser, & Moser, 2005). Several studies over the years have revealed that place cells encode more than just space, including odors, textures, temporal sequences, and prior events (Hampson, Heyser, & Deadwyler, 1993; Moita et al., 2004; Wood, Dudchenko, & Eichenbaum, 1999; Wood, Dudchenko, Robitsek, & Eichenbaum, 2000; Young, Fox, & Eichenbaum, 1994), and the place cell network is known to support a number of discrete and graded representations in the same environment (Bostock, Muller, & Kubie, 1991; J. Leutgeb et al., 2005; Markus et al., 1995; Muller & Kubie,

1987). This multiplicity of the hippocampal spatial map contrasts strongly with the universal nature of representations one synapse upstream, in the superficial layers of the medial entorhinal cortex, which interfaces most of the external sensory information from the cortex to the hippocampus and back (Fyhn, Molden, Witter, Moser, & Moser, 2004). The key cell type among the entorhinal inputs to the hippocampus is the grid cell, which fires at sharply defined locations like place cells in the hippocampus but differs from such cells in that each cell has multiple firing locations and that the firing locations of each cell form a tessellating triangular pattern across the entire environment available to the animal (Hafting, Fyhn, Molden, Moser, & Moser, 2005). Different grid cells have nonoverlapping firing fields; that is, the grids are offset relative to each other (Hafting et al., 2005), but the grids of different colocalized cells keep a constant spatial relationship between different environments, implying that a single spatial map may be used in all behavioral contexts, very much unlike the recruitment of discrete and apparently nonoverlapping representations in the hippocampus (Fyhn, Hafting, Treves, Moser, & Moser, 2007). These observations, taken as a whole, suggest that self-location is maintained and perhaps generated in entorhinal cortex (McNaughton, Battaglia, Jensen, Moser, & Moser, 2006), whereas the role of the hippocampus is to differentiate between places and experiences associated with places, and to associate each of them to the particular features of each environment. Such a regional differentiation would be consistent with a critical role for the hippocampus in memory for individual episodes.

But how are associative memories encoded and retrieved in the place cell system? It is commonly believed that memories are encoded at the level of neural ensembles and that the ensembles are implemented in neural attractor networks (Amit, Gutfreund, & Sompolinsky, 1985, 1987; Hopfield, 1982). An attractor network has one or several preferred positions or volumes in the space of network states, such that when the system is started from any location outside the preferred positions, it will evolve until it reaches one of the attractor basins (figure 7.8A). It will then stay there until the system receives new input. These properties allow stored memories (the preferred positions of the system) to be recalled from degraded versions of the original input (positions that are slightly different from the preferred positions). Storing different places and episodes as discrete states in such a network keeps memories separate and avoids memory interference. Attractor networks could, in principle, be hardwired, but for the hippocampus, as well as any other memory-storing system, this is quite unlikely considering that thousands of new memories are formed in the system each day. It is more likely that representations evolve over time, with new states being formed each time a new event is experienced. The formation of hippocampal attractor states is thought to

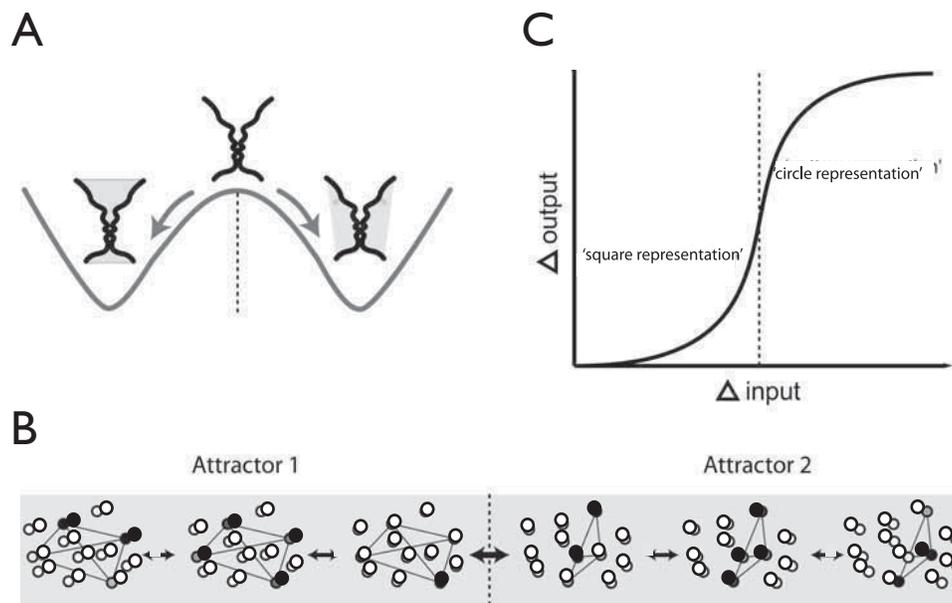

FIGURE 7.8 Patterns of activity in cell assemblies with attractor dynamics. (A) Ambiguous patterns tend to converge to a familiar matching pattern (i.e., pattern completion) and, simultaneously, diverge away from interfering patterns (i.e., pattern separation). This nonlinear process can be illustrated with an illusion using an ambiguous visual object. The perceived image in A will tend to fluctuate between two familiar images (a chalice on the left, or two kissing faces on the right), instead of stabilizing on the ambiguous white object in the middle. (B) The presence of attractor states in a neural network favors the emergence of familiar patterns even when the initial input is severely degraded. Activating just a few cells in an attractor network (“partial” representations with just one or two black dots on the left and right examples in “Attractor 1” and “Attractor 2”) is sufficient to restore the full ensemble activity of

cells participating in the representation (“complete” patterns shown in the middle of “Attractor 1” and “Attractor 2”). (C) Attractor networks are thought to aid in disambiguating similar patterns of input by favoring sharp transitions between network states as inputs are changed gradually, as in the study by Wills, Lever, Cacucci, Burgess, and O’Keefe (2005). It was found that spatial maps in the hippocampus snapped sharply from a “square-environment” representation to a “circle-environment” representation as a recording enclosure was gradually “morphed” from one shape to the other. (Modified with permission from S. Leutgeb, J. K. Leutgeb, Moser, & Moser, Place cells, spatial maps and the population code for memory, *Current Opinion in Neurobiology*, 15, 738–746, © 2005, Elsevier Ltd.)

be based on LTP- and LTD-like synaptic modifications between the cells that participate in the individual representations and between these ensembles and external signals providing information about the features of the environment or episode for which a representation is generated.

Unfortunately, there is limited direct experimental evidence for LTP and LTD in attractor dynamics. Several recent studies have suggested that the hippocampus *has* attractor properties, however. For example, place cells keep their location of firing after removal of a significant subset of the landmarks that defined the original training environment—for example, when a cue card is removed or the lights are turned off (Muller & Kubie, 1987; O’Keefe & Conway, 1978; Quirk, Muller, & Kubie, 1990). The persistence of the place fields suggests that representations can be activated even under severely degraded input conditions (as schematized in figure 7.8B). However, such experiments do not rule out the possibility that firing is controlled by subtle cues that are still present in the deprived version of the environment. In response to this concern, more recent experiments have measured hippocampal place

representations during progressive equal-step transformation of the recording environment, using so-called morph boxes. Recording in CA1, Wills and colleagues trained rats in a square and a circular version of a box with flexible walls until place cell representations in the two environments were very different (Wills, Lever, Cacucci, Burgess, & O’Keefe, 2005). The rats were then exposed to several intermediate shapes. A sharp transition from squarelike representations to circlelike representations was observed near the middle between the familiar shapes, as predicted if the network had discrete attractor-based representations corresponding to the trained shapes (figure 7.8C). Parallel work by Leutgeb and colleagues showed that the representations are not always discrete (J. Leutgeb et al., 2005). Under conditions where the spatial reference frame is constant, place cells in CA3 and CA1 assimilate gradual or moderate changes in the environment into the preexisting representations. It was observed that stable states can be attained along the entire continuum between two preestablished representations, as long as the spatial environment remains unchanged. Adding the dimension of time, this ability to represent

continua may allow hippocampal networks to encode and retrieve sequential inputs as uninterrupted episodes. The existence of both discrete and continuous representations and their dependence on the exact experience in the environment are consistent with the existence of attractors in the hippocampus, but the attractors must be dynamic, implying a possible role for LTP and LTD in their formation and maintenance.

Where should we begin the study of synaptic plasticity in hippocampal attractor dynamics? Theoretical models have pointed to the neural architecture of CA3 as a good candidate (Marr, 1971; McNaughton & Morris, 1987). The dense and modifiable recurrent circuitry of this system (Amaral & Witter, 1989; Lorente de N6, 1934) and the sparse firing of the pyramidal cells in this area (Barnes, McNaughton, Mizumori, Leonard, & Lin, 1990; S. Leutgeb, J. K. Leutgeb, Treves, Moser, & Moser, 2004) are properties that would be expected if the system were to form rapid distinguishable representations that could be recalled in the presence of considerable noise. Widespread collaterals interconnect pyramidal cells along nearly the entire length of the CA3 (Ishizuka, Weber, & Amaral, 1990; Li, Somogyi, Ylinen, & Buzsaki, 1994). On average, each pyramidal neuron makes synapses with as many as 4% of the pyramidal cells in the ipsilateral CA3, and more than three-quarters of the excitatory synapses on a CA3 pyramidal cell are from other CA3 pyramidal neurons (Amaral, Ishizuka, & Claiborne, 1990). The recurrent synapses exhibit LTP (Zalutsky & Nicoll, 1990), enabling the formation of an extensive number of interconnected cell groups in the network. In agreement with these ideas, CA3 cells show remarkably persistent and coherent firing after removal of significant parts of the original sensory input (Lee, Yoganarasimha, Rao, & Knierim, 2004; S. Leutgeb et al., 2004; Vazdarjanova & Guzowski, 2004). NMDA-receptor-dependent plasticity in CA3 is necessary for this neural reactivation process as well as the ability to retrieve spatial memories from small subsets of the cues of the original environment (see figure 7.7B) (Nakazawa et al., 2002). Formation of discrete representations is apparent in the same network as a nearly complete replacement of the active cell population in CA3 when animals are transferred between enclosures with common features (S. Leutgeb et al., 2004). Thus several studies suggest that CA3 has the predicted properties of an attractor network and that NMDA receptor-dependent long-term plasticity may underlie its functions in encoding and recall of memory.

Summary

There is still some work to do. Demonstrating that LTP plays a role in memory is only a first step to a deeper mechanistic understanding of how the brain achieves infor-

mation storage and recall. The available data suggest that the question is no longer *whether* LTP is involved in memory, but *how*. A major challenge for future research will be to determine more exactly how LTP and LTD contribute to dynamic representation in the heavily interconnected neural networks of the hippocampus and elsewhere. The evidence for attractors is indirect, and we do not know, for example, what numbers of cells are involved in each representation, whether there are multiple representations, and, if there are, whether and how they overlap and interact. The mechanisms for maintaining and separating discrete representations, as well as the processes by which new information is assimilated into existing network states, are not known. LTP and LTD, as well as more short-term plasticity processes, are likely to play major functions in these processes, but how these functions are implemented in the network remains an enigma.

8 Visual Cortical Plasticity and Perceptual Learning

WU LI AND CHARLES D. GILBERT

ABSTRACT Plasticity is an integral property of a functioning brain throughout life. In the visual system, cortical plasticity is engaged for encoding the geometric regularities of the visual environment early in life, as well as for functionally adaptive changes in response to lesions and neurodegenerative diseases. In addition to the pliability during postnatal maturation and during the restoration of disrupted functions, the visual system also maintains remarkable plasticity for encoding the specific shapes of figures to which we become familiar. This is known as perceptual learning, and it is important for rapid recognition of the learned shapes in complex environments and for enhanced sensitivity to delicate nuances of the learned stimulus features. Moreover, the visual system also exhibits fast functional switching capabilities, whereby response properties of neurons are dynamically adjusted by top-down influences for efficient processing of behaviorally relevant stimuli. The dynamic nature of neuronal responses is tightly coupled with the long-term plasticity seen in perceptual learning, as repeated performing of the same perceptual task, and therefore, repetitive invoking of top-down influences specific to the task, can potentiate the dynamic changes useful for solving the perceptual tasks, leading to encoding and retrieving of the implicit memory formed during perceptual learning.

Our brain needs to constantly adapt to the environment and to assimilate knowledge about the external world by maintaining a certain degree of functional and architectural malleability. This notion has been appreciated for centuries. The idea that our perceptual and cognitive functions can be shaped by an individual's experience was originally expressed by philosophers such as John Locke, who asserted that the human mind at birth is like a blank slate, and that all ideas and knowledge are derived from individual's experiences (Locke, 1689/1995). The earliest psychological inference and definition of cortical plasticity were made by William James (1890/1950), who compared the formation of habits and skills to the plastic changes of materials, and attributed behavioral changes to the plasticity of the brain. One of the most influential speculations about the neuronal substrates of cortical plasticity was vividly drawn by Santiago Ramón y Cajal (1911), who proposed that changes in connections between neurons are responsible for our ability to learn (see

review, Jones, 1994). As for the rule governing wiring and rewiring between neurons, Donald Hebb theoretically postulated that neurons are wired together if they fire together (Hebb, 1949). This Hebbian rule of synaptic plasticity has been widely adopted into physiological, psychophysical, and computational studies of learning and memory. At the system and behavior levels, Jerzy Konorski (1948) distinguished plasticity from excitability as an independent property of the brain whereby "certain permanent functional transformations arise in particular systems of neurons as the result of appropriate stimuli." On top of these earlier insightful reasoning and speculations, the last half century has witnessed the advances of our understanding of cortical plasticity in various respects, from different perspectives, and using a variety of approaches. This chapter focuses on the cortical plasticity in the visual system.

Processing of visual information in the brain is distributed among more than 30 cortical areas (Van Essen, Anderson, & Felleman, 1992). These functionally specialized and hierarchically organized areas are interwired by feedforward and feedback connections, forming partially segregated modules and pathways for processing different attributes of visual stimuli. On the one hand, this specific connectivity has been genetically determined or innately hardwired for mediating both stimulus-driven bottom-up process and behavior-driven top-down influences. On the other hand, accumulated evidence has revealed that visual experience can modify the preexisting functionality and connectivity of the visual system throughout life.

Plasticity in postnatal development

EARLY DEVELOPMENT The maturation process of the visual system continues well into postnatal periods in terms of both circuitry and functionality. The neural circuitry within a cortical area, such as the primary visual cortex (area V1), comprises two types of connections (for reviews see Gilbert, 1983; Callaway, 1998). The vertical connections, which link neurons across different cortical layers that represent the same visual field location, are responsible for processing local simple stimulus attributes. The horizontal connections, which extend parallel to the cortical surface

WU LI Beijing Normal University, Beijing, China
CHARLES D. GILBERT The Rockefeller University, New York, New York

and tend to link cells with nonoverlapping receptive fields (RFs), are involved in integrating information over a large area in the visual field (for review see Gilbert, 1992). Anatomical studies have shown that the vertical connections in human V1 develop prenatally, but the development of the horizontal connections is much later and is asynchronous within different cortical layers (Callaway & Katz, 1990; Burkhalter, Bernardo, & Charles, 1993). In the middle (the input) layers, the horizontal connections propagate rapidly only after birth and become more adultlike in about two months. The horizontal connections in the superficial (the output) layers develop at an even later age, emerging after birth and reaching mature form after more than one year. The anisotropy of development and maturation of local circuits in V1 suggests that different visual functions emerge at different stages of development and that postnatal experience could be important for the maturation of cortical circuitry and visual functions. Recent studies have provided compelling evidence that early visual experience can influence the maturation of neural circuitry by shaping axonal and dendritic structures, regulating synapse formation and elimination, and altering synaptic transmission (for review see Fox & Wong, 2005). These experience-dependent changes during postnatal development can be observed at different levels of the visual pathway, including the visual cortex, the lateral geniculate nucleus, and even the retina.

The susceptibility of functional architecture of visual cortex to anomalous visual experience was first discovered by Hubel and Wiesel (Wiesel & Hubel, 1963; Hubel & Wiesel, 1970, 1977). In the normal developmental condition, the visual input to area V1 from the two eyes is balanced. This balance can be disrupted by depriving an animal of the visual input from one eye within a period of several months after birth, resulting in an enlargement in representation of the normal eye and shrinkage in the representation of the deprived eye. The time window within which a brain function is highly susceptible to experience-dependent modifications is referred to as the critical period. Depending on

different brain functions and different species, the onset and closure of the critical period can be different. For example, in humans the critical period for susceptibility of stereopsis begins soon after birth and extends into childhood for at least 4–5 years (Fawcett, Wang, & Birch, 2005). Since the heightened plasticity is maintained only within a finite period of postnatal development, it leads to the conjecture that the response properties of neurons and the functional architecture of the cortex become fixed in adulthood. As we will see in the other sections of this chapter, this idea has been challenged in the last couple of decades.

LATE MATURATION An extreme case of late maturation of some visual functions is seen in the perceptual ability to link discrete contour elements into a global coherent visual contour within a complex background (for a demonstration of visual contours, see figure 8.1). This process, known as contour integration, is an important intermediate step in object recognition. According to the Gestalt rule of “good continuation,” our visual system has built-in apparatus to link contour elements that are arranged along smooth and continuous paths (Wertheimer, 1923). Recent studies have suggested that the long-range horizontal connections in V1, which link neurons with similar preference for contour orientations, are ideally suited for mediating contour integration, both in terms of its orientation specificity and its spatial extent (W. Li & Gilbert, 2002; Stettler, Das, Bennett, & Gilbert, 2002; W. Li, Piech, & Gilbert, 2006). Moreover, this hardwired connectivity ecologically coincides with the geometries and regularities of natural scene images that are rich in collinear and cocircular contours (Geisler, Perry, Super, & Gallogly, 2001; Sigman, Cecchi, Gilbert, & Magnasco, 2001), suggesting an evolutionary and developmental impact on the formation and maturation of the circuitry. As mentioned previously, the horizontal connections in V1 do not become adultlike until late infancy (Burkhalter et al., 1993). Moreover, it has been shown that the ability of children to detect visual contours camouflaged

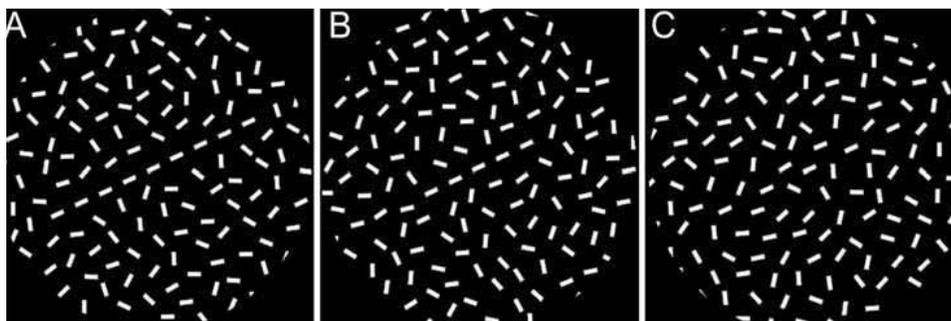

FIGURE 8.1 Contour integration. Within a complex background, those discrete line segments following the Gestalt law of continuity are easily grouped together, forming a visual contour. A contour consisting of more collinear lines is more salient than a shorter one

(compare *A* with *B*); and the same array of collinear lines appears less salient when they are spaced further apart (compare *B* with *C*). (From W. Li, Piech, & Gilbert, 2008.)

in a complex background improves with age and does not approximate the adult's level until adolescence (Kovacs, Kozma, Feher, & Benedek, 1999). Surface segmentation, another important intermediate level visual function, also matures at a late age comparable to contour integration (Sireteanu & Rieth, 1992). Similar to contour integration, the process of partitioning visual images into segregated surfaces relies heavily on integration of information across a large visual field area. The late maturation of contour-integration and surface-segmentation capabilities suggests that natural scene geometries and regularities continue to shape neural circuitry as well as response properties of visual neurons during a very long period of time after birth.

Plasticity in response to lesions

The closure of critical periods does not necessarily mean that the neural connections and circuits in the adult brain have been completely fixed. Abnormal experiences like injuries and neurodegenerative diseases during adulthood can also trigger marked plastic reactions in the central nervous system.

LESION EXPERIMENTS Pronounced changes were first reported in the spinal cord of adult animals after an injury to the periphery nerves (Devor & Wall, 1978, 1981). Subsequently, striking reorganization in adult primary sensory cortices has also been widely demonstrated, including the somatosensory cortex in response to deafferentation of sensory input from a skin area (Rasmusson, 1982; Merzenich et al., 1983a, 1983b, 1984; Calford & Tweedale, 1988; Pons et al., 1991; Weiss, Miltner, Liepert, Meissner, & Taub, 2004), the primary auditory cortex in response to restricted cochlear lesions (Robertson & Irvine, 1989; Rajan, Irvine, Wise, & Heil, 1993), and the primary visual cortex in response to lesions on the retina (Kaas et al., 1990; Heinen & Skavenski, 1991; Chino, Kaas, Smith, Langston, & Cheng, 1992; Gilbert & Wiesel, 1992; Schmid, Rosa, Calford, & Ambler, 1996; Eysel et al., 1999; Calford et al., 2000; Giannikopoulos & Eysel, 2006). All these lesion-induced plastic changes have comparable effects in the relevant cortical regions: the cortical territory devoted to representing the deafferented region on the sensory surface (the skin, the cochlea, or the retina) becomes responsive to adjacent sensory surfaces spared from the lesion, a process referred to as cortical reorganization.

Here we use retinal lesions as an example. The retina is mapped point-by-point onto the primary visual cortex, generating a two-dimensional topographic map called the retinotopic map. A restricted lesion on the retina destroys the photoreceptors within a small area (figure 8.2A). This retinal scotoma cuts off visual input to the corresponding retinotopic region in V1, known as the lesion projection zone

(LPZ), and silences neurons within that cortical region (figure 8.2B). After the lesion, continuous plastic changes in V1 have been observed within a period of time ranging from minutes to months (for example, see Gilbert & Wiesel, 1992). Within minutes after the lesion, a remarkable increase in RF sizes occurs for V1 neurons whose RFs are located near the boundary of the retinal scotoma. A couple of months after the retinal injury, the size of the LPZ dramatically shrinks (figure 8.2C): neurons within the original cortical LPZ regain responsiveness by shifting their RFs outside the retinal scotoma. This plastic change is not simply a consequence of a rearrangement of thalamocortical afferents; but rather, it is cortically mediated through the long-range horizontal connections intrinsic to V1 (Gilbert & Wiesel, 1992; Darian-Smith & Gilbert, 1995; Calford, Wright, Metha, & Taglianetti, 2003).

Even for the intact visual system in adults, a dramatic change in visual experiences by itself can cause a large-scale functional reorganization of the visual cortex. V1 neurons in a cerebral hemisphere are driven by inputs from the contralateral visual field. After monkeys wore special spectacles for several months to reverse their left and right visual field, some V1 cells begin to respond to stimuli presented in both hemifields (Sugita, 1996).

NEURODEGENERATIVE DISEASES Similar to the retinal lesion experiments, macular degeneration (MD) has also been

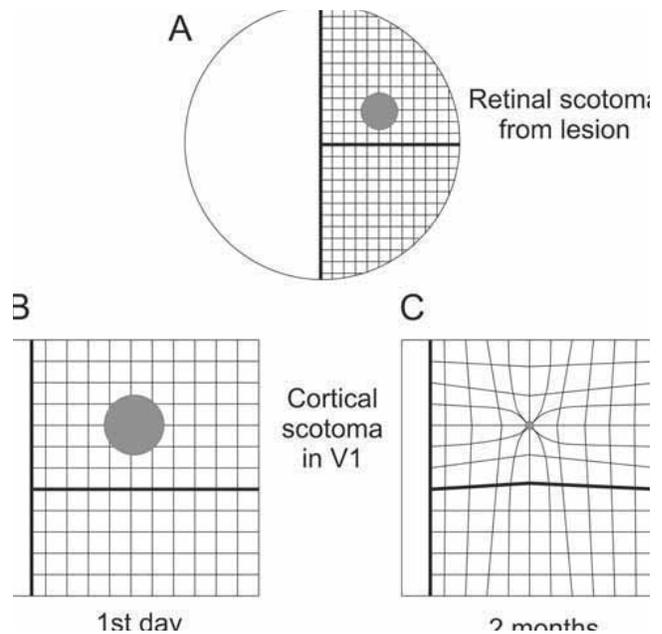

FIGURE 8.2 Reorganization of V1 in response to retinal lesion. A retinal scotoma produced by focal laser lesion (A, the small gray area) creates a silent region in V1 (B, the gray area). During recovery (C), neurons within the cortical scotoma regain responsiveness to visual input from the retinal area surrounding the laser-induced scotoma. (Adapted from Gilbert, 1992.)

reported to cause large-scale reorganization of the visual cortex, including area V1 (Baker, Peli, Knouf, & Kanwisher, 2005). Macular degeneration is the leading cause of vision loss in old people. It results from a deterioration of the macula, the central area of the retina that offers the highest spatial resolutions in visual processing. Damage to the macula results in deprivation of visual input to the V1 regions representing the central visual field. It has been shown that in MD patients the cortical regions that normally respond to central visual stimuli are strongly activated by peripheral stimuli (Baker et al., 2005; but see Masuda, Dumoulin, Nakadomari, & Wandell, 2008, which argued that the responses seen in the cortical scotoma of MD patients could largely result from top-down influences mediated by feedback connections from higher cortical areas).

In addition to retinal damages, an fMRI study has shown significant cortical reorganization in V1 of an adult patient who suffered from a stroke that destroyed the input fibers to V1 corresponding to the upper-left visual field (Dilks, Serences, Rosenau, Yantis, & McCloskey, 2007). Behavioral tests showed that this patient perceived stimuli located in the intact lower-left visual field as being elongated upward into the blind upper-left visual field. Correspondingly, fMRI experiments confirmed that the deprived V1 region originally representing the blind visual-field area had reorganized to be responsive to the intact visual-field area. This study provides convincing evidence in support of cortical reorganization and its impact on visual perception during recovery of lost visual functions.

Although visual cortex is specialized in processing visual information, in extreme cases like complete sight loss, visual cortical areas can also be recruited to process other sensory information such as enhancing auditory and tactile processing, or even recruited to process higher-order cognitive tasks (for reviews see Burton, 2003; Pascual-Leone, Amedi, Fregni, & Merabet, 2005).

Perceptual learning

PSYCHOPHYSICS Learning-induced modification of perception had already been noticed in the 19th century by Herrmann von Helmholtz, who made an incisive observation that “the judgment of the senses may be modified by experience and by training derived under various circumstances, and may be adapted to the new conditions. Thus, persons may learn in some measure to utilize details of the sensation which otherwise would escape notice and not contribute to obtaining any idea of the object” (Helmholtz, 1866, page 5). Studies within the last couple of decades have identified two distinct classes of long-term learning and memory (for review see Squire, Stark, & Clark, 2004): the explicit or declarative form of memory mediated

by a unified memory system—the medial temporal lobe; and the implicit or nondeclarative form of memory distributed in different cortical areas or brain structures. Perceptual learning falls within the category of implicit memory. It is the unconscious acquisition of improved ability with practice in simple perceptual tasks, as demonstrated in many visual tasks, such as discrimination of spatial resolution (McKee & Westheimer, 1978; Poggio, Fahle, & Edelman, 1992; Saarinen & Levi, 1995; Crist, Kapadia, Westheimer, & Gilbert, 1997), orientation (Vogels & Orban, 1985; Shiu & Pashler, 1992; Schoups, Vogels, Qian, & Orban, 2001), direction of motion (Ball & Sekuler, 1982), depth (Fendick & Westheimer, 1983; Ramachandran & Braddick, 1973), texture (Karni & Sagi, 1991), the waveform of sinusoidal stimuli (Fiorentini & Berardi, 1980), and contrast (Yu, Klein, & Levi, 2004). Perceptual training leads to a substantial decrease in the threshold for discriminating subtle changes in the trained stimulus attributes; it also facilitates detection of familiar shapes embedded in an array of similar distracters (Wang, Cavanagh, & Green, 1994; Ellison & Walsh, 1998; Sigman & Gilbert, 2000; Sireteanu & Rettenbach, 2000).

An indication of the possible cortical loci of perceptual learning comes from a large number of psychophysical observations that the learning effect is usually specific to the trained visual field location and to simple stimulus attributes (for review see Gilbert, Sigman, & Crist, 2001). There is little transfer or interference of learning between the trained and untrained visual-field locations, and between different stimuli. For example, training human subjects to discriminate the differences in orientation of an orientated stimulus improves discrimination performance that is only restricted to the trained location and the trained orientation (Schoups, Vogels, & Orban, 1995). Specificity of perceptual learning suggests that learning-induced changes involve early visual cortex like V1, where the visual field is topographically mapped at a fine scale and neurons are selective for simple stimulus attributes like orientation. However, some studies argue that the improved performance could simply be a consequence of retuning the readout connections between the decision stage and the visual cortex, namely, a refinement of the decision criteria (Doshier & Lu, 1998; R. Li, Levi, & Klein, 2004; Yu et al., 2004). A dichotomy of learning mechanisms has also been proposed, whereby some training mainly enhances sensory processing while the other mainly improves decision making (Adini, Wilkonsky, Haspel, Tsodyks, & Sagi, 2004). Despite a lack of general consensus about the cortical loci where the plastic changes take place, physiological and imaging studies have shed light on neural mechanisms of perceptual learning.

CORTICAL RECRUITMENT Cortical plasticity associated with perceptual learning was first demonstrated in the

somatosensory and auditory systems. The observed changes are analogous to the cortical reorganization observed in the primary somatosensory and auditory cortices in response to peripheral lesions. For example, training monkeys to perform a tactile frequency discrimination task using a restricted skin area induces remarkable reorganization of the primary somatosensory cortex, leading to a significant increase in the size and complexity of the territory representing the trained skin area (Recanzone, Merzenich, & Jenkins, 1992; Recanzone, Merzenich, Jenkins, Grajski, & Dinse, 1992). Similarly, training on an acoustic frequency discrimination task dramatically increases the cortical territory representing the trained frequencies in the primary auditory cortex (Recanzone, Schreiner, & Merzenich, 1993). This mechanism has been referred to as cortical recruitment, whereby a larger cortical region and thus a greater number of neurons are recruited to encode the trained stimuli. Nonetheless, it is still a matter of debate whether the cortical recruitment is directly responsible for the improved discrimination ability, as the recruitment seems unnecessary for enhanced performance on acoustic frequency discrimination (Brown, Irvine, & Park, 2004). Moreover, overrepresentation of the familiar frequencies in the auditory cortex could even be detrimental to discrimination of the overrepresented frequencies (Han, Kover, Insanally, Semerdjian, & Bao, 2007).

In the visual system, an fMRI study has shown that practicing a coherent-motion detection task, in which a small proportion of randomly positioned dots move in the same direction among randomly moving dots, causes a significant enlargement of the cortical territory representing the trained stimulus in area MT, a cortical area involved in motion processing (Vaina, Belliveau, Roziers, & Zeffiro, 1998). However, cortical recruitment associated with perceptual training has never been documented so far in early visual areas (for an attempt to search for such a change in V1, see Crist, Li, & Gilbert, 2001). The lack of transfer or interference of learning across visual field locations and between visual stimuli also argues against cortical recruitment as an effective mechanism of visual perceptual learning, because recruiting by “robbing” adjacent cortical regions would inevitably interfere with processing of other stimuli. However, studies in search of the neural basis of perceptual learning have shown some other cortical changes that can better account for the observed learning effects.

NEURONAL MECHANISMS The visual stimuli and tasks used for studies of perceptual learning can be roughly put into two categories: visual discrimination and visual detection or identification. In discrimination tasks, observers need to discriminate a subtle change in stimulus with respect to a reference dimension or attribute, such as an orientation discrimination task, to judge whether a line is slightly tilted

to the left or to the right with respect to the vertical. In detection tasks, either a target presented alone near its contrast detection threshold or a target embedded in a background of noise or distracters needs to be identified as present or absent. Instead of getting more neurons involved by recruiting, other potential mechanisms to improve performance on these tasks are to increase neuronal selectivity for the stimulus attribute that is relevant to the discrimination task, or to enhance signal-to-noise ratio by selectively boosting neuronal responsiveness to the familiar target, or to achieve automatization and accelerated processing speed by shifting cortical representation of the learned stimulus from higher to lower cortical areas. Neural correlates in all these respects have been found in visual cortical areas, including V1—the first stage of cortical visual processing.

Increased neuronal selectivity in discrimination learning Simple discrimination tasks, such as orientation discrimination, only involve processing of a basic stimulus attribute. It has been shown that training monkeys on orientation discrimination selectively sharpens orientation-tuning functions of those V1 neurons whose RFs are at the trained visual field location and whose preferred orientations are close to the trained orientation (Schoups et al., 2001; but see Ghose, Yang, & Maunsell, 2002). Similar and stronger effects have also been observed in area V4, an intermediate stage in the visual pathway responsible for object recognition (Yang & Maunsell, 2004; Raiguel, Vogels, Mysore, & Orban, 2006). The theoretical interpretations of these observations are mixed. Intuitively, a sharpening of the orientation-tuning curve around the trained orientation would result in an increase in neuronal selectivity for the trained orientation, which would in turn benefit the discrimination task. This idea is supported by a computational study (Teich & Qian, 2003). Conversely, a modeling study argues that a sharpening of original tuning curves actually causes a general loss of information content conveyed by neuronal responses (Series, Latham, & Pouget, 2004).

Unlike discrimination of a simple stimulus attribute, some discrimination tasks require lateral integration of contextual information. The visual percept of a stimulus, as well as responses of visual neurons to the stimulus, can be modified by the global stimulus context within which the stimulus is displayed (for reviews see Gilbert, 1998; Albright & Stoner, 2002; Allman, Miezin, & McGuinness, 1985). This phenomenon, known as contextual modulation, takes place throughout visual cortical areas along the visual pathways, representing a general lateral integrative mechanism of visual processing. Contextual interactions seen in V1 indicate that V1 neurons are selective for more complex features in visual scenes in addition to simple stimulus attributes like contour orientation. It has been shown that extensive

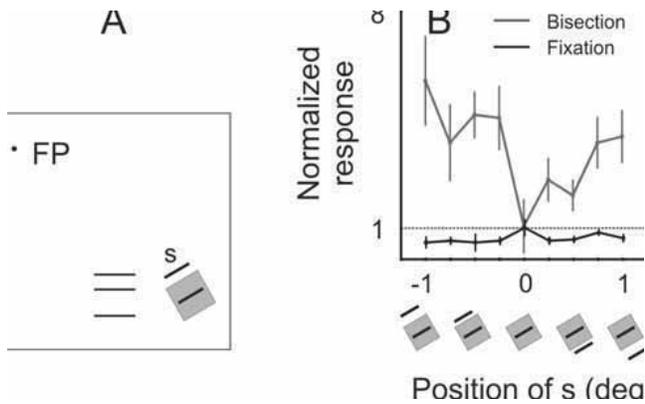

FIGURE 8.3 Perceptual learning modifies contextual influences in V1. (A) The stimulus paradigm. The three horizontal parallel lines indicate the task stimulus. Monkeys were trained to determine whether the middle line was closer to the upper or the lower flanker. After training monkeys on this bisection discrimination task, responses of single V1 neurons to another stimulus, the test stimulus, were recorded when the animal either performed the trained bisection task, or simply maintained its fixation at the fixation point (FP). The test stimulus consisted of two lines, an optimally oriented line fixed in the center of the receptive field (denoted by the gray square), and a second parallel line (indicated by “s”) placed at different locations on either side of the RF (see the cartoons at the bottom of B). (B) The normalized responses of a typical V1 cell to the test stimulus as a function of the position of line “s.” When the animal was performing the simple fixation task, placing “s” on either side of the RF slightly suppressed neuronal responses relative to the responses at position 0 deg, where the two test lines were superimposed in the RF center. In contrast, when the animal was performing the bisection task, the weak contextual inhibition was changed into strong facilitation. (Adapted from Crist, Li, & Gilbert, 2001.) (See color plate 5.)

training of monkeys in a three-line bisection discrimination task greatly enhances the animals’ discrimination ability and markedly modifies contextual influences on V1 responses (Crist et al., 2001). The latter is characterized by an increase in the modulatory strength of contextual lines and, in some cases, a reversal of the modulatory effect from inhibition to facilitation (figure 8.3). That is, V1 neurons become more sensitive with training to positional displacement of parallel lines, an ability that is important in bisection discrimination. This change was present only in the trained retinotopic area while the monkey was doing the trained bisection task, suggesting that both encoding and retrieving the learned information require task-specific top-down influences.

While training on discrimination of simple stimuli can sharpen neuronal selectivity in early visual areas, learning to discriminate among complex shapes can enhance shape selectivity of neurons in the inferior temporal cortex (area IT), the last stage in cortical processing of visual objects (Logothetis, Pauls, & Poggio, 1995; Kobatake, Wang, & Tanaka, 1998; Freedman, Riesenhuber, Poggio, & Miller, 2006). This enhancement shows orientation dependency as

well: neuronal selectivity was stronger for stimuli presented at the trained orientation than for rotated versions of the same stimuli (Logothetis et al., 1995; Freedman et al., 2006).

Enhanced neuronal responsiveness and shifted cortical representation A sharpening of neuronal selectivity seen in training on discrimination of delicate changes in the related stimulus attributes implies that fewer cells would respond to the stimulus, leading to an overall decrease in neuronal activity. This speculation has been supported by some imaging studies: training on orientation discrimination (Schiltz et al., 1999) and contrast discrimination (Mukai et al., 2007) reduces activation in visual cortical areas. This is in contrast with training on detection of low-saliency targets that are presented near the contrast detection threshold or are camouflaged within a noisy background. Neuronal responsiveness is usually enhanced specifically to the familiar target when the intensity or signal-to-noise ratio of the target is low.

In a study that trained monkeys to detect visual contours embedded in a complex background, striking parallel changes were observed in response properties of V1 neurons and the behavioral performance of the animals (W. Li, Piech, & Gilbert, 2008). As illustrated in figure 8.1, visual saliency of the embedded contour increases with the number of collinear lines forming the contour. For monkeys that have never been trained on the detection task, V1 neuronal responses are independent of the presence and length of the embedded contours, regardless of whether or not the animals’ attention is directed to the target location (figure 8.4A). During the training, the animals’ ability to detect the camouflaged contours increases gradually. Correspondingly, contour-related neuronal responses, which are closely correlated with the animals’ performance on contour detection, are built up in V1 (figure 8.4B). Analyses based on signal detection theory indicate that responses of individual V1 neurons in well-trained animals are predictive of the animals’ performance in the contour detection task (see also W. Li et al., 2006). Moreover, the learning effects are specific to the trained retinotopic location in terms of both the behavioral and neuronal responses. These findings highlight the importance of a specific combination of stimulus and task, or a specific interaction between the bottom-up and top-down processes, in inducing learning-associated cortical changes. In fact, the same set of interactions is important in the retrieving process, since doing a task irrelevant to contour detection significantly reduces neuronal responses to the embedded contours in the trained animals (figure 8.4C). Furthermore, a complete removal of any potential forms of top-down influences with anesthesia, which largely spares neuronal selectivity for basic stimulus attributes, completely abolishes the contour-related responses in V1 (figure 8.4D).

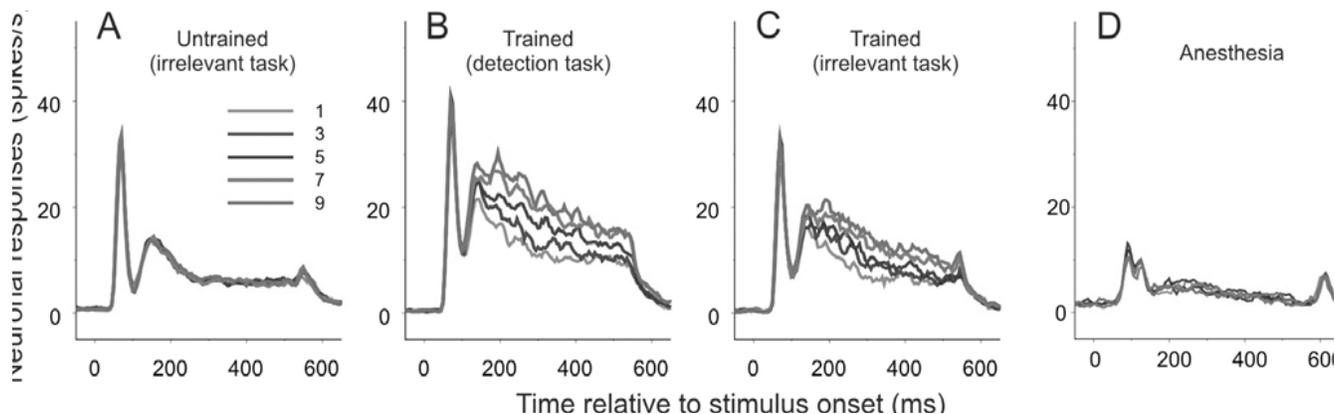

FIGURE 8.4 Learning- and task-dependent changes in V1 associated with training on contour detection. Shown here are averaged population neuronal responses to visual contours consisting of 1, 3, 5, 7, and 9 collinear lines embedded in an array of randomly oriented lines (for example see figure 8.1). Time 0 indicates stimulus onset. (A) Neuronal responses in V1 of untrained monkeys are independent of contour lengths (the six peristimulus time histograms are superimposed), indicating the absence of contour infor-

Similar to contour integration, the detection of a difference in texture between a small area and a large area surrounding it involves the horizontal integrative mechanisms. A study showed that a single session of training on such a surface segmentation task increases fMRI signals in early visual areas (Schwartz, Maquet, & Frith, 2002). A further study has shown that the maximal increases occur in the first couple of weeks of training before the subjects' detection performance reaches a plateau (Yotsumoto, Watanabe, & Sasaki, 2008). With prolonged training, the elevated fMRI signals drop back to the levels before training. This result is opposite to the electrophysiological finding that for monkeys extensively trained on contour detection, the learning-induced neuronal responses in V1 are retained (W. Li et al., 2008).

Training on detection of an isolated target near contrast threshold can also selectively boost activity in early visual cortex. After training human subjects to detect a near-threshold grating patch, the fMRI signals in V1 are significantly increased for the trained orientation (Furmanski, Schluppeck, & Engel, 2004). Enhancement of neuronal responsiveness associated with detection training has also been demonstrated in higher cortical areas along the visual processing streams. For instance, training monkeys to identify natural scene images that are degraded by noise specifically enhances V4 neuronal responses to those familiar and degraded pictures (Rainer, Lee, & Logothetis, 2004). In detection of coherent motion of dynamic random dots, an improvement in monkeys' performance is correlated by enhanced neuronal responses in areas MT and MST (Zohary, Celebrini, Britten,

mation in V1 responses. (B) Over the course of training the animals on contour detection, a late response component associated with contour saliency emerges—the longer the contours, the stronger the neuronal responses. (C) In trained animals the contour-related V1 responses are much weakened when the animals perform tasks that are irrelevant to contour detection. (D) Contour-related responses disappear in the trained V1 region under anesthesia. (Adapted from Li, Piech, & Gilbert, 2008.) (See color plate 6.)

& Newsome, 1994; but see Law & Gold, 2008, which argues that learning-associated improvement in detection of coherent motion does not involve changes in MT, but rather it largely relies on the stage that makes perceptual decisions).

Visual search can be taken as a special detection task in which a target is camouflaged in an array of similar distractors. Increased neuronal responsiveness in V1 has been reported to be associated with animals' familiarity with the target (Lee, Yang, Romero, & Mumford, 2002). In addition to heightened activity in early visual areas, learning to search for a simple geometric shape within distractors causes a concomitant decrease in fMRI signals in higher visual areas involved in shape processing (Sigman et al., 2005). This finding suggests that extensive training can shift cortical representation of the learned shape from higher to lower visual areas for more efficient and less effortful processing. This idea is further supported by the evidence that extensive training on a perceptual task significantly reduces activity in the frontoparietal cortical network for attentional control (Pollmann & Maertens, 2005; Sigman et al., 2005; Mukai et al., 2007).

Temporal code In addition to the firing rates, changes in temporal response properties of neurons have also been suggested to be related to perceptual learning. In the primary somatosensory cortex, neuronal responses become more coherent with training on tactile frequency discrimination. This change correlates better with the improved discrimination ability than does cortical recruitment (Recanzone, Merzenich, & Schreiner, 1992). Likewise, in

the primary auditory cortex, neuronal responses become more phase-locked to the trained and behavior-relevant acoustic pulses (Bao, Chang, Woods, & Merzenich, 2004). In the early visual areas of cats, gamma oscillations—an indication of response synchrony between neurons (Singer, 1999)—are increased for a behaviorally relevant visual stimulus on which the cats are trained (Salazar, Kayser, & Konig, 2004). An enhancement of coherence and synchrony in neuronal responses may reflect plastic changes at synaptic levels.

Task-specific top-down influences

Psychophysical studies reveal that perceptual learning usually does not happen simply by repeated passive exposure to a stimulus. For the same visual stimulus, a subject's performance on discrimination of a stimulus attribute can be improved only if the attribute is attended and used in the perceptual task (Shiu & Pashler, 1992; Ahissar & Hochstein, 1993; Saffell & Matthews, 2003). Moreover, the improvement does not generalize to discrimination of the other stimulus attributes of the same stimulus. Task specificity of perceptual learning indicates that top-down influences play an important role in encoding the learned information. Changes in neuronal response properties

with training exhibit similar task dependency. As mentioned earlier (figure 8.4), when a naïve monkey is passively exposed to the embedded visual contours, no change in V1 responses is observed. Most importantly, the same is true when the animal attends to the target location but does a task irrelevant to contour detection, indicating that spatial attention by itself cannot differentiate neuronal responses to contours of different lengths. The contour-related responses emerge and get strengthened only when the animal starts learning the contour detection task. These findings suggest that top-down influences are not limited to spatial attention, but can convey much more information, including information about specific perceptual tasks.

Task-dependent modification of neuronal responses has been clearly demonstrated by a physiological study (W. Li, Piech, & Gilbert, 2004) in which monkeys were trained to perform either a bisection or a vernier discrimination task with an identical set of stimulus patterns (figure 8.5). Neuronal responses in V1 are strongly modulated by the stimulus attribute relevant to the immediate task, but they are little affected by the other task-irrelevant attribute.

Taken together, accumulated evidence indicates that V1 neurons take on novel response properties related to the perceptual task over the course of perceptual learning.

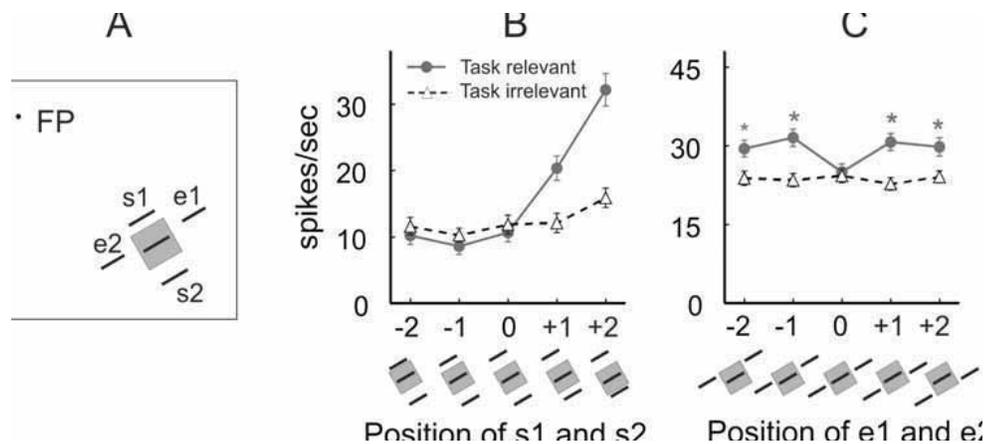

FIGURE 8.5 Task-specific top-down influences on V1 responses. (A) Monkeys were trained to do two different discrimination tasks with identical stimulus patterns at the same visual field location. The stimuli consisted of five simultaneously presented lines: an optimally oriented line fixed in the RF center and flanked by four additional lines surrounding the RF. In different trials, the arrangement of the two side flankers (s1, s2) was randomly assigned from a set of five different configurations (illustrated in the cartoons at the bottom of B, labeled from -2 to +2). Each configuration differs from the others in the separation between the three side-by-side lines (in condition 0 the three lines were equidistant; in the other conditions either s1 or s2 was closer to the central line). In the same trials, the two end-flankers (e1, e2) were also independently assigned a random configuration from a set of predefined arrangements, such that the end flankers were collinear with each other but

misaligned with the central line to either side (the cartoons at the bottom of C). The animal was cued to perform either a bisection task based on the three side-by-side lines or a vernier task based on the three end-to-end lines, using the same set of five-line stimuli. (B) Responses of a V1 cell were examined as a function of the position of the two side flankers s1 and s2 when the animal either performed the bisection task, in which s1 and s2 were task-relevant; or performed the vernier task, in which the same s1 and s2 were task-irrelevant. (C) Responses of a V1 cell were examined as a function of the position of the two end flankers e1 and e2 when the animal either performed the vernier task, in which e1 and e2 were task-relevant; or performed the bisection task, in which the same e1 and e2 were task-irrelevant (Adapted from W. Li, Piech, & Gilbert, 2004.) (See color plate 7.)

Moreover, similar to so-called state-dependent learning (for example, see Shulz, Sosnik, Ego, Haidarliu, & Ahissar, 2000), retrieval of the acquired neuronal response properties requires a recurrence of the same stimulus and task used for the training. Task-dependent modification of neuronal response properties has also been reported in auditory cortex (for review see Fritz, Elhilali, & Shamma, 2005). This cortical mechanism can account for the stimulus and task specificity of perceptual learning. The information related to a given stimulus attribute is represented at the level of subsets of inputs to a cell, which are gated by the top-down signals via interactions between feedback connections from higher cortical areas and intrinsic connections within V1. This mechanism enables multiple attributes to be represented by the same cells without crosstalk, greatly expanding the information-processing capability of neurons. The fast functional switching or multiplexing capability of visual neurons under task-specific top-down control is tightly coupled with perceptual learning, as repeated execution of the same perceptual task, and therefore, repetitive invoking of top-down influences specific to the task can potentiate the dynamic changes useful for solving the perceptual tasks, leading to encoding and retrieving of the implicit memory formed during perceptual learning.

Epilogue

Visual cortical plasticity is not limited to postnatal development and to contingent reactions induced by anomalous experiences. It is a lifelong ongoing process accompanying visual perception, as shown in various cortical changes associated with perceptual learning. There has been considerable debate about the neural basis of perceptual learning regarding the cortical loci where the plastic changes occur, since conflicting results are often reported. To derive an unbiased point of view based on the mixed results, one must take into account the nature of visual perception, which, according to Helmholtz, is nothing more than our subjective ideas or inference derived from sensory stimulation (Helmholtz, 1866). It is now evident that the generation of visual percepts depends on information processing distributed across a large number of cortical areas, such as the visual areas dedicated to sensory processing, the attentional network engaged in top-down control, and the executive network involved in making perceptual decisions. Therefore, it is not surprising that changes associated with perceptual learning could be observed in any of these cortical areas. Another complication comes from the variety of possible visual stimuli and tasks, as well as the limitation of individual approaches used in different studies. The classical fable of “the blind men and the elephant” is always good to keep in mind when considering the rigorous debate on perceptual learning and on cortical plasticity.

9 Characterizing and Modulating Neuroplasticity of the Adult Human Brain

ALVARO PASCUAL-LEONE

ABSTRACT Neurons are highly specialized structures, are resistant to change, but are engaged in distributed networks that do dynamically change over the lifespan. Changes in functional connectivity, for example by shifts in synaptic strength, can be followed by more stable structural changes. Therefore, the brain is continuously undergoing plastic remodeling. Plasticity is not an occasional state of the nervous system but is the normal ongoing state of the nervous system throughout the lifespan. It is not possible to understand normal psychological function or the manifestations or consequences of disease without invoking the concept of brain plasticity. The challenge is to understand the mechanisms and consequences of plasticity in order to modulate them, suppressing some and enhancing others, in order to promote adaptive brain changes. Behavioral, neurostimulation, and targeted neuropharmacological interventions can modulate plasticity and promote desirable outcomes for a given individual.

Human behavior is molded by environmental changes and pressures, physiological modifications, and experiences. The brain, as the source of human behavior, must thus have the capacity to dynamically change in response to shifting afferent inputs and efferent demands. However, individual neurons are highly complex and exquisitely optimized cellular elements, and their capacity for change and modification is necessarily very limited. Fortunately, these stable cellular elements are engaged into neural networks that assure functional stability while providing a substrate for rapid adaptation to shifting demands. Dynamically changing neural networks might thus be considered evolution's invention to enable the nervous system to escape the restrictions of its own genome (and its highly specialized cellular specification) and adapt fluidly and promptly to environmental pressures, physiological changes, and experiences.

Therefore, representation of function in the brain may be best conceptualized by the notion of distributed neural networks, a series of assemblies of neurons (nodes) that might

be widely dispersed anatomically but are structurally interconnected, and that can be functionally integrated to serve a specific behavioral role. Such nodes can be conceptualized as operators that contribute a given computation independent of the input (“metamodal brain”; see Pascual-Leone & Hamilton, 2001). However, the computations at each node might also be defined by the inputs themselves. Inputs shift depending on the integration of a node in a distributed neural network, and the layered and reticular structure of the cortex with rich reafferent loops provides the substrate for rapid modulation of the engaged network nodes. Depending on behavioral demands, neuronal assemblies can be integrated into *different* functional networks by shifts in weighting of connections (functional and effective connectivity). Indeed, *timing* of interactions between elements of a network, beyond integrity of structural connections, might be a critical binding principle for the functional establishment of given network action and behavioral output. Such notions of dedicated, but multifocal, networks, which can dynamically shift depending on demands for a given behavioral output, provide a current resolution to the long-standing dispute between localizationists and equipotential theorists. Function comes to be identified with a certain pattern of activation of specific, spatially distributed, but interconnected neuronal assemblies in a specific time window and temporal order. In such distributed networks, specific nodes may be critical for a given behavioral outcome. Knowledge of such instances is clinically useful to explain findings in patients and localize their lesions, but it provides an oversimplified conceptualization of brain-behavior relations. In the setting of dynamically plastic neural networks, behavior following an insult is never simply the result of the lesion, but rather the consequence of how the rest of the brain is capable of sustaining function following a given lesion. Neural plasticity can confer no perceptible change in the behavioral output of the brain, cannot lead to changes demonstrated only under special testing conditions, and cannot cause behavioral changes that constitute symptoms of disease. There may be loss of a previously acquired

ALVARO PASCUAL-LEONE Berenson-Allen Center for Noninvasive Brain Stimulation, Department of Neurology, Beth Israel Deaconess Medical Center, Boston, Massachusetts

behavioral capacity, release of behaviors normally suppressed in the uninjured brain, takeover of lost function by neighboring systems (albeit perhaps incompletely or by means of different strategies and computations), or emergence of new behaviors that may prove adaptive or maladaptive for the individual.

Therefore, plasticity is not an occasional state of the nervous system; instead, it is the normal ongoing state of the nervous system throughout the life span. A full, coherent account of any motor, sensory, or cognitive theory has to build into its framework the fact that the nervous system undergoes continuous changes in response to modifications in its input afferents and output targets. It is not possible to understand normal psychological function or the manifestations or consequences of disease without invoking the concept of brain plasticity. However, plasticity at the neural level does not speak to the question of behavioral change and certainly does not necessarily imply functional recovery or even functional change. The challenge we face is to learn enough about the mechanisms of plasticity and the mapping relations between brain activity and behavior to be able to guide them, suppressing changes that may lead to undesirable behaviors while accelerating or enhancing those that result in a behavioral benefit for the subject or patient.

Activity across neural networks changes dynamically to preserve behavior

As long as an output pathway to manifest the behavior is preserved (even if alternate pathways need to be unmasked or facilitated), changes in the activity across a distributed neural network may be able to establish new patterns of brain activation and sustain function, even in the face of a focal insult.

This dynamic changing capacity of neural networks is illustrated by the following experiment (Pascual-Leone, Amedi, Fregni, & Merabet, 2005). Normal subjects were asked to open and close their fist deliberately at a self-paced rhythm of approximately one movement every second while lying in an fMRI scanner. As compared with rest, during movement there was a significant activation of the primary motor cortex (M1) contralateral to the moving hand and of the rostral supplementary motor cortex (SMA) (figure 9.1A). If motor cortex activity is modified by repetitive transcranial magnetic stimulation (TMS), the pattern of brain activation changes while behavioral integrity is maintained (figure 9.1A). Slow, repetitive TMS (rTMS) suppresses activity in the targeted cortical area (Valero-Cabre, Payne, & Pascual-Leone, 2007; Valero-Cabre, Payne, Rushmore, Lomber, & Pascual-Leone, 2005). After slow rTMS has been applied to the contralateral M1, the subjects are able to sustain behavior, but they reveal an increased activation of the rostral

SMA and of M1 ipsilateral to the moving hand. Conversely, increasing excitability in the contralateral M1 (by application of fast rTMS; Valero-Cabre et al., 2007, 2005) is associated with a decrease in activation of rostral SMA.

Lee and colleagues (2003), combining TMS and positron emission tomography (PET), have revealed the shifts in cortico-cortical and cortico-subcortical connectivity underlying the changes in cortical activation patterns that are associated with sustained behavior in the face of focal cortical disruption (figure 9.1B). Following repetitive TMS (rTMS), motor performance remained unchanged while task-dependent increases in regional cerebral blood flow (rCBF) were seen during movement in the directly stimulated M1 and the dorsal premotor cortex. Analyses of effective connectivity showed that after rTMS there is a remodeling of the motor system, with increased movement-related connectivity from the SMA and premotor cortex to sites in primary sensorimotor cortex.

Thus, in the face of an imposed disruption of focal brain activity, performance of a relatively simple task can be maintained by rapid operational remapping of representations, recruitment of additional brain areas, and task-related changes in cortico-cortical and cortico-muscular coherence (Chen et al., 2003; Lee et al., 2003; Oliviero, Strens, Di Lazzaro, Tonali, & Brown, 2003; Strens, Fogelson, Shanahan, Rothwell, & Brown, 2003). However, under other circumstances, modulation of activity in a focal node of a distributed neural network can give rise to changes in behavior in a controlled and specific manner. For example, a right parietal lesion can result in spatial neglect (the failure to explore contralesional space), yet remarkably, the neglect symptoms can completely and abruptly disappear following a second lesion to the left frontal cortex (Vuilleumier, Hester, Assal, & Regli, 1996) (figure 9.2A). Such a paradoxical effect of a brain lesion (Kapur, 1996), resulting in a behavioral improvement, is consistent with animal studies by Sprague (Sprague, 1966) and later Payne and Lomber (Payne, Lomber, Geeraerts, van der Gucht, & Vandebussche, 1996). Given reciprocal interhemispheric inhibition and the proposed link to attentional performance, suppression of one parietal cortex may lead to contralateral neglect, but at the same time, the disinhibition of structures involved in interhemispheric competition might lead to a functional release in the opposite hemisphere, which could result in a measurable ipsilateral behavioral enhancement. Indeed, Hilgetag, Theoret, and Pascual-Leone (2001) provided experimental support for such notions. Normal subjects had to detect small rectangular stimuli briefly presented on a computer monitor either unilaterally in the left or right periphery, or bilaterally in both. Spatial detection performance was tested before and immediately after a 10-minute, 1-Hz rTMS train to (a) right parietal cortex; (b) left parietal

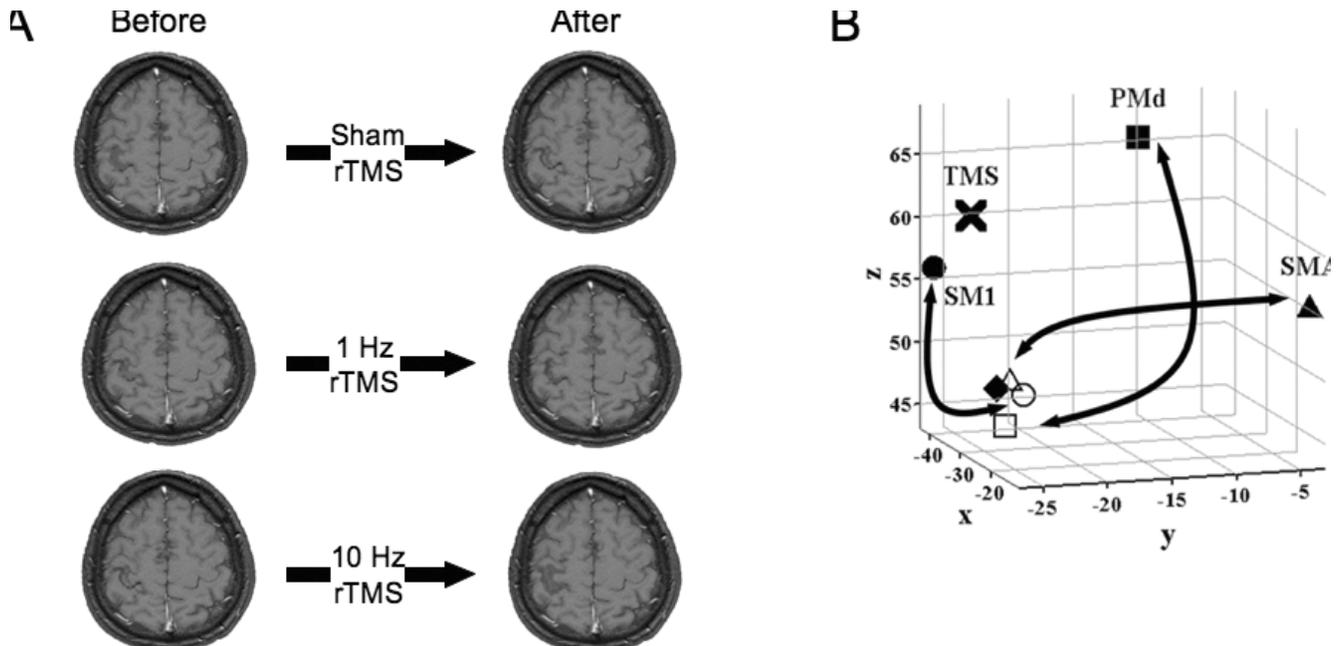

FIGURE 9.1 (A) Brain activation in fMRI while subjects performed the same rhythmic hand movement (under careful kinematic control) before and after repetitive transcranial magnetic stimulation (rTMS) of the contralateral motor cortex. Following sham rTMS (*top row*) there is no change in the significant activation of the motor cortex (M1) contralateral to the moving hand and of the rostral supplementary motor cortex (SMA). After M1 activity is suppressed using 1-Hz rTMS (1,600 stimuli, 90% of motor threshold intensity; *middle row*), there is an increased activation of the rostral SMA and of M1 ipsilateral to the moving hand. Increasing excitability in the contralateral M1 using high-frequency rTMS

(20 Hz, 90% of motor threshold intensity, 1,600 stimuli; *bottom row*) results in a decrease in activation of rostral SMA. (See color plate 8.) (B) Areas of the brain showing differential movement-related responses and coupling after rTMS. Circle, square, and triangle symbols indicate sites in primary motor cortex (*open symbols*) that are more strongly coupled to activity in sensorimotor cortex (SM1), dorsal premotor cortex (PMd), and supplementary motor cortex (SMA) during a finger movement task after rTMS. X marks the site of stimulation with 1-Hz rTMS. (B) modified from Lee and colleagues (2003).

cortex; (c) right primary motor cortex; and (d) sham stimulation. Hilgetag and colleagues observed a clear extinction phenomenon for stimuli presented contralaterally to the stimulated hemisphere (right or left parietal cortex). However, the deficit was accompanied by increased detection for unilateral stimuli presented on the side of the stimulated hemisphere compared to baseline (figure 9.2B). None of the control stimulation sites had any effect on the detection performance. These insights can be translated to parietal-damaged patients with neglect, in whom rTMS to the undamaged (frequently left) hemisphere can alleviate hemi-inattention symptoms (Brighina et al., 2003; Oliveri et al., 1999).

Therefore, activity in neural networks is dynamically modulated, and this fact can be illustrated by the neurophysiological adaptations to focal brain disruptions or lesions. Behavioral outcome, however, does not map in a fixed manner to changes in activity in distributed networks. Thus changes in network activity can give rise to no behavioral change, behavioral improvements, or losses. The frequently held notion that the brain optimizes behavior is therefore

not correct, for it implies, for example, that a lesion to the brain will always lead to a loss rather than enhancement of function. In fact, we have seen that this view is challenged by the conceptualization of the brain as endowed with dynamic plasticity.

However, the scope of possible dynamic changes across a given neural network is defined by existing connections. Genetically controlled aspects of brain development define neuronal elements and initial patterns of connectivity. Given such initial, genetically determined, individually different brain substrates, the same events will result in diverse consequences as plastic brain mechanisms act upon individually distinct neural substrates. Similarly, within each individual, differences across neural networks (e.g., visual system, auditory system, or language system) will also condition the range of plastic modification (Bavelier & Neville, 2002; Neville & Bavelier, 2002). Plastic changes across brain systems vary as a function of differences in patterns of existing connections and in molecular and genetically controlled factors across brain systems that define the range, magnitude, stability, and chronometry of plasticity.

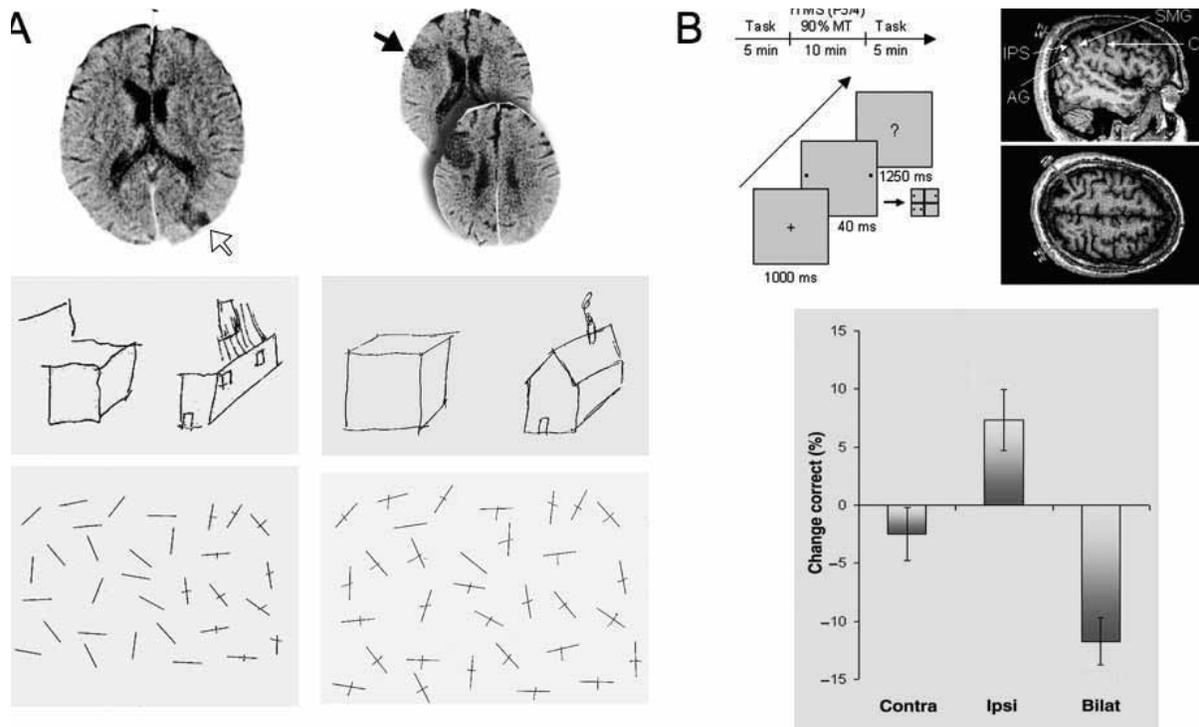

FIGURE 9.2 (A) Findings of neglect in house-drawing and line-cancellation tasks (left panel) due to a right parietal stroke (open arrow). The signs of neglect acutely resolved (right panel) as a consequence of a second stroke in the left, frontal cortex (filled arrow). (Modified from Vuilleumier, Hester, Assal, & Regli, [1996].) (B) Impact of image-guided rTMS to the right parietal cortex on a visual stimulus detection task. During the task subjects were presented with carefully titrated visual stimuli on the right, left, or bilateral side of a computer monitor (top left) and had to respond by pressing the appropriate response button (right, left, or both). TMS was applied

guided by the subject's own anatomical MRI using a frameless stereotaxic system (top right). There was a decrease in contralateral performance (neglect) but an even greater increase in performance ipsilateral to the parietal rTMS location (bottom). This summed up to a significant decrease in bilateral stimuli, where subjects neglected the contralateral stimulus and responded as if only the ipsilateral one had been presented (extinction of double simultaneous stimulation). (B modified from Hilgetag, Theoret, & Pascual-Leone, [2001]). (See color plate 9.)

Dynamic network changes can be followed by more stable plastic changes

Rapid, ongoing changes in neural networks in response to environmental influences (for example, by dynamic shifts in the strength of preexisting connections across distributed neural networks, changes in task-related cortico-cortical and cortico-subcortical coherence, or modifications of the mapping between behavior and neural activity) may be followed by the establishment of new connections through dendritic growth and arborization resulting in structural changes and establishment of new pathways.

These two steps of plasticity are illustrated by the following experiment (Pascual-Leone et al., 1995). Normal subjects were taught to perform with one hand a five-finger exercise on a piano keyboard connected to a computer through a musical interface. They were instructed to perform the sequence of finger movements fluently, without pauses, and without skipping any keys, while paying particular attention to keeping the interval between the individual key presses constant and the duration of each key press the same. A

metronome gave a tempo of 60 beats per minute for which the subjects were asked to aim, as they performed the exercise under auditory feedback. Subjects were studied on five consecutive days, and each day they had a two-hour practice session followed by a test. The test consisted of the execution of 20 repetitions of the five-finger exercise. The number of sequence errors decreased, and the duration, accuracy, and variability of the intervals between key pushes (as marked by the metronome beats) improved significantly over the course of the five days. Before the first practice session on the first day of the experiment and daily thereafter, we used TMS to map the motor cortical areas targeting long finger flexor and extensor muscles bilaterally. As the subjects' performance improved, the threshold for TMS activation of the finger flexor and extensor muscles decreased steadily. Even considering this change in threshold, the size of the cortical representation for both muscle groups increased significantly (figure 9.3A, Week 1). Remarkably, this increase in size of the cortical output maps could be demonstrated only when the cortical mapping studies were conducted shortly after the practice session, but no longer the next day, after a night

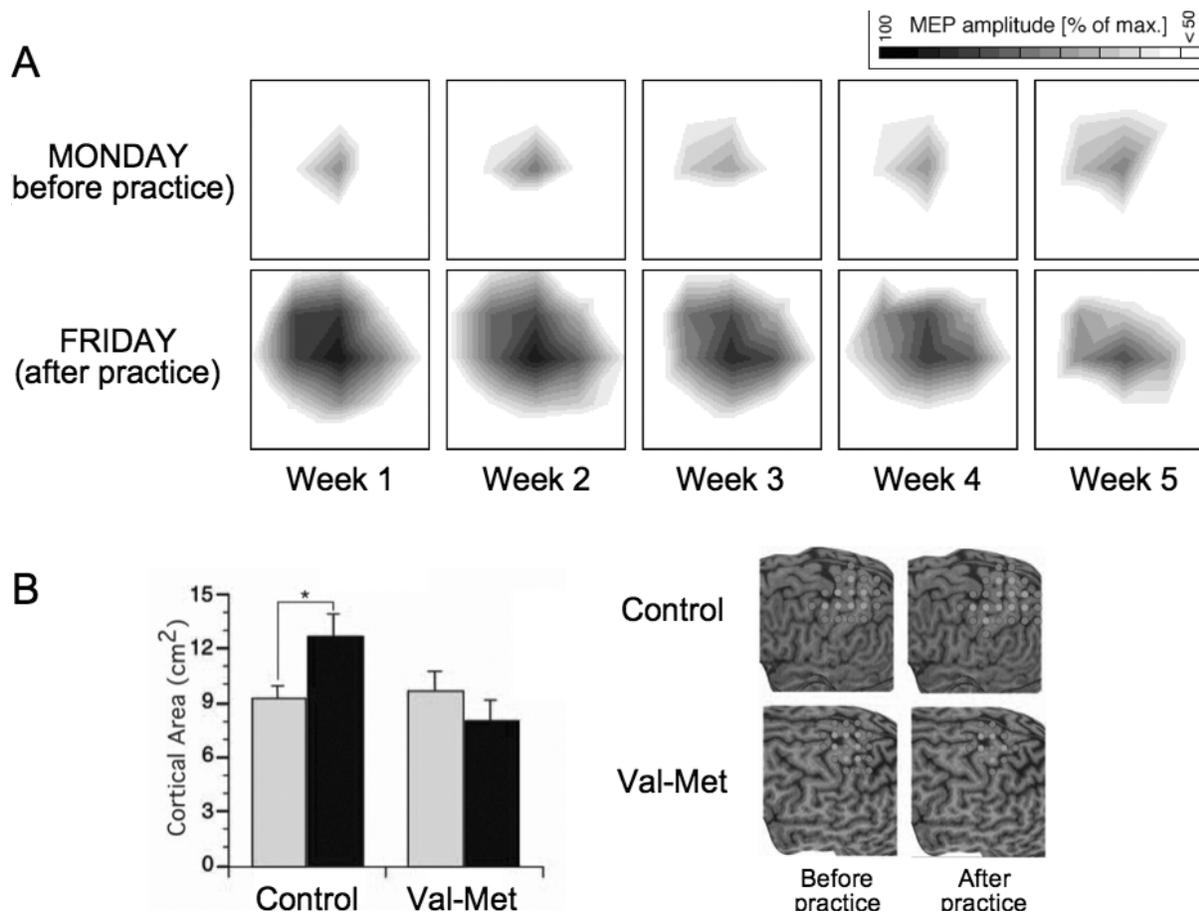

FIGURE 9.3 (A) Cortical output maps for the finger flexors during acquisition of a five-finger movement exercise on a piano. There are marked changes of the output maps for finger flexors of the trained hand over the five weeks of daily practice (Monday to Friday). Note that there are two distinct processes in action, one accounting for the rapid modulation of the maps from Mondays to Fridays and the other responsible for the slow and more discrete changes in Monday maps over time. (Modified from Pascual-Leone, 1996; Pascual-Leone et al., 1995.) (B) Histogram displaying the size of the cortical output maps before (gray bars) and after

exercise (black bars) in control subjects and subjects with a val66met polymorphism for BDNF (left side). Following exercise, control subjects had significantly larger representations than at baseline, whereas subjects with a Met allele did not show a significant change. This difference is further illustrated by the representative motor maps from control and Val-Met polymorphism subjects superimposed onto a composite brain MRI image of the cortex (right side). Sites from which TMS evoked criterium responses in the target muscle are marked in green; negative sites are marked in red. (Modified from Kleim et al., 2006.) (See color plate 10.)

of sleep and before the next day's practice session. Interestingly, even such initial steps of experience- and practice-related plasticity seem critically regulated by genetic factors. Kleim and colleagues (2006) used TMS to map cortical motor output and show that training-dependent changes in motor-evoked potentials and motor map organization are reduced in subjects with a val66met polymorphism in the brain-derived neurotrophic factor (BDNF) gene, as compared to subjects without the polymorphism (figure 9.3B).

Once a near-perfect level of performance was reached at the end of a week of daily practice, subjects continued daily practice of the same piano exercise during the following four weeks (Group 1) or stopped practicing (Group 2) (Pascual-Leone, 1996). During the four weeks of follow-up (figure 9.3A, Weeks 2–5), cortical output maps for finger flexor and extensor muscles were obtained in all subjects on Mondays

(before the first practice session of that week in Group 1) and on Fridays (after the last practice session for the week in Group 1). In the group that continued practicing (Group 1), the cortical output maps obtained on Fridays showed an initial peak and eventually a slow decrease in size despite continued performance improvement. However, the maps obtained on Mondays, before the practice session and following the weekend rest, showed a small change from baseline with a tendency to increase in size over the course of the study. In Group 2, the maps returned to baseline after the first week of follow-up and remained stable thereafter.

This experiment illustrates two distinct phases of modulation of motor output maps. The rapid time course in the initial modulation of the motor outputs, by which a certain region of motor cortex can reversibly increase its influence on a motoneuron pool, is most compatible with

the unmasking of previously existing connections. Supporting this notion, the initial changes are quite transient: demonstrable after practice, but returning to baseline after a weekend rest. As the task becomes overlearned over the course of five weeks, the pattern of cortical activation for optimal task performance changes as other neural structures take a more leading role in task performance. Flexible, short-term modulation of existing pathways represents a first and necessary step leading up to longer-term structural changes in the intracortical and subcortical networks as skills become overlearned and automatic. A growing number of neuroimaging studies have suggested a similar two-step process (Grafton et al., 1992; Jenkins, Brooks, Nixon, Frackowiak, & Passingham, 1994; Karni et al., 1995, 1998; Seitz, Roland, Bohm, Greitz, & Stone, 1990), and animal studies support the notion of different processes involved, over time, in early acquisition and later consolidation of skill learning (Kleim et al., 2004).

Two complementary mechanisms control plasticity

As indicated in the preceding section, dynamic network changes can lead to more stable plastic changes, which involve synaptic plasticity as well as dendritic arborization and network remodeling. Such changes might be conceptualized as the result of a balance between two complimentary mechanisms—one promoting and the other limiting plasticity (figure 9.4). Both these mechanisms are critical in assuring that appropriate synapses are formed and unnecessary synapses are pruned in order to optimize functional systems necessary for cognition and behavior. Though the molecular mechanisms that contribute to plasticity are numerous and complex, the plasticity-promoting mechanism appears to be critically dependent on the neurotrophin BDNF (brain-derived neurotrophic factor) (Lu, 2003), while genes within the major histocompatibility complex (MHC) Class I appear to be involved in the plasticity-limiting mechanism (Boulanger, Huh, & Shatz, 2001; Huh et al., 2000).

At the synaptic level, mechanisms of long-term potentiation (LTP) and long-term depression (LTD) involve a series of induction and consolidation steps that are dependent on various structural changes and can be modified, increased, or suppressed by distinct modulatory influences (Lynch, Rex, & Gall, 2007). LTP is initiated by the influx of calcium through glutamate receptors in the postsynaptic density. Calcium-activated kinases and proteinases disassemble the cytoskeleton, made up of actin filaments cross-linked by spectrin and other proteins, that normally maintains the shape of the dendritic spines. Thus the spine becomes rounder and shorter, effectively enlarging the surface of the postsynaptic density, which can then accept a greater number of glutamate receptors and provide better access to proteins

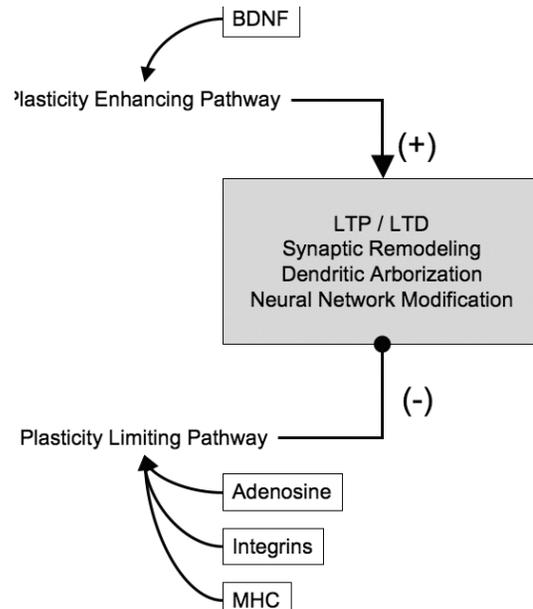

FIGURE 9.4 A schematic diagram of the conceptualization of plasticity as the balance of plasticity-enhancing and plasticity-limiting mechanisms, which are dependent on different neuromodulators.

that enhance current flow through the receptors. In parallel, signaling from adhesion receptors, particularly integrins, and modulatory receptors, particularly BDNF, induces the rapid polymerization of actin and the formation of a new cytoskeleton. This polymerization of actin filaments consolidates the new dendritic spine morphology and thus the LTP. Despite the complexity of such a process and the numerous molecules involved, BDNF appears to be the most potent enhancer of plasticity discovered thus far, playing a critical role in LTP consolidation across multiple brain regions. BDNF has been shown to facilitate LTP in the visual cortex (Akaneya, Tsumoto, Kinoshita, & Hatanaka, 1997) and the hippocampus (Korte et al., 1995). At CA1 synapses, a weak tetanic stimulation, which in and of itself would only induce short-term potentiation of low magnitude, leads to strong LTP when paired with BDNF (Figurov, Pozzo-Miller, Olafsson, Wang, & Lu, 1996). During motor training, BDNF levels are elevated within motor cortex (Klintsova, Dickson, Yoshida, & Greenough, 2004), and human subjects who have a single nucleotide polymorphism in the BDNF gene (val66met) show reduced experience-dependent plasticity of the motor cortex following a voluntary motor task (Kleim et al., 2006).

In contrast, adenosine (Arai, Kessler, & Lynch, 1990) and ligands for integrins (Staubli, Vanderklish, & Lynch, 1990) block LTP when applied immediately after theta burst stimulation because of the disruption of actin polymerization and LTP consolidation. Along these lines, a blind screen for

genes involved in normal developmental activity-dependent remodeling of neuronal connectivity revealed a region of DNA better known for its role in immune functioning, namely Class I major histocompatibility complex (Class I MHC) (Corriveau, Huh, & Shatz, 1998). More recent studies suggest that MHC Class I genes are an integral part of an experience-dependent plasticity-limiting pathway (Syken, Grandpre, Kanold, & Shatz, 2006). Such negative modulators of synaptic plasticity are needed. Establishing and strengthening new synapses is an important part of developmental plasticity, but this has to be coupled with normal regressive events including activity-dependent synaptic weakening and elimination of inappropriate connections. Without these regressive events, superfluous synapses may persist and may impair normal neural development.

Therefore, different modulators, including BDNF on the one side and adenosine or MHC Class I genes on the other, serve complimentary functions that lead to the development and rapid modulation of functional circuits across the whole brain. Such dynamic systems do harbor potential dangers, and disruption of these pathways or their relative balance may lead to severe pathological states. However, these opposing pathways offer the opportunity for interventions and thus for guiding plasticity for the benefit of individual subjects.

Plasticity as the cause of disease

Focal hand dystonia (Quartarone, Siebner, & Rothwell, 2006) may be a good example of pathological consequences of plasticity that can be promoted by suitable genetic predispositions, such as DYT-1 or others. Importantly, though, the mere induction of certain plastic changes is not sufficient to lead to disability. Similar plastic changes can be documented in patients with focal dystonia and proficient musicians (Quartarone et al., 2006; Rosenkranz, Williamon, & Rothwell, 2007). Furthermore, musicians can develop focal hand dystonia (Chamagne, 2003), and the underlying pathophysiology appears to be slightly different than in other forms of dystonia, such as writer's cramp (Rosenkranz et al., 2008). Perhaps "faulty" practice or excessive demand in the presence of certain predisposing factors may result in unwanted cortical rearrangement and lead to disease. It seems clear, though, that plastic changes in the brain do not speak to behavioral impact. Similar changes can be associated with behavioral advantages (as in the professional musicians) or neurological disability (as in the case of focal dystonia), presumably on the basis of modulatory influences from distributed neural activity.

Chronic, neuropathic pain syndromes have also been argued to represent "pathological" consequences of plasticity (Flor, 2008; Fregni, Pascual-Leone, & Freedman, 2007; Zhuo, 2008). Tinnitus may be the result of plasticity in

the auditory system induced by abnormal cochlear input (Bartels, Staal, & Albers, 2007). Schizophrenia, depression, posttraumatic stress disorder, and attention-deficit/hyperactivity disorder are all conditions that may, in part, represent disorders of brain plasticity (Frost et al., 2004; Hayley, Poulter, Merali, & Anisman, 2005; Rapoport & Gogtay, 2008). Drug addiction and perhaps addictive behaviors in general are argued to represent examples of pathology as the consequence of plasticity (Kalivas & O'Brien, 2008; Kauer & Malenka, 2007). Alzheimer's disease appears to be linked to abnormal synaptic plasticity that may in fact constitute a crucial initial step in the pathogenesis of the disease (Selkoe, 2008). Autism may be another example of plasticity-mediated pathology: genetic factors may lead to a predisposition such that developmentally mediated plasticity (possibly in itself controlled by abnormal regulators) results in pathological complex behaviors affecting social interactions, language acquisition, or sensory processing (Morrow et al., 2008).

Therefore, human behavior and the manifestations of human disease are ultimately heavily defined by brain plasticity. An initial, genetically determined neural substrate is modified during development and environmental interactions by plasticity. The processes of neural plasticity themselves can be normal, but may act upon an abnormal nervous system as a consequence of genetic or specific environmental factors. Alternatively, the mechanisms of plasticity themselves may be abnormal, potentially compounding the consequences of an abnormal substrate on the basis of a genetically determined "starting point" or environmental insult. In any case, interventions to guide behavior or treat pathological symptomatology might be more immediate in their behavioral repercussions and thus more effective if aimed at modulating plasticity than if intent on addressing underlying genetic predispositions.

Fragile X syndrome provides a suitable illustration for such notions (Bear, Dolen, Osterweil, & Nagarajan, 2008; O'Donnell & Warren, 2002; Penagarikano, Mulle, & Warren, 2007). The genetic mutation responsible for fragile X syndrome, *FMRI*, leads to the absence of the encoded protein FMRP, which appears to play an important role in synaptic plasticity by regulating metabotropic-glutamate-receptor-dependent LTD. Thus in the absence of FMRP there is excessive experience-dependent LTD. Mouse models of fragile X syndrome have also demonstrated impairments in LTP, possibly as a result of immature development of dendritic spines. However, the application of BDNF to slices from FMR1 knockout mice fully restores LTP to normal levels (Lauterborn et al., 2007), and thus it might be possible to normalize cognitive function and behavior in patients with fragile X by pharmacologically "normalizing" the affected mechanisms of plasticity.

Plasticity as an opportunity for intervention

The plastic nature of the brain provides, following injury, a risk of maladaptive change and perpetuation of deficits, but also an opportunity for intervention and overcoming of symptoms. Following brain injury, behavior (regardless of whether normal or manifesting injury-related deficits) remains the consequence of the functioning of the entire brain, and thus the consequence of a plastic nervous system. Ultimately, symptoms are not the manifestation of the injured brain region, but rather the expression of plastic changes in the rest of the brain. Following an insult, cortico-cortical and cortico-subcortico-cortical interactions will shift weights across the involved neural network, aiming to adapt to the functional disruption and establish a suitable brain activation map for a desired behavioral result. Different mechanisms, which may proceed partly in parallel but which have variable time frames, are likely involved. Initial plastic changes aim to minimize damage. Dysfunctional, but not damaged, neuronal elements may recover from the postinjury shock and penumbra processes. Partially damaged neural elements may be able to be repaired relatively quickly after the insult as well, thus contributing to early functional improvement. Subsequent processes, once the final damage has been established, involve relearning (rather than recovery) and may, as we have discussed, follow a two-step process: initial unmasking and strengthening of existing neural pathways, and eventually the establishment of new structural changes. At all these stages of plastic adaptation, neurostimulation and targeted neuropharmacological interventions may be able to guide the neural processes and promote adaptive, desirable outcomes for a given individual.

Consider, for example, the recovery of hand motor function following a stroke (Alonso-Alonso, Fregni, & Pascual-Leone, 2007; Cramer & Riley, 2008; Di Filippo et al., 2008; Nudo, 2006). After stroke, there is an increase in the excitability of the unaffected hemisphere, presumably owing to reduced transcallosal inhibition from the damaged hemisphere and increased use of the intact hemisphere. For example, in patients with acute cortical stroke, intracortical inhibition is decreased and intracortical facilitation increased in the unaffected hemisphere (Liepert, Storch, Fritsch, & Weiller, 2000). Furthermore, the interhemispheric inhibitory drive from the unaffected to the affected motor cortex in the process of voluntary movement generation is abnormal (Murase, Duque, Mazzocchio, & Cohen, 2004), and this imbalance of excitability between the hemispheres is inversely correlated with the time since the stroke (Shimizu et al., 2002).

Acutely after a stroke, increased inhibitory input from the undamaged to the damaged hemisphere makes conceptual sense if one considers it a manifestation of a neural

attempt to control perilesional activity, reduce oxygen and glucose demands in the penumbra of the stroke, and thus limit the extension of the lesion. However, after an acute phase, and once the injury is stable, input to the perilesional area would seem to be best as excitatory in nature to maximize the capability of the preserved neurons in the injured tissue to drive behavioral output. If so, following the acute phase, we might expect a shift of interhemispheric (and many intrahemispheric) interactions from inhibitory to excitatory. Should such a shift fail to take place, the resulting functional outcome may be undesirable, with limited behavioral restoration, in part owing to persistent inhibitory inputs from the intact to the damaged hemisphere. In fact, some neuroimaging studies demonstrate that long-term, persistent activation of the ipsilateral cortex during motor tasks is associated with poor motor outcomes, whereas a good motor recovery is associated with a decrease in activity in the unaffected area and an increase in the affected primary sensorimotor cortex activity (Fregni & Pascual-Leone, 2006; Rossini et al., 2007; Ward & Cohen, 2004). If so, neuromodulatory approaches targeting the intact hemisphere may be useful to limit injury and promote recovery after a stroke. For instance, suppression of the ipsilateral motor cortex through slow rTMS may enhance motor performance in patients stable following the acute phase of a stroke (figure 9.5). In patients 1–2 months after a stroke, Mansur and colleagues (2005) applied 0.5 Hz rTMS for 10 min to the unaffected hemisphere to suppress cortical activity and thus release the damaged hemisphere from potentially excessive transcallosal inhibition. The results of this study support the notion that the overactivity of the unaffected hemisphere (ipsilateral hemisphere) may hinder hand-function recovery, and neuromodulation can be an interventional tool to accelerate this recovery. However, Werhahn, Conforto, Kadom, Hallett, and Cohen (2003) conducted a similar study to evaluate the modulation effects of 1 Hz rTMS of the unaffected hemisphere on the paretic hand and found different results. In that study, 1 Hz rTMS of the unaffected hemisphere did not affect the finger tapping in the paretic hand in a small sample of five patients more than one year after a stroke. The time since the brain insult is likely to be a critical variable to consider.

Of course, the alternative neuromodulatory approach, directly aimed at enhancing excitability of the damaged hemisphere perilesionally, can also be entertained. Khedr, Ahmed, Fathy, and Rothwell (2005) have reported extremely encouraging results along these lines. Similar principles of neuromodulation can be applied to the recovery of nonmotor strokes and other focal brain lesions as illustrated by studies on the effects of cortical stimulation on neglect discussed earlier (Brighina et al., 2003; Hilgetag et al., 2001; Oliveri et al., 1999) or the experience with aphasia (Martin

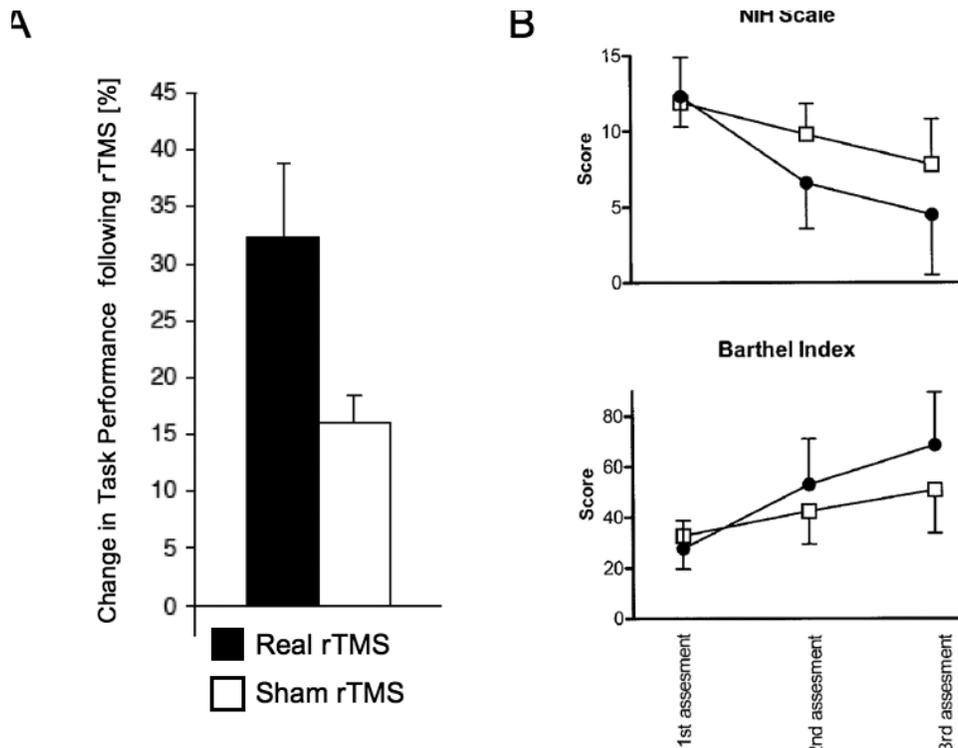

FIGURE 9.5 (A) Histogram illustrates the significant improvement in performance of the Purdue Pegboard task in stroke patients (on average 12 months after the stroke) following real (but not sham) slow-frequency repetitive transcranial magnetic stimulation (rTMS) to the unaffected hemisphere to decrease interhemispheric inhibition of the lesioned hemisphere and improve motor function. (Modified from Mansur et al., 2005.) (B) Serial assessments in

patients with acute ischemic strokes undergoing 10 days of daily sessions of real or sham, fast rTMS over the affected motor cortex. Disability scales (Barthel Index and NIH Stroke Scale) measured before rTMS, at the end of the last rTMS session, and 10 days later show that real rTMS (filled symbols) improved patients' scores significantly more than sham (open symbols). (Modified from Khedr, Ahmed, Fathy, & Rothwell, 2005.)

et al., 2004; Naeser et al., 2005). However, challenges for such approaches remain, as our understanding of the various issues involved and how to optimize and individualize the neuromodulatory interventions is still rather sketchy. In any case, neuromodulatory approaches based on brain stimulation techniques are certainly not the only potential avenues to guide plasticity with therapeutic intent. Behavioral interventions, including technology-supported approaches, such as robotic or computerized task training, as well as pharmacological methods, might be equally effective.

A most intriguing question to consider is the possibility of similarly modulating plasticity in the attempt to promote functional gains in normal subjects (Canli et al., 2007; de Jongh, Bolt, Schermer, & Olivier, 2008; Farah et al., 2004; Lanni et al., 2008). Might it, for example, be possible to promote skill acquisition or verbal or nonverbal learning by enhancing certain plastic processes and suppressing others? This type of question raises important ethical issues, but also offers the potential for interventions that might be applicable in educational settings and translationally to patients. For example, consistent with the findings in recovery of hand motor function after a stroke, noninvasive cortical stimulation that suppresses excitability in the M1

ipsilateral or enhances excitability in the M1 contralateral to a training hand might result in varying degrees of improvement in motor function in healthy humans. Anodal transcranial direct current stimulation (tDCS) applied over M1 to increase its excitability before or during practice can lead to improvements in implicit motor learning as measured with the serial reaction time task (Nitsche et al., 2003), performance of a visuomotor coordination task (Antal et al., 2004) and a sequential finger movement task (Vines, Nair, & Schlaug, 2006), and performance of the Jebsen Taylor Hand function test (JTT) (Boggio et al., 2006). Similarly, the application of 1-Hz rTMS to suppress excitability of M1 ipsilateral to a training hand results in improvements in motor sequence learning (Kobayashi, Hutchinson, Théoret, Schlaug, & Pascual-Leone, 2004). However such effects might be task and condition specific. For example, learning of a more complex finger tracking task was not modified by the same 1 Hz rTMS to suppress excitability of M1 ipsilateral to a training hand (Carey, Fregni, & Pascual-Leone, 2006), and the beneficial effects of anodal tDCS to the contralateral hand in the JTT were limited to the non-dominant hand in young healthy adults and the elderly (Boggio et al., 2006).

Conclusions

The brain is highly plastic, and that plasticity represents evolution's invention to enable the nervous system to escape the restrictions of its own genome (and its highly specialized cellular specification) and adapt to rapidly shifting and often unpredictable environmental and experiential changes. Plastic changes may not necessarily represent a behavioral gain for a given subject. Instead, plasticity may be as much a cause of pathology and disease as it is the substrate for skill acquisition, learning, environmental adaptation, and recovery from insult. Recovery of function after a focal brain injury, such as a stroke, is essentially learning with a partially disrupted neural network and illustrates the dangers and opportunities of such a plastic brain. We might conceive of a two-step process of plasticity, with initial rapid modulation of connectivity across neural networks possibly followed by more stable, structural changes. Both these steps can be conceptualized as regulated by distinct plasticity-enhancing and plasticity-suppressing mechanisms that may account for different pathologies, but also offer targets for neuromodulatory and targeted neuropharmacological interventions to promote shifts in brain-behavior mapping that might be most adaptive for a given individual.

10 Exercising Your Brain: Training-Related Brain Plasticity

DAPHNE BAVELIER, C. SHAWN GREEN, AND MATTHEW W. G. DYE

ABSTRACT Learning and brain plasticity are fundamental properties of the nervous system, and they hold considerable promise when it comes to learning a second language faster, maintaining our perceptual and cognitive skills as we age, or recovering lost functions after brain injury. Learning is critically dependent on experience and the environment that the learner has to face. A central question then concerns the types of experience that favor learning and brain plasticity. Existing research identifies three main challenges in the field. First, not all improvements in performance are durable enough to be relevant. Second, the conditions that optimize learning during the acquisition phase are not necessarily those that optimize retention. Third, learning is typically highly specific, showing little transfer from the trained task to even closely related tasks. Against these limiting factors, the emergence of complex learning environments provides promising new avenues when it comes to optimizing learning in real-world settings.

The ability to learn is fundamentally important to the survival of all animals. Brain plasticity, together with the learning it enables, therefore embodies a pivotal evolutionary force. The human species appears remarkable in this respect, as more than a century of research has demonstrated that humans possess the ability to acquire virtually any skill given appropriate training. Yet, while the exceptional capacity of humans to learn should certainly reassure those seeking to design educational or rehabilitative training programs, there are still several key obstacles that need to be overcome before these programs can reach their full potential.

The first is that brain plasticity is typically highly specific. While individuals trained on a task will improve on that very task, other tasks, even closely related ones, often show little or no improvement. Obviously, this obstacle potentially limits the benefits of learning-based interventions, be they educational or clinical. After all, it is of little use to improve the performance of a stroke patient on a visual motion task in the laboratory if this same training will not allow her to effectively see moving cars as she tries to safely cross the street.

The second obstacle is that while brain plasticity is typically adaptive and beneficial, it can also be maladaptive, dramatically so at times, as when expert string musicians suffer from dystonia or motor weaknesses in their fingers as a result of extensive practice with their instruments.

Finally, and subsumed in the first two obstacles, is the fact that we are still missing the recipe for successful brain plasticity intervention at the practical level. Our current understanding of the causal relationship between one type of training experience and the functional changes it induces through brain plasticity is still very much incomplete.

However, progress is being made in each of these areas. In particular, research in recent years has revealed the potential benefits of what are sometimes termed complex learning environments. These appear to promote behaviorally beneficial plastic changes at a more general level than previously seen. This chapter provides an overview of these recent advances.

Specificity of learning

In the field of learning, transfer of learning from the trained task to even other very similar tasks is generally the exception rather than the rule. This fact is well documented in the field “perceptual learning” literature. For instance, Fiorentini and Berardi (1980) trained subjects to discriminate between two complex gratings that differed only in the relative spatial phase of the two component sinusoids (figure 10.1A). Performance on this task improved very rapidly over the course of a single training session and remained consistently high when subjects were tested on two subsequent days. However, when the gratings were rotated by 90 degrees or the spatial frequency was doubled, no evidence of transfer was observed (figure 10.1B). Specificity has also been demonstrated in the discrimination of oriented texture objects, where learning is specific to the location and orientation of the trained stimuli (Karni & Sagi, 1991), in the discrimination of dot motion direction, where the learning is specific to the direction and speed of the trained stimuli (Ball & Sekuler, 1982; Saffell & Matthews, 2003), and in some types of hyperacuity tasks, where in addition to being specific for location and orientation, learning can even be specific for the trained eye (Fahle, 2004).

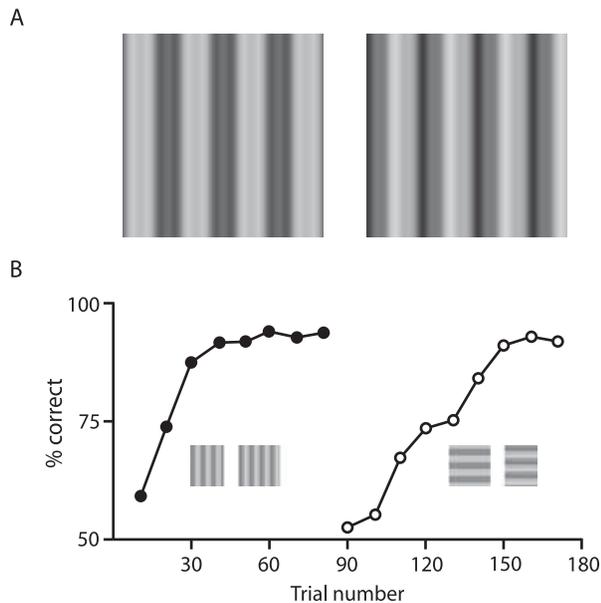

FIGURE 10.1 (A) Schematic illustration of the stimulus gratings to be discriminated in Fiorentini and Berardi (1980). (B) Subjects' performance on the vertical gratings improved steadily as training proceeded. Yet, when the gratings were abruptly rotated by 90 degrees halfway through the session, performance dropped back to pretraining levels, illustrating the high specificity of the learning.

Similar examples of specificity can also be found in the motor domain (Bachman, 1961; Rieser, Pick, Ashmead, & Garing, 1995). For example, participants trained to aim at a target with their aiming hand visible demonstrate increases in the speed and accuracy of their aiming movements. However, these improvements do not transfer to conditions in which the aiming hand is not visible (Proteau, 1992). In prism adaptation studies, subjects wear goggles that displace the visual world laterally, thus requiring a recalibration of the motor system to bring it back in alignment with the nondisplaced real world. In this literature there is evidence for learning that is specific to the trained limb (Martin, Goodkin, Bastian, & Thach, 1996), to the start and end position of the learned movement, and to the action performed (Redding, Rossetti, & Wallace, 2005; Redding & Wallace, 2006).

Specificity of learning is also a feature of more cognitive learning. For instance, Pashler and Baylis (1991) trained subjects to associate one of three keys with visually presented symbols (left key = P or 2, middle key = V or 8, right key = K or 7). Over the course of multiple training blocks, participant reaction time decreased significantly. However, when new symbols were added that needed to be mapped to the same keys in addition to the learned symbols (left key = P, 2, F, 9; middle key = V, 8, D, 3; right key = K, 7, J, 4), no evidence of transfer was evident. In fact, reaction times to the previously learned symbols increased to pretraining levels. Similarly, studies of object recognition point to highly

specific learning. Furmanski and Engel (2000) trained subjects to name backward masked images of common objects over 5 days. Recognition thresholds decreased by up to 20%; however, little transfer was seen when a new set of objects was used. Thus learning did not proceed through general enhancement of vision or by learning the visual context in which the objects were presented but rather at an object-specific level.

Specificity of learning is not just a feature of training-induced brain plasticity. Plasticity as a result of altered experience, even early in life, also leads to surprisingly specific functional changes. For example, individuals born deaf do not exhibit a general enhancement of vision; they exhibit comparable performance to hearing individuals on a range of visual psychophysical thresholds, be it for brightness discrimination, visual flicker, different aspects of contrast sensitivity, or direction and velocity of motion (Bosworth & Dobkins, 2002; Brozinsky & Bavelier, 2004; Finney & Dobkins, 2001). Instead, enhanced performance has been reported only under specific conditions, such as processing of the visual periphery or motion processing, and mainly under conditions of attention. A review of the literature indicates that the changes documented after early deafness are best captured in terms of a change in the spatial distribution of visual spatial attention, whereby deaf individuals exhibit enhanced peripheral attention compared to hearing individuals, with little to no changes in other aspects of vision or visuospatial attention (Bavelier, Dye, & Hauser, 2006).

Enhanced performance through practice: Is it always learning?

Establishing the presence of experience-dependent learning effects is not always straightforward. At least two main classes of effects may masquerade as experience-dependent learning effects—transient effects and effects caused by hidden or unmeasured variables.

Many types of transient effects may indeed be causally related to the training intervention; however, they are not considered true learning effects because they last for only a few minutes following the cessation of training. An excellent example is the so-called Mozart effect, wherein listening to only 10 minutes of a Mozart sonata was reported to lead to significant performance increases on the Stanford Binet IQ spatial-reasoning task (Rauscher, Shaw, & Ky, 1993). Unfortunately, in addition to proving difficult to replicate consistently (Fudin & Lembessis, 2004; McCutcheon, 2000; Rauscher et al., 1997; Steele, Brown, & Stoecker, 1999), the validity of this enhancement as a true learning effect has been questioned, as any positive effects last only a few minutes. The source of the effect has instead been attributed to short-term arousal or mood changes, as several studies have indicated that the type of music further

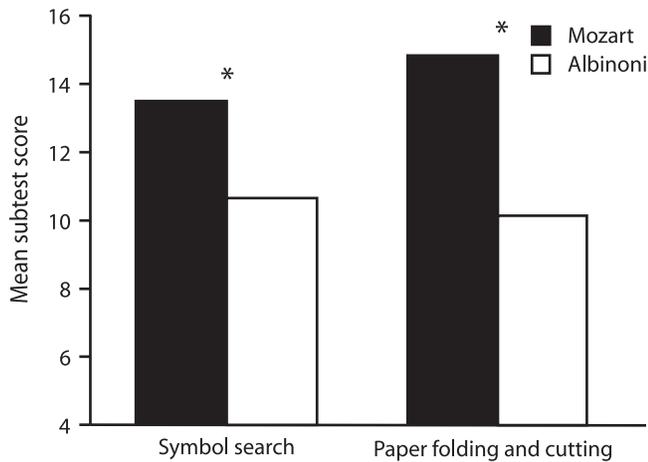

FIGURE 10.2 Participants' performance on the letter-number sequencing test (a measure of working memory skills) and the paper folding and cutting test (a measure of visuospatial constructive skills). Participants were tested shortly after listening to either an up-tempo sonata of Mozart in a major key, which conveyed a mood of happiness, or a slow-tempo adagio of Albinoni in a minor key, which conveyed a mood of sadness. Participants performed better on both tests after listening to the Mozart piece compared to the Albinoni piece. This work illustrates that the "Mozart effect" has little to do with learning per se. Rather, music listening seems to affect performance for better or for worse on a wide variety of tests by changing arousal and mood just before testing. Asterisks denote statistical significance. (Adapted from Schellenberg, Nakata, Hunter, & Tomato, 2007, figure 2; Thompson, Schellenberg, & Husain, 2001, figure 1.)

influences performance. For example, pop music such as "Country House" by Blur led to a greater spatial IQ enhancement than a piece by Mozart (Schellenberg & Hallam, 2005). Further confirming the arousal-mood hypothesis, listening to a high-tempo piece by Mozart was found to lead to better verbal IQ measures than listening to a slower piece by Albinoni (figure 10.2; Schellenberg, Nakata, Hunter, & Tomato, 2007).

Along the same line, studies that have examined the impact of playing violent video games on aggressive behavior may suffer from the same weakness, as the tests used to assess changes in the dependent variables of interest (behavior, cognition, affect, etc.) are typically given within minutes of the end of exposure to the violent video games. Given that violent video games are known to trigger a host of transient physiological changes associated with increased arousal and stress (i.e., "fight-or-flight" responses), it is important to demonstrate that any changes in behavior or cognition are not likewise transient in nature. It is interesting to note that while several recent papers in this field have reported changes in aggressive cognition and affect as well as desensitization to violence immediately following 30 minutes of exposure to violent video games, the same studies failed to find a significant relationship between these variables and being a regular player of violent video games, suggesting that the effects may

indeed be fleeting rather than constituting true learned aggression effects (Carnagey & Anderson, 2005; Carnagey, Anderson, & Bushman, 2007).

The second class of effects that may masquerade as experience-dependent learning consists of effects caused by hidden or unmeasured variables that are unrelated to the experience of interest. While these effects may represent learning, they do not represent experience-dependent learning. For instance, it is well documented that individuals who have an active interest taken in their performance tend to improve more than individuals who have no such interest taken—an effect often dubbed the Hawthorne effect (Lied & Karzandjian, 1998). This effect can lead to powerful improvements in performance that have little to do with the specific cognitive training regimen being studied, but instead reflect social and motivational factors that influence performance. In the same vein, the mere presence of mental or physical stimulation may lead to performance changes in groups that are chronically understimulated (as may be the case with the institutionalized elderly), which again would not be considered experience-dependent learning as it is not dependent on the type of experience.

A related issue arises when researchers attempt to infer the presence of experience-dependent learning by examining behavioral differences in groups that perform various activities as part of their everyday lives (for instance, athletes, musicians, or video game players). The obvious concern here is population bias—in other words, inherent differences in abilities may lead to the differences in the activities experienced, rather than the other way around. For example, individuals born with superior hand-eye coordination may be quite successful at baseball and thus preferentially tend to play baseball, while individuals born with poor hand-eye coordination may tend to avoid playing baseball. A hypothetical study that examined differences in hand-eye coordination between baseball players and nonplayers may observe a difference in hand-eye coordination, but it would be erroneous to link baseball experience to superior hand-eye coordination when a population bias was truly at the root of the effect.

Training studies aiming to establish experience-dependent learning should therefore demonstrate (1) benefits that go beyond the temporary arousal or mood changes an experience can induce, and (2) a clear causal link between the specific training experience and learning. The effect of training should be measured at least a full day after completion of training to ensure that it is a robust learning effect. As illustrated by the Mozart effect, training participants for 20 minutes and immediately showing changes in measures of their performance does not mean that a long-lasting alteration of performance has taken place. Furthermore, to establish a definitive causal link between a given form of experience and any enhancement in skills, it is necessary not only to train nonexperts on the experience in question and

to observe the effects of this training, but also to control for the source of this improvement. Training studies should include a group that controls for test-retest effects (i.e., how much improvement can be expected simply from repeating a test) and, just as importantly, for psychological and motivational effects. Control groups that are passive, that are only pre- and posttested but not asked to train or only asked to train at a low level of difficulty on the same task as the experimental group, may not be ideal as such studies fail to differentiate the contribution of motivational factors such as being challenged by the training episode versus true cognitive exercising on performance changes. Finally, evaluation of the efficiency of training critically depends on the choice of outcome measures. Outcome measures closely related to the training experience are more likely to show robust improvements given the specificity of learning discussed earlier. Yet it is critical to show transfer to new tasks within the same domain if one is interested in enhancing skills in a cognitive domain rather than performance on a given specific laboratory test. For example, training on a version of a Stroop task is likely to result in reduced Stroop interference. To what extent does this improvement reflect a generalized improvement in executive skills? Various kinds of transfer and generalization tests that also measure executive skills, but do not do so in the same context or using the same stimuli as the Stroop task, would have to be evaluated before concluding that the training regimen leads to be an improvement in executive skills (see Schmidt & Bjork, 1992, for an excellent review of this issue).

Complex learning environments and general learning

Against a backdrop of highly specific learning, a few training regimens have recently come under close scrutiny, as they seem to induce learning that is much more general than previously thought possible. These learning paradigms are typically more complex than simple laboratory manipulations and correspond to real-life experiences such as musical training, athletic training, and action video game playing.

In the musical domain for instance, Schellenberg (2004) assessed the effect of music lessons on IQ. A large sample of children was randomly assigned to one of four groups. Two groups received music training (keyboard or vocal), one control group received drama training, and the final group received no training. The primary measures of interest were scores on the Wechsler Intelligence Scale for Children (WISC-III) before and after training. While IQ scores increased for children in all groups, the largest increases were observed in the two music training groups. This effect held in all but two of the twelve subtests of the full IQ scale, indicating a widespread beneficial effect on cognition (figure 10.3). Rauscher and colleagues (1997) monitored the spatiotemporal reasoning skills of young

children (3–4 years old) who were given 6 months of musical keyboard lessons. Significantly larger improvements in spatiotemporal reasoning were noted in the keyboard-trained children than in two control groups—one a computer training and the other a no-training group (see also Hetland, 2000). Finally, it has also been suggested that music training enhances mathematical ability and verbal memory (Gardiner, Fox, Knowles, & Jefferey, 1996; Graziano, Peterson, & Shaw, 1999; Ho, Cheung, & Chan, 2003). These studies demonstrate a causal effect of music playing on a range of cognitive skills during development. Although the motor component of music lessons is likely to be a key factor, it remains unknown whether different musical activities (string playing, keyboard playing, or singing) differ in altering cognition. Similarly, it is not clear whether these differences remain into adulthood and whether they can be induced through music playing in adulthood.

In the athletic domain, Kiomourtzoglou, Kourtessis, Michalopoulou, and Derri (1998) compared athletes with expertise in various sports (basketball, volleyball, and water polo) on a number of measures of perception and cognition. Expert athletes demonstrated enhancements (compared to novices) in skills that are intuitively important to performance in their given sports. Basketball players exhibited superior selective attention and hand-eye coordination, volleyball players outperformed novices at estimating the speed and direction of a moving object, and water polo players had

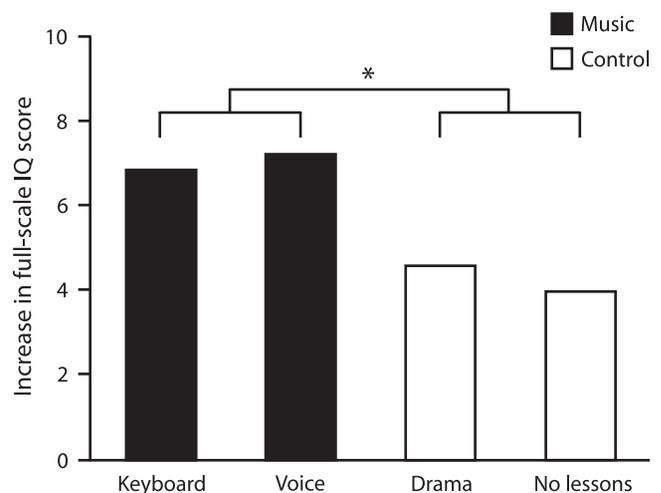

FIGURE 10.3 A large sample of children was randomly assigned to one of four groups. Two groups received music training (keyboard or vocal), a first control group received drama training, and a second control group received no training. The primary measures of interest were scores on the Wechsler Intelligence Scale for Children (WISC-III) obtained before and after training. Children in the music groups showed greater improvements between pre- and post-assessment than the two control groups. This study demonstrates a causal effect of music lessons on a range of cognitive skills during development. Asterisks denote statistical significance. (Data reprinted from Schellenberg, 2006.)

faster visual reaction times and better spatial orienting abilities. Lum, Enns, and Pratt (2002), McAuliffe (2004), and Nougier, Azemar, and Stein (1992) observed similar sports-related differences in a Posner cuing task, while Kida, Oda, and Matsumura (2005) demonstrated that trained baseball players respond faster than novices in a go-no-go task (press the button if you see color A, do not press the button if you see color B), but interestingly show no enhancements in simple reaction time tasks (press a button when a light turns on). Unfortunately, no training studies are available at this point to establish a causal link between these performance enhancements and the specific physical activity under investigation. The possibility that aerobic exercise of any sort may enhance cognitive abilities has received much attention lately with respect to aging. Consistently positive results have been reported in many cross-sectional studies comparing older adults who normally exercise with those who do not. Enhancements have been documented in tasks as varied as dual-task performance or executive attention/distractor rejection (for recent reviews see Colcombe et al., 2003; Hillman, Erickson, & Kramer, 2008; Kramer & Erickson, 2007). More training studies are needed to unambiguously establish the causal effect of aerobic exercise on perception and cognition. Yet, taken together, studies of the effect of athletic training and exercise on perception and cognition are tantalizing, and they have prompted renewed interest for demonstrating a causal link between the physical nature of the training regimen and enhancement of cognitive skills.

Perhaps the most popular training regimen over the past decade has been video games. The possibility that perceptual and cognitive abilities are enhanced in video game players has raised much attention (for a review, see Green & Bavelier, 2006b). Indeed, the variety of different skills and the degree to which they are modified in video game players appears remarkable. These include improved hand-eye coordination (Griffith, Voloschin, Gibb, & Bailey, 1983), increased processing in the periphery (Green & Bavelier, 2006c), enhanced mental rotation skills (Sims & Mayer, 2002), greater divided attention abilities (Greenfield, DeWinstanley, Kilpatrick, & Kaye, 1994), faster reaction times (Castel, Pratt, & Drummond, 2005), and even job-specific skills such as laparoscopic manipulation (Rosser, Lynch, Cuddihy, Gentile, & Merrell, 2007) and airplane piloting procedures (Gopher, Weil, & Bareket, 1994). Although intriguing, this literature has little to say about learning *per se* unless the causal effect of game playing is unambiguously established. So far, only a few studies have established a causal link between video game play and long-lasting changes in performance. Among these is a series of studies that provide compelling evidence that playing action video games—such as first-person perspective shooter games—promotes widespread changes ranging from early sensory functions to higher cognitive functions in adults.

Playing action video games improves fundamental properties of vision (Green & Bavelier, 2007; Li, Polat, Makous, & Bavelier, *in press*). One visual ability often diminished in patients with poor vision, such as amblyopes or older adults (Bonneh, Sagi, & Polat, 2007), is the ability to read small print, with letters appearing unstable and jumbled. The tendency for the resolvability of letters to be adversely affected by near neighbors, termed crowding, is typically evaluated by asking subjects to identify the orientation of a letter flanked by distractors, and by determining the smallest distance between target and distractors at which subjects can still correctly identify the target (figure 10.4A). Individuals with better vision can tolerate distractors being brought nearer to the target while still maintaining high-accuracy performance. To establish the causal effect of action video game playing on this visual skill, a training study was carried out whereby subjects were randomly assigned to one of two training groups: an action video games trained group (e.g., Unreal Tournament,) or a control trained group (e.g., Tetris). Each group was tested pre- and post-training on the crowding task. Participants trained on the action game improved significantly more than those trained on the control game (figure 10.4B). The inclusion of a control game group allows us to measure any possible improvements due to test-retest (i.e., familiarity with the task) or to Hawthorne-like effects (Lied & Karzandjian, 1998). Finally, the control games were chosen to be as pleasurable and engrossing as the experimental training games in order to minimize differences in arousal across groups. Critically, posttraining evaluation was always performed at least a day after the completion of the training phase.

Playing action video games was also shown to enhance several different aspects of visual selective attention. Action game training improves the ability of young adults to search their visual environment for a prespecified target, to monitor moving objects in a complex visual scene, and to process a fast-paced stream of visual information (Feng, Spence, & Pratt, 2007; Green & Bavelier, 2003, 2006c, 2006d). In one such experiment, the efficiency with which attention is distributed across the visual field was measured with a visual search task called the Useful Field of View paradigm (Ball, Beard, Roenker, Miller, & Griggs, 1988). This task is akin to looking for a set of keys on a cluttered desk. Subjects are asked to localize a briefly presented peripheral target in a field of distracting objects; accuracy of performance is recorded (figure 10.5A). Training on an action video game for just 10 hours improved performance on that task by about 30%, an improvement which is greatly in excess of that which can be induced by training on a control game (figure 10.5B). In a related study, Feng and colleagues (2007) showed that performance on the Useful Field of View task differs across gender, with males showing an advantage. Yet, after 10 hours of action game training, this gender difference was

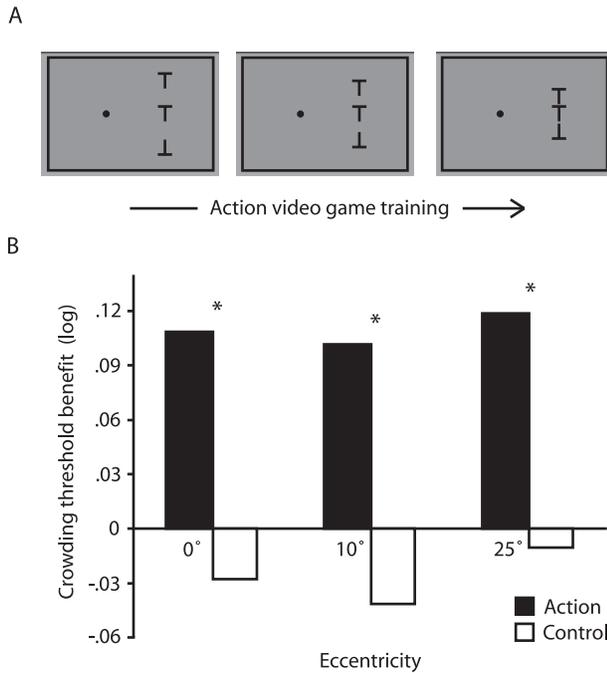

FIGURE 10.4 (A) Participants were presented with a display containing three vertically aligned *T*'s and asked to determine whether the central *T* was upright or inverted. Crowding thresholds were measured by determining the smallest distance between the target and the distractors at which participants could still perform this discrimination task with 79% accuracy. Enhanced performance on this task results in participants being able to process more densely packed letters, as illustrated here. Participants were trained either on an action video game hypothesized to enhance their visual resolution or on a control video game. (B) The crowding thresholds were measured at three different eccentricities (central vision, 10 degrees, and 25 degrees). This procedure allowed testing of central vision, often thought to have optimal performance, as well as peripheral locations, allowing one to test generalization of learning at untrained locations. The action game training group improved significantly more than the control group at all three eccentricities tested, reflecting generalization of learning at untrained locations and greater plasticity than previously thought in central vision. Asterisks denote statistical significance.

reduced, as well as the oft-documented difference in mental rotation skills between males and females (Feng et al., 2007).

In addition to basic visual skills and selective attention, action game playing has also been linked to better performance on dual tasks (Green & Bavelier, 2006a), task switching (Green & Bavelier, 2006a), and decision-making processes (Green, Pouget, & Bavelier, 2007). A training regimen that promotes robust changes in such a wide range of skills demonstrates that efficient learning transfer can occur given the appropriate training.

Determinants of learning and learning transfer

A major challenge for future work is to pinpoint which factors, or combination of factors, inherent to the complex

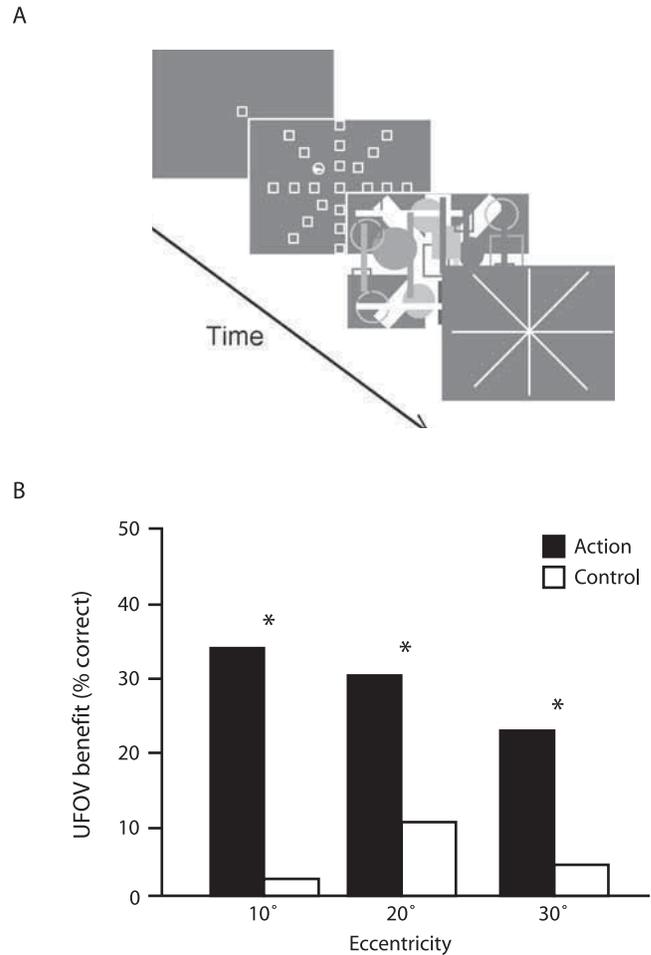

FIGURE 10.5 (A) Illustration of the Useful Field of View Task as adapted by Green and Bavelier (2003). Participants viewed a briefly flashed display containing one target, a filled triangle, embedded in a circle of distractors. They were asked to report the location of the target by indicating along which of the main eight directions the target was presented. Half of the participants were trained on an action video game hypothesized to enhance their visual attention, while the other half were trained on a control game. (B) Percent correct target localization was measured at each of the three eccentricities tested (10, 20, and 30 degrees of visual angle) before and after training. The action game training group improved more from pre- to post-training tests than the control game training group. This was even the case at 30 degrees of visual angle, an eccentricity seldom used in video gaming, establishing generalization of learning to untrained locations. Asterisks denote statistical significance.

training regimens discussed earlier are responsible for the enhancement in learning and learning transfer. This point is important both theoretically, in terms of designing models of human learning and behavior, and practically, for those seeking to devise effective rehabilitation programs to ameliorate specific deficits.

The ultimate goal is to see the learner flexibly acquire new knowledge, while using prior knowledge to constrain and accelerate learning. Models of complex human learning,

such as those derived from connectionism or machine learning, provide some clues about the factors that facilitate bottom-up learning based upon the statistics of the input. Recently, the framework of Bayesian inference has been proposed to provide a good first-order model of how subjects learn to optimize behavior in dynamic complex tasks, be they perceptual or cognitive in nature (Courville, Daw, & Touretzky, 2006; Ernst & Banks, 2002; Orbán, Fiser, Aslin, & Lengyel, 2008; Tenenbaum, Griffiths, & Kemp, 2006). Another key feature of recent advances has been the realization that actions and the feedback they provide about the next step to be computed can greatly reduce the computational load of a task, as well as facilitate learning and generalization (Ballard, Hayhoe, Pook, & Rao, 1997; Taagten, 2005). Finally, symbolic cognitive architectures such as SOAR and ACT-R provide insights into how knowledge representations should be structured to explain the acquisition of abstract systems of knowledge, and possibly transfer of knowledge across these systems (Anderson et al., 2004; Lehman, Laird, & Rosenbloom, 1998). Based on this variety of theoretical approaches, one can begin to identify characteristics inherent to complex training regimens that seem more likely to be at the root of general learning. These include, but are not limited to, (1) level of representation, (2) task difficulty, (3) goals, action, and feedback, and (4) motivation and arousal.

LEVELS OF REPRESENTATION Learning is more likely to be flexible and general if it occurs at the level of richly structured representations that contribute to a wide array of behaviors, rather than if it changes neural networks whose functions are highly specialized. The field of perceptual learning has identified task difficulty as one of the main factors controlling the level of representation at which learning occurs. In their reverse hierarchy theory of perceptual learning, Ahissar and Hochstein (2004) hypothesize that learning is a top-down guided process, where learning occurs at the highest level of representation that is sufficient for the given task. Easy tasks can be learned at a reasonably high level of representation that may be shared with many other tasks, allowing for sizable learning transfer. When tasks become exceedingly difficult—at least in the perceptual domain, such as in Vernier acuity tasks near the hyperacuity range—lower levels of representation with better signal-to-noise ratios are required for adequate task performance. In such cases, only tasks that make use of this low-level neural network, down to the specific retinal location and stimulus orientation, will benefit. Although the reverse hierarchy theory was developed to account for perceptual learning effects, it aligns well with the more general proposal that transfer of learned knowledge to different tasks and contexts will be more likely when learning and inference operate at higher levels of representation.

A key factor in ensuring flexible learning is high variability. Variability is important both at the level of the exemplars to be learned and the context in which they appear (Schmidt & Bjork, 1992). For example, subjects learn to recognize objects in a more flexible way if the objects are presented in a highly variable context (Brady & Kersten, 2003). High contextual variability ensures that subjects learn to ignore the specifics of the objects, such as are brought about by changes in view, lighting, camouflage, or shape, and rather learn to extract more general principles about object category. Statistical approaches such as mutual information show that subjects implicitly develop knowledge of the fragments or chunks that carry information about the categories to be learned (Hegd , Bart, & Kersten, 2008; Orbán et al., 2008). A key issue then arises as to when these informative fragments allow for learning that generalizes as compared to learning that is item specific. Work on object classification and artificial grammar learning shows that low input variability induces learning at levels of representation that are specific to the items being learned, and thus too rigid to generalize to new stimuli. High variability is crucial in ensuring that the newly learned informative fragments be at levels of representation that can flexibly recombine (Gomez, 2002; Onnis, Monaghan, Christiansen, & Chater, 2004; Reeler, Newport, & Aslin, 2008). Research on the video game Tetris and its effect on mental rotation illustrates this point well. Even though mental rotation is at a premium in Tetris, expert Tetris players have been found to exhibit mental rotation capacities similar to those of naïve subjects, except when tested on Tetris or Tetris-like shapes (Sims & Mayer, 2002). The use of a limited number of shapes in Tetris allows the learner to memorize spatial configurations and moves (Destefano & Gray, 2007). This approach allows for the development of excellent expertise at the game itself, but what is learned in this low-variability game is less likely to generalize to other environments. By this view, an efficient scheme to enforce mental rotation learning would be to use a highly variable set of objects preventing learning of specific configurations.

TASK DIFFICULTY The proposal that task difficulty controls the type and rate of learning is implicit in all theories of learning. The perceptual learning literature nicely illustrates the impact of manipulating task difficulty appropriately (Sireteanu & Rettenbach, 1995, 2000). In particular, when it comes to promoting learning transfer, harder tasks are at a disadvantage. For example, in a task where participants had to view arrays of oriented lines and determine which contained a single oddly oriented line, task difficulty was manipulated by limiting exposure time (Ahissar & Hochstein, 1997). With practice, the minimal exposure time that could be tolerated by the participants decreased substantially. Interestingly, when the task was started at a

difficult level (short exposure times), learning was slow and specific for the trained orientation and location. When the task was made easier by starting with long exposure times, learning progressed quickly and transferred to novel orientations. Other conditions that made the task more difficult, such as using small differences in orientation between target and nontarget lines or greater visual eccentricity, also led to the same effect. In the same vein, Liu and Weinshall (2000) demonstrated that learning an easy motion-direction discrimination (9 degrees of motion direction) transferred substantially to novel orientations, whereas Ball and Sekuler (1982) had previously reported no such transfer using the same task but with a greater degree of difficulty (3 degrees of motion direction). Similarly, albeit with barn owls rather than human subjects, Linkenhoker and Knudsen (2002) demonstrated that adult barn owls could adjust to sizable shifts in visual experience (brought about by prism goggles) when the shifts were made in small enough increments. In contrast, large shifts led to no learning in these adult barn owls.

This is not to say that efficient learning will occur through exposure of the learner to situations that are easy to master. In fact, easy tasks that typically require the reenactment of already mastered skills lead to little to no learning (Olesen, Westerberg, & Klingberg, 2004). Intuitively the task difficulty should be set such that the learner can gain some satisfaction from his or her performance. In other words, it should be challenging enough to avoid boredom and lack of interest, but not too hard to allow for sizable positive feedback. This balance may be understood more formally as choosing the task difficulty that allows the learner to optimize over time the amount of reward gained from doing the task. Strikingly, the video game industry may have focused in on the conditions for generalized learning by using variable entry level, and therefore allowing each learner to enter the learning task at the proper level of challenge, and by implementing incremental increases in task difficulty as the game progresses. In our own work on video game training we have acknowledged these principles explicitly by progressing players to the next level of difficulty during training only when they have demonstrated sufficient mastery of their current level. This is not to say that the type of game is unimportant, rather that an appropriate training regimen must also be administered in an appropriate manner.

GOALS, ACTION, AND FEEDBACK A productive view of learning holds that it derives from the need to minimize “surprise,” or the difference between the anticipated outcome of an event or action and its actual outcome (Courville et al., 2006; Schultz, Dayan, & Montague, 1997). In that framework, actions provide an opportunity for learners to evaluate their internal representations and fine-tune them if a discrepancy is noted between the actual

and predicted outcome of the action (Sutton & Barto, 1998). Learning is thus critically under the control of the expected value, or reward, that the learner ascribes to a future event or action and the actual value received as the event or action unfolds.

Although clearly critical for learning, the exact role that feedback plays in learning is a subject of much debate. There are numerous examples demonstrating that feedback is necessary for learning (Herzog & Fahle, 1997; Seitz, Nanez, Holloway, Tsushima, & Watanabe, 2006). Yet many counterexamples also exist (Amitay, Irwin, & Moore, 2006; Ball & Sekuler, 1987; Fahle, Edelman, & Poggio, 1995; Karni & Sagi, 1991). The extent to which these are counterexamples is complicated by the fact that, even when experimenter-generated explicit feedback is not provided, if above-threshold stimuli are employed subjects will nevertheless have varying degrees of confidence that their response was correct. Such internally generated confidence judgments could themselves act as feedback signals (Mollon & Danilova, 1996). An added complication stems from the finding that the type of feedback that optimizes learning during performance acquisition is not necessarily that which optimizes learning in the long run (Schmidt & Bjork, 1992). For example, during the learning of a complex arm movement, subjects provided with feedback about their movement-time error after every trial learned faster than those provided with the same feedback but in a summary form every 15 trials. Yet upon retesting two days later, those provided with feedback every 15 trials showed greater accuracy and thus better performance on the task than those provided with feedback every trial (Schmidt, Young, Swinnen, & Shapiro, 1989). Whether feedback frequency systematically affects skill acquisition differently than skill retention remains to be firmly established; yet such findings certainly call for caution in considering the roles of feedback in learning.

While most major theories of learning require that some type of learning signal be present (often in the form of an error signal), they do not necessarily require that the feedback be explicit, nor do they require that feedback be given on a trial-to-trial basis. There are many algorithms that can learn quite efficiently when feedback is only given after a series of actions have been completed (Walsh, Nouri, & Littman, 2007). This is analogous to the situation that commonly occurs in action video games, where feedback (typically in the form of killing an opponent or dying) only becomes available at the conclusion of a very complicated pattern of actions. How best to solve this credit assignment problem, as well as how this affects the generality of what is learned, is a topic of ongoing research (Fu & Anderson, 2008; Ponzi, 2008). Interestingly, complex learning environments with the variety of actions they encompass allow for error signals that are varied both in nature and in time scale, a feature that may facilitate flexible learning.

The importance of reward in learning is already supported by neurophysiology studies that show that the brain systems thought to convey the utility of reward, such as the ventral tegmental area and the nucleus basalis, play a large role in producing plastic changes in sensory areas. In particular, when specific auditory tones are paired with stimulation of either of these structures, the area of primary auditory cortex that represents the given tone increases dramatically in size (Bao, Chan, & Merzenich, 2001; Kilgard & Merzenich, 1998). Interestingly, at least some of the brain areas known to be sensitive to reward have been shown to be extremely active when individuals play action video games. For instance, Koeppe and colleagues (1998) demonstrated that roughly the same amount of dopamine is released in the basal ganglia when playing an action video game as when methamphetamines are injected intravenously. Determining the exact role of reward-processing areas in the promotion of learning and neural plasticity will continue to be an area of active research.

MOTIVATION AND AROUSAL Motivation is a critical component of most major theories of learning, with motivation level being posited to depend highly on an individual's internal belief about her ability to meet the current challenge. Vygotsky's (1978) concept of a zone of proximal development matches well with the skill-learning literature discussed previously. According to this theory, motivation is highest and learning is most efficient when tasks are made just slightly more difficult than can be matched by the individual's current ability. Tasks that are much too difficult or much too easy will lead to lower levels of motivation and thus substantially reduced learning. This is not to say that learning will never occur if the task is too difficult or too easy (Amitay et al., 2006; Seitz & Watanabe, 2003; Watanabe, Nanez, & Sasake, 2001), but learning rate should be at a maximum when the task is challenging, yet still doable.

Like motivation, arousal is a key component of many learning theories. The Yerkes-Dodson law predicts that learning is a U-shaped function of arousal level (Yerkes & Dodson, 1908). Training paradigms that lead to low levels of arousal will tend to lead to low amounts of learning, as will training paradigms that lead to excessively high levels of arousal (Frankenhaeuser & Gardell, 1976). Between these extremes there is an arousal level that leads to a maximum amount of learning, which no doubt differs greatly between individuals. Interestingly, video games are known to elicit both the autonomic responses (Hebert, Beland, Dionne-Fournelle, Crete, & Lupien, 2005; Segal & Dietz, 1991; Shosnik, Chatterton, Swisher, & Park, 2000) and neurophysiological responses (Koeppe et al., 1998) that are characteristic of arousal. These responses

represent a salient difference between traditional learning paradigms and video game play. In the same vein, although again with barn owls, Bergan, Ro, Ro, & Knudsen (2005) observed that adult owls who were forced to hunt (an activity that involves motivation and arousal) while wearing displacing prisms demonstrated significant learning compared to adult owls who wore the prisms for the same period of time, but who were fed dead prey. The latter failed to adapt to the displacing prism.

Conclusions

The field of experience-dependent plasticity is rapidly expanding, thanks in part to new technologies. Cognitive training on handheld devices and job-related training in immersive environments are now within the reach of most institutions, if not individuals. This trend is exciting because the most successful interventions, when it comes to ameliorating deficits in patients or enhancing skills in an educational context, rely on complex training regimens. These regimens require the simultaneous use of perceptual, attentional, memory, and motor skills to trigger learning that goes beyond the specifics of the training regimen itself. New technologies are perfectly positioned to enhance the development of such complex learning environments. For all the excitement, challenges lie ahead. First among these is developing an understanding of which ingredients should be included in training regimens in order to promote widespread learning. Studies of the neural bases of arousal, motivation, and reward processing hold promise in that respect. Second, although the type of improvement desired is usually clear, as when educators or rehabilitation therapists state their goals for a student or a patient, identifying the cognitive component of a training regimen aimed at realizing those goals is not always so straightforward. At first glance, playing action video games does not appear to be a mind-enhancing activity. Yet it seems to generate beneficial effects for perception, attention, and decision making beyond what one may have expected. In contrast, the game Tetris clearly requires mental rotation, and yet it does not lead to a general benefit in mental rotation skill. Cognitive analysis is needed to determine the level of representation at which the learning is most likely to occur given the nature of the training regimen. We are understanding more about the conditions necessary to develop interventions that will lead to generalizable learning effects, and these hold promise for benefiting individuals and the societies within which they live.

ACKNOWLEDGMENTS This research was supported by grants to DB from the National Institutes of Health (EY016880 and CD04418) and the Office of Naval Research (N00014-07-1-0937). We also thank Bjorn Hubert-Wallander for help in figure preparation and manuscript preparation.

11 Profiles of Development and Plasticity in Human Neurocognition

COURTNEY STEVENS AND HELEN NEVILLE

ABSTRACT We describe changes in neural organization and related aspects of processing after naturally occurring alterations in auditory, visual, and language experience. The results highlight the considerable differences in the degree and time periods of neuroplasticity displayed by different subsystems within vision, hearing, language, and attention. We also describe results showing the two sides of neuroplasticity, that is, the capability for enhancement and the vulnerability to deficit. Finally we describe several intervention studies in which we have targeted systems that display more neuroplasticity and show significant improvements in cognitive function and related aspects of brain organization.

Extensive research on animals has elucidated both genetic and environmental factors that constrain and shape neuroplasticity (Hunt et al., 2005; Garel, Huffman, & Rubenstein, 2003; Bishop et al., 1999; Bishop, 2003). Such research, together with noninvasive neuroimaging and genetic sequencing techniques, has guided a burgeoning literature characterizing the nature, time course, and mechanisms of neuroplasticity in humans (Pascual-Leone, Amedi, Fregni, & Merabet, 2005; Bavelier & Neville, 2002; Movshon & Blake-more, 1974). Electron microscopic studies of synapses and neuroimaging studies of metabolism and of gray and white matter development in the human brain reveal a generally prolonged postnatal development that nonetheless displays considerable regional variability in time course (Chugani, Phelps, & Mazziotta, 1987; Huttenlocher & Dabholkar, 1997; Neville, 1998; Webb, Monk, & Nelson, 2001). In general, development across brain regions follows a hierarchical progression in which primary sensory areas mature before parietal, prefrontal, and association regions important for higher-order cognition (Giedd et al., 1999; Gogtay et al., 2004). Within each region there is a pattern of prominent overproduction of synapses, dendrites, and gray matter that is subsequently pruned back to about 50% of the maximum value, which is reached at different ages in differ-

ent regions. The prolonged developmental time course and considerable pruning of connections are considered major forces that permit and constrain human neuroplasticity. Recently an additional factor that appears to be important has been identified. The occurrence of polymorphisms in some genes is widespread in humans and rhesus monkeys but apparently not in other primate species. Polymorphisms provide the capability for environmental modification of the effects of gene expression (gene \times environment interactions), and such effects have been observed in rhesus monkeys and humans (Suomi, 2003, 2004, 2006; Sheese, Voelker, Rothbart, & Posner, 2007; Bakermans-Kranenberg, Van Ijzendoorn, Pijlman, Mesman, & Femie, 2008).

For several years we have employed psychophysics, electrophysiological (ERP), and magnetic resonance imaging (MRI) techniques to study the development and plasticity of the human brain. We have studied deaf and blind individuals, people who learned their first or second spoken or signed language at different ages, and children of different ages and of different cognitive capabilities. As detailed in the sections that follow, in each of the brain systems examined in this research—including those important in vision, audition, language, and attention—we observe the following characteristics:

- Different brain systems and subsystems and related sensory and cognitive abilities display different degrees and time periods (“profiles”) of neuroplasticity. These may depend on the variable time periods of development and redundant connectivity displayed by different brain regions.
- Neuroplasticity within a system acts as a double-edged sword, conferring the possibility for either enhancement or deficit.
- Multiple mechanisms both support and constrain modifiability across different brain systems and subsystems.

In the sections that follow, we describe our research on neuroplasticity within vision, audition, language, and attention. In each section, we note different profiles of plasticity observed in the system, situations in which enhancements

COURTNEY STEVENS Willamette University, Salem, Oregon
HELEN NEVILLE Department of Psychology, University of Oregon,
Eugene, Oregon

versus deficits are observed, and likely mechanisms contributing to these different profiles of plasticity. A final section describes our preliminary studies testing the hypothesis, raised by this basic research on human neuroplasticity, that interventions that target the most plastic, and thus potentially vulnerable, neurocognitive systems can protect and enhance children with, or at risk for, developmental deficits.

Vision

In a number of studies we observe that some, but not all, aspects of visual function are enhanced in deaf adults. Those aspects of vision showing the greatest changes are mediated by structures along the dorsal visual pathway that have been shown to be important in the representation of the peripheral visual fields, as well as in motion processing. By contrast, aspects of processing mediated by the ventral visual pathway, including color perception and processing within the central visual field, are not altered (Baizer, Ungerleider, & Desimone, 1991; Bavelier et al., 2001; Corbetta, Miezin, Dobmeyer, Shulman, & Petersen, 1990; Livingstone & Hubel, 1988; Merigan, 1989; Merigan & Maunsell, 1990; Schiller & Malpeli, 1978; Ungerleider & Mishkin, 1982; Ungerleider & Haxby, 1994; Zeki et al., 1991). For example, congenitally deaf individuals have superior motion detection compared with hearing individuals for peripheral, but not central, visual stimuli (Neville, Schmidt, & Kutas, 1983; Neville & Lawson, 1987b; Stevens & Neville, 2006). These behavioral improvements are accompanied by increases in the amplitudes of early event-related potentials (ERPs) and increased functional magnetic resonance imaging (fMRI) activation in motion-sensitive middle temporal (MT) and middle superior temporal (MST) areas of the dorsal visual pathway (Bavelier et al., 2000, 2001; Neville et al., 1983; Neville & Lawson, 1987b).

In a study comparing ERPs to isoluminant color stimuli (designed to activate the ventral pathway) and motion stimuli (designed to activate the dorsal pathway), no differences were observed between hearing and congenitally deaf individuals in ERPs to color stimuli. In contrast, ERPs to motion were significantly larger and distributed more anteriorly in deaf than in hearing subjects. These differences were only observed for stimuli presented in the peripheral visual field (Armstrong, Hillyard, Neville, & Mitchell, 2002). These results are consistent with the hypothesis that early auditory deprivation has more pronounced effects on the functions of the dorsal than the ventral visual pathway. A parallel literature on developmental disorders suggests that the dorsal visual pathway might also be more vulnerable to deficit in certain developmental disorders, including autism, Williams and fragile X syndromes, and reading or language impairments (Atkinson, 1992; Atkinson et al., 1997; Eden et al., 1996). For example, a number of studies indicate that at least

some individuals with specific reading disorder, or dyslexia, have lower sensitivity to detecting coherent motion in random-dot kinetograms despite showing normal thresholds for detecting coherent form in similar arrays of static line segments (Cornelissen, Richardson, Mason, Fowler, & Stein, 1995; Everatt, Bradshaw, & Hibbard, 1999; Hansen, Stein, Orde, Winter, & Talcott, 2001; Talcott, Hansen, Assoku, & Stein, 2000). Dyslexic individuals also show higher thresholds for detecting changes in the speed of motion flow fields (Demb, Boynton, Best, & Heeger, 1998), as well as higher critical flicker fusion thresholds for monochromatic, but not isoluminant, color stimuli when tested with a paradigm using identical task structure to assess each visual pathway (Sperling, Lu, Manis, & Seidenberg, 2003). In addition, there are reports that dyslexic individuals show deficits in pattern contrast sensitivity for high-contrast, low-spatial frequency gratings (Lovegrove, Martin, & Slaghuis, 1986). The behavioral evidence for a visual deficit in dyslexia has been corroborated by recent neuroimaging studies showing decreased (Demb et al., 1998) or even nonsignificant (Eden et al., 1996) activations in motion-sensitive areas MT/MST of dyslexic individuals, though no differences are observed during stationary pattern processing (Eden et al.). These results are parallel and opposite to those described previously showing *improved* behavioral performance and *increased* MT/MST activation in response to motion stimuli in congenitally deaf adults.

Taken together, these data suggest that the dorsal visual pathway may exhibit a greater degree of neuroplasticity than the ventral visual pathway, rendering it capable of either enhancement (as is the case following congenital deafness) or deficit (as is the case in some individuals with some developmental disorders). However, the two literatures have developed largely in parallel, and different tasks have been used to assess dorsal and ventral visual pathway function in each literature. To address this limitation, in a recent study we used the same tasks to assess visual function in both dyslexic adults and congenitally deaf adults, as well as matched controls (Stevens & Neville, 2006). We observed that whereas neither deaf nor dyslexic adults differ from matched controls on a central visual field contrast sensitivity task (figure 11.1A), on a peripheral motion detection task, deaf adults show enhancements whereas dyslexic adults show deficits on the same task (figure 11.1B). These findings help bridge the two literatures and suggest that the dorsal and ventral pathways show different profiles of neuroplasticity.

A number of mechanisms may render the dorsal pathway more developmentally labile, either to enhancement or deficit, including subsystem differences in rate of maturation, extent and timing of redundant connectivity, and presence of chemicals and receptors known to be important in plasticity. For example, anatomical studies suggest that connections within the regions of the visual system that represent

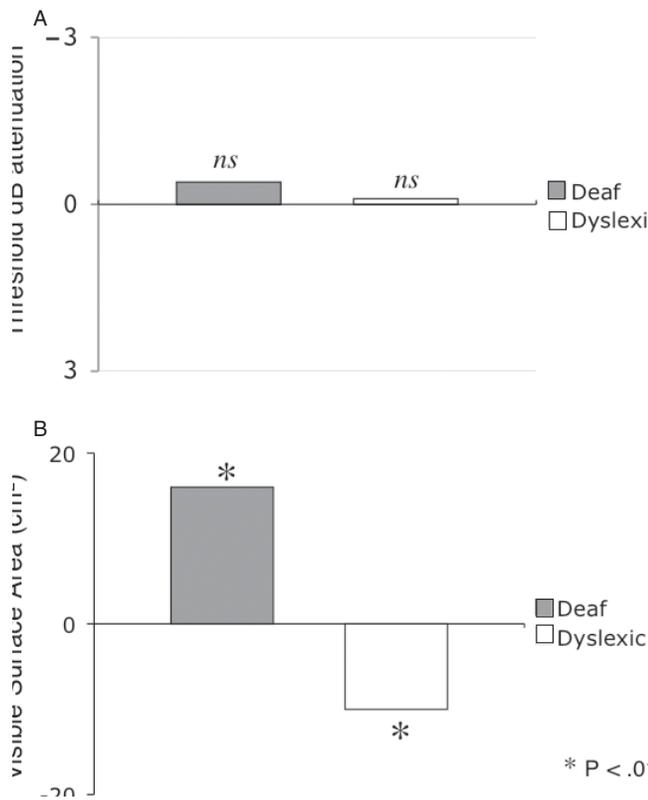

FIGURE 11.1 Performance on two visual tasks for deaf participants (gray bars) and dyslexic participants (white bars) relative to matched control groups. (A) On a central visual field contrast sensitivity task, neither deaf nor dyslexic participants differed from matched controls. (B) On a peripheral visual field motion detection task, deaf participants showed enhancements ($P < .001$) and dyslexic participants showed deficits ($P < .01$) relative to matched controls. (Data from Stevens & Neville, 2006.)

the central visual field are more strongly genetically specified, whereas connections within the portions of the visual system that represent the visual periphery contain redundant connections that can be shaped by experience over a longer developmental time course (Chalupa & Dreher, 1991). A molecular difference has also been observed between the two visual pathways. In cats and monkeys the dorsal pathway has a greater concentration of the Cat-301 antigen, a molecule hypothesized to play a role in stabilizing synaptic connections by means of experience-dependent plasticity (DeYoe, Hockfield, Garren, & Van Essen, 1990; Hockfield, 1983). Moreover, recent anatomical studies in nonhuman primates (Falchier, Clavagnier, Barone, & Kennedy, 2002; Rockland & Ojima, 2003) and neuroimaging studies of humans (Eckert et al., 2008) report cross-modal connections between primary auditory cortex and the portion of primary visual cortex that represents the periphery (anterior calcarine sulcus). In addition there is considerable, though not unequivocal, evidence indicating that the dorsal pathway matures more slowly than the ventral pathway (Hickey,

1981; Hollants-Gilhuijs, Ruijter, & Spekreijse, 1998a, 1998b; Packer, Hendrickson, & Curcio, 1990). Further, in developmental studies using the color and motion stimuli described previously and in Armstrong and colleagues (2002), we observed that while children aged 6–19 years show responses to color stimuli that are very similar to adults, their ERPs to the motion stimuli are delayed in latency relative to those for adults (Coch, Skendzel, Grossi, & Neville, 2005; Mitchell & Neville, 2004). Together, these anatomical, chemical, and developmental mechanisms could render the dorsal pathway more modifiable by experience and more likely to display either enhanced or deficient processing.

In addition to enhanced dorsal pathway functioning we have recently observed that deaf (but not hearing) participants recruit a large, additional network of supplementary cortical areas when processing far peripheral relative to central flickering visual stimuli (Scott, Dow, & Neville, 2003, see figure 11.2). These include contralateral primary auditory cortex (figure 11.2). Studies of a mouse model of congenital deafness suggest that altered subcortical-cortical connectivity could account for such changes (Hunt et al., 2005). In deaf but not hearing mice the retina projects to the medial (auditory) geniculate nucleus as well as the lateral (visual) geniculate nucleus. In our study of deaf humans we also observe significant increases in anterior, primary visual cortex and regions associated with multisensory integration (STS), motion processing (MT/MT+), and attention (posterior parietal and anterior cingulate regions) (Dow, Scott, Stevens, & Neville, 2006; Scott et al., 2003; Scott, Dow, Stevens, & Neville, under review). In a separate study, we used structural equation modeling to estimate the strength of cortical connections between early visual areas (V1/V2), area MT/MST, and part of the posterior parietal cortex (PPC) (Bavelier et al., 2000). During attention to the center the connectivity was comparable across groups, but during the attend-periphery condition the effective connectivity between MT/MST and PPC was increased in the deaf as compared with the hearing subjects. The findings of increased activation and effective connectivity between visual areas and areas important in attention suggest that the enhanced responsiveness to peripheral motion in deaf individuals may be in part linked to increases in attention (see next section for further discussion).

Audition

To test whether the specificity of plasticity observed in the visual system generalizes to other sensory systems, we have conducted studies of the effects of visual deprivation on the development of the auditory system. Although less is known about the organization of the auditory system, as in the visual system there are large (magno) cells in the medial geniculate nucleus that conduct faster than the smaller

Deaf greater than hearing: Periphery (right visual field)

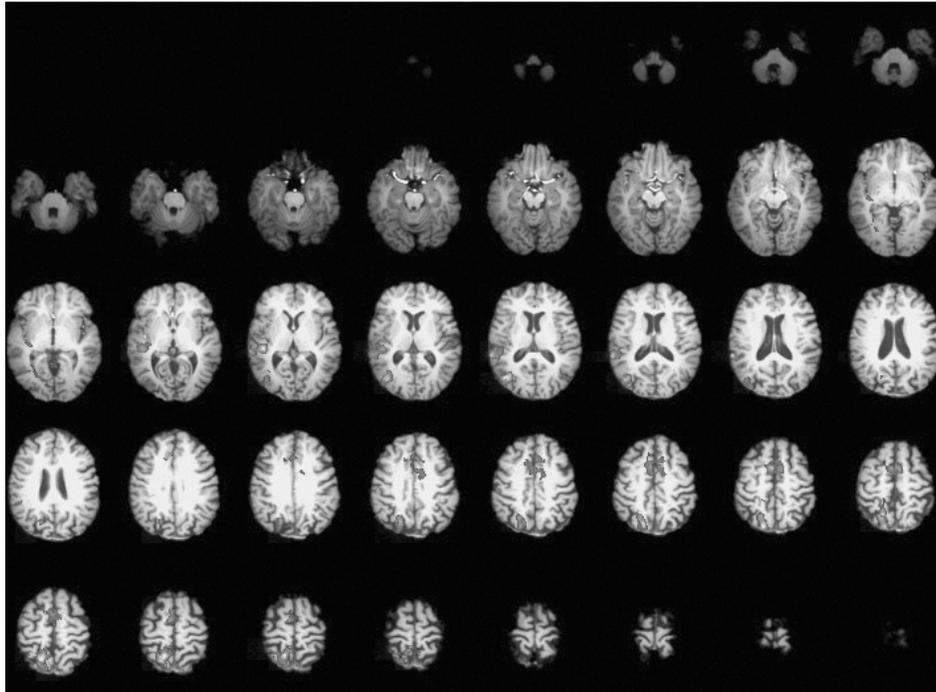

FIGURE 11.2 Deaf and hearing participants completed a visual retinotopy experiment that included mapping of far peripheral visual space. The data show regions where activation was greater in deaf versus hearing participants in response to more peripheral

(parvo) cells, and recent evidence suggests that there may be dorsal and ventral auditory processing streams with different functional specializations (Rauschecker, 1998). Furthermore, animal and human studies of blindness have reported changes in the parietal cortex (i.e., dorsal pathway) as a result of visual deprivation (Hyvarinen & Linnankoski, 1981; Pascual-Leone et al., 2005; Weeks et al., 2000).

To determine whether similar patterns of plasticity occur following auditory and visual deprivation, we developed an auditory paradigm similar to one of the visual paradigms employed in our studies of deaf adults. Participants detected infrequent pitch changes in a series of tones that were preceded by different interstimulus intervals (Röder, Rösler, Hennighausen, & Näcker, 1996). Congenitally blind participants were faster at detecting the target and displayed ERPs that were less refractory, that is, recovered amplitude faster than normally sighted participants. These results parallel those of our study showing faster amplitude recovery of the visual ERP in deaf than in hearing participants (Neville et al., 1983) and suggest that rapid auditory and visual processing may show specific enhancements following sensory deprivation.

Similar to the two sides of plasticity observed in the dorsal visual pathway, the refractory period for rapidly presented acoustic information, which is enhanced in the blind, shows deficits in many developmental disorders (Bishop &

visual stimuli presented in two distinct experiments ($45\text{--}56^\circ$ versus $11\text{--}23^\circ$ and $11\text{--}15^\circ$ versus $2\text{--}7^\circ$). Significant clusters included contralateral auditory cortex, STS, MT, anterior visual cortex, IPS, and anterior cingulate. (See color plate 11.)

McArthur, 2004; Tallal & Piercy, 1974; Tallal, 1975, 1976). In a study of children with specific language impairment (SLI), we observed that auditory ERPs were smaller (i.e., more refractory) than in controls at short interstimulus intervals (Neville, Coffey, Holcomb, & Tallal, 1993). This finding suggests that in audition, as in vision, neural subsystems that display more neuroplasticity show both greater potential for enhancement and also greater vulnerability to deficit under other conditions.

The mechanisms that give rise to greater modifiability of rapid auditory processing are as yet unknown. However, as mentioned earlier, some changes might be greater for magnocellular layers of the medial geniculate nucleus. For example, magno cells in both the lateral and medial geniculate nucleus are smaller than normal in dyslexia (Galaburda & Livingstone, 1993; Galaburda, Menard, & Rosen, 1994). Rapid auditory processing, including the recovery cycles of neurons, might also engage aspects of attention to a greater degree than other aspects of auditory processing. In the case of congenital blindness, changes in auditory processing may be facilitated by compensatory reorganization. A number of studies have confirmed that visual areas are functionally involved in nonvisual tasks in congenitally blind adults (Cohen, Weeks, Celnik, & Hallett, 1999; Sedato et al., 1996). More recently, studies have reported highly differentiated auditory language processing in primary visual cortex in

congenitally blind humans (Burton et al., 2002; Röder, Stock, Bien, Neville, & Rösler, 2002). Thus aspects of auditory processing that either depend upon or can recruit multimodal, attentional, or normally visual regions may show greater degrees of neuroplasticity. Parallel studies of animals have revealed information about mechanisms underlying this type of change. For example, in blind mole rats, normally transient, weak connections between the ear and primary visual cortex become stabilized and strong (Bavelier & Neville, 2002; Cooper, Herbin, & Nevo, 1993; Doron & Wollberg, 1994; Heil, Bronchti, Wollberg, & Scheich, 1991).

Language

It is reasonable to hypothesize that the same principles that characterize neuroplasticity of sensory systems—including different profiles, degrees, and mechanisms of plasticity—also characterize language. Here, we focus on the subsystems of language examined in our studies of neuroplasticity, including those supporting semantics, syntax, and speech segmentation.

Several ERP and fMRI studies have described the non-identical neural systems that mediate semantic and syntactic processing. For example, semantic violations in sentences elicit a bilateral negative potential that is largest around 400 ms following the semantic violation (Kutas & Hillyard, 1980; Neville, Nicol, Barss, Forster, & Garrett, 1991; Newman, Ullman, Pancheva, Waligura, & Neville, 2007). In contrast, syntactic violations elicit a biphasic response consisting of an early, left-lateralized anterior negativity (LAN) followed by a later, bilateral positivity, peaking over posterior sites ~600 ms after the violation (P600; Friederici, 2002; Neville et al., 1991). The LAN is hypothesized to index more automatic aspects of the processing of syntactic structure and the P600 to index later, more controlled processing of syntax associated with attempts to recover the meaning of syntactically anomalous sentences. These neurophysiological markers of language processing show a degree of biological invariance as they are also observed when deaf and hearing native signers process American Sign Language (ASL) (Capek, 2004; Capek et al., under review). While spoken and signed language processing share a number of modality-independent neural substrates, there is also specialization based on language modality. The processing of ASL, for example, is associated with additional and/or greater recruitment of right-hemisphere structures, perhaps owing to the use of spatial location and motion in syntactic processing in ASL (Capek et al., 2004; Neville et al., 1998). In support of this hypothesis, we have recently shown that syntactic violations in ASL elicit a more bilateral anterior negativity for violations of spatial syntax, whereas a left-lateralized anterior negativity is observed for other classes of syntactic violations in ASL (Capek et al., under review).

We conducted a series of ERP studies to develop a neural index of one aspect of phonological processing: speech segmentation. By 100 ms after word onset, syllables at the beginning of a word elicit a larger negativity than acoustically similar syllables in the middle of the word (Sanders & Neville, 2003a). This effect has been demonstrated with natural speech and with synthesized nonsense speech in which only newly learned lexical information could be used for segmentation (Sanders, Newport, & Neville, 2002). The early segmentation ERP effect resembles the effect of temporally selective attention, which allows for the preferential processing of information presented at specific time points in rapidly changing streams, and it has also been shown to modulate early (100 ms) auditory ERPs (Lange, Rösler, & Röder, 2003; Lange & Röder, 2005; Sanders & Astheimer, in press). Thus the neural mechanisms of speech segmentation may rely on the deployment of temporally selective attention during speech perception to aid in processing the most relevant rapid acoustic changes.

To the extent that language is made up of distinct neural subsystems, it is possible that, as in vision and audition, these subsystems show different profiles of neuroplasticity. In support of this hypothesis, behavioral studies of language proficiency in second-language learners document that phonology and syntax are particularly vulnerable following delays in second-language acquisition (Johnson & Newport, 1989). In several studies, we have examined whether delays in second-language exposure are also associated with differences in the neural mechanisms underlying these different language subsystems. In one study, we compared the ERP responses to semantic and syntactic errors in English among Chinese/English bilinguals who were first exposed to English at different ages (Weber-Fox & Neville, 1996). Accuracy in judging the grammaticality of the different types of syntactic sentences and their associated ERPs were affected by delays in second-language exposure as short as 4–6 years. By comparison, the N400 response and the behavioral accuracy in detecting semantic anomalies were altered only in subjects who were exposed to English after 11–13 years of age. In studies of the effects of delayed second-language acquisition on indices of speech segmentation, second-language learners who were exposed to their second language late in life (>14 years) show a delay in the ERP measure of speech segmentation when processing their second language (Sanders & Neville, 2003b).

Many deaf children are born to hearing parents and, because of their limited access to the spoken language that surrounds them, do not have full access to a first language until exposed to a signed language, which often occurs very late in development. Behavioral studies of deaf individuals with delayed exposure to sign language indicate that with increasing age of acquisition, proficiency in sign language decreases (Mayberry & Eichen, 1991; Mayberry, 1993;

Mayberry, Lock, & Kazmi, 2002; Mayberry, 2003). Recently, studies have examined the effects of this delayed first-language acquisition on brain organization. We employed fMRI to examine whether congenitally deaf individuals who learned ASL later in life showed a different neural organization for ASL. In this study, we demonstrated that whereas the right angular gyrus is active when native signers process ASL, it is not in individuals who acquired ASL after puberty (Newman, Bavelier, Corina, Jezzard, & Neville, 2002). Employing ERPs, we have also studied groups of deaf individuals who acquired ASL either from birth, from 2 to 10 years, or between 11 and 21 years of age (Capek, 2004; Capek et al., in preparation). In all three groups of participants, the N400 index of semantic processing displays the same amplitude, latency, and cortical distribution. However, the early anterior negativity thought to index more automatic aspects of syntactic processing is only evident in those who acquired ASL before the age of 10 years. These data suggest that, in contrast to semantic processing, aspects of syntactic processing are subject to maturational constraints that render them more vulnerable following delays in either first- or second-language acquisition.

Several lines of evidence suggest that language proficiency might be a key factor in predicting the variability observed in the neural substrates of syntax. For example, we have observed that the neural response to syntactic violations also differs among monolingual native English speakers who vary in language proficiency. Specifically, adults who score lower on standardized tests of grammatical knowledge show a less left-lateralized and more prolonged ERP response to grammatical violations (Pakulak, Hyde, Jackobs, & Neville, 2007; Pakulak & Neville, under review). In developmental studies as well, the neural response to known and unknown words and to syntactic anomalies is more strongly predicted by a child's language proficiency than by chronological age (Adamson, Mills, Appelbaum, & Neville, 1998; Adamson-Harris, Mills, & Neville, 2000; Mills, Coffey-Corina, & Neville, 1993, 1997). Furthermore, the development of neural systems important for syntactic processing shows a longer time course than systems important for semantic processing (Hahne, Eckstein, & Friederici, 2004; Sabourin, Pakulak, Paulsen, Fanning, & Neville, 2007; and unpublished observations from data in our laboratory), again suggesting that systems with a longer developmental time course may be more modifiable during development.

Attention

As noted previously, many of the changes in vision, audition, and language observed in studies of neuroplasticity may depend at least in part on selective attention. The importance of selective attention for certain types of adult neuroplasticity is strongly supported by animal research. For

example, when monkeys are provided with extensive exposure to auditory and tactile stimuli, experience-dependent expansions in associated auditory or somatosensory cortical areas occur, but *only* when attention is directed toward those stimuli in order to make behaviorally relevant discriminations (Recanzone, Jenkins, Hradek, & Merzenich, 1992; Recanzone, Schreiner, & Merzenich, 1993). Mere exposure is not enough. These data strongly suggest that attention is important in enabling neuroplasticity. Given this suggestion, as well as the central role of attention in learning more generally, we have conducted several studies on the development and neuroplasticity of attention.

In these studies, we examined the effects of sustained, selective attention on neural processing employing the “Hillyard principle,” that is, while keeping the physical stimuli, arousal levels, and task demands constant. For example, competing streams of stimuli are presented (e.g., two different trains of auditory stimuli delivered to different ears), with participants alternating attention to one stream at a time in order to detect rare target events. By comparing neural activity to the same physical stimuli when attended versus ignored, the effects of selective attention can be ascertained. Studies with fMRI revealed that selective attention modulates the magnitude and extent of cortical activation in the relevant processing areas (Corbetta et al., 1990). Complementary studies using the ERP methodology have clarified the time course of attentional modulation. These studies revealed that in adults, selective attention amplifies the sensorineural response by 50–100% during the first 100 ms of processing (Hillyard, Hink, Schwent, & Picton, 1973; Hillyard, Di Russo, & Martinez, 2003; Luck, Woodman, & Vogel, 2000; Mangun & Hillyard, 1990). This early attentional modulation is in part domain general in that it is observed across multiple sensory modalities and in selection based on spatial, temporal, or other stimulus attributes. Moreover, in between-group and change-over-time comparisons, ERPs can separately index processes of signal enhancement (ERP amplitude gains for attended stimuli) and distractor suppression (amplitude reductions for unattended stimuli).

In a number of studies, we have documented that neuroplasticity in the early neural mechanisms of selective attention, as in other neural systems, shows considerable specificity. In the case of adults born deaf, employing ERPs and fMRI, we observed enhancements of attention that were specific to the peripheral, but not central, visual field (Bavelier et al., 2000, 2001; Neville & Lawson, 1987b). In parallel studies of auditory spatial attention among congenitally blind adults, we have observed similar specificity. When attending to central auditory space, blind and sighted participants displayed similar localization abilities and ERP attention effects. In contrast, in the periphery, blind participants were superior to sighted controls at localizing sounds

in peripheral auditory space, and ERPs revealed a sharper tuning of early spatial attention mechanisms (the N1 attention effect) (Röder et al., 1999). In a recent study of adults blinded later in life, we observed possible limits on the time periods during which these early mechanisms of attention are enhanced (Fieger, Röder, Teder-Sälejärvi, Hillyard, & Neville, 2006). Whereas adults blinded later in life showed similar behavioral improvements in peripheral auditory attention, these improvements were mediated by changes in the tuning of later ERP indices of attention, several hundred milliseconds after stimulus onset (i.e., P300). There were no group differences in the early (N1) attention effects. If the early neural mechanisms of selective attention can be enhanced after altered experience, it is possible that, as with other systems that display a high degree of neuroplasticity, attention may be particularly vulnerable during development. In line with this hypothesis, recent behavioral studies suggest that children at risk for school failure, including those with poor language or reading abilities or from lower socioeconomic backgrounds, exhibit deficits in aspects of attention including filtering and noise exclusion (Atkinson, 1991; Cherry, 1981; Farah et al., 2006; Lipina, Martelli, Vuelta, & Colombo, 2005; Noble, Norman, & Farah, 2005; Sperling, Lu, Manis, & Seidenberg, 2005; Stevens, Sanders, Andersson, & Neville, 2006; Ziegler, Pech-Georgel, George, Alanio, & Lorenzi, 2005). These attentional deficits span linguistic and nonlinguistic domains within the auditory and visual modalities, suggesting that the deficits are both domain general and pansensory. In order to determine whether these attentional deficits can be traced to the earliest effects of attention on sensorineural processing, we have recently used ERPs to examine the neural mechanisms of selective attention in typically developing, young children and in groups of children at risk for school failure.

These studies were modeled after those we and others have used with adults (Hillyard et al., 1973; Neville & Lawson, 1987a; Röder et al., 1999; Woods, 1990). The task was designed to be difficult enough to demand focused selective attention, while keeping the physical stimuli, arousal levels, and task demands constant. Two different children's stories were presented concurrently from speakers to the left and right of the participant. Participants were asked to attend to one story and ignore the other. Superimposed on the stories were probe stimuli to which ERPs were recorded. Adults tested with this paradigm showed typical N1 attention effects (Coch, Sanders, & Neville, 2005). Children, who showed a different ERP morphology to the probe stimuli, also showed early attentional modulation within the first 100 ms of processing. This attentional modulation was an amplification of the broad positivity occurring in this time window. In a later study (Sanders, Stevens, Coch, & Neville, 2006), we found that this attention effect was complete by 200 ms in older children age 6–8 years but prolonged

through 300 ms in children age 3–5. These data suggest that with sufficient attentional cues, children as young as three years of age are able to attend selectively to an auditory stream and that doing so alters neural activity within 100 ms of processing.

We have employed this paradigm to examine the timing and mechanisms of selective auditory attention in children with specific language impairment (SLI) aged six to eight years and typically developing (TD) control children matched for age, gender, nonverbal IQ, and socioeconomic status (SES) (Stevens, Sanders, & Neville, 2006). As shown in figure 11.3A,C, by 100 ms, typically developing children in this study showed an amplification of the sensorineural response to attended as compared to unattended stimuli, just as observed in our larger samples of typically developing children. In contrast, children with SLI showed no evidence of sensorineural modulation with attention, despite behavioral performance indicating that they were performing the task as directed (figure 11.3B,D). Moreover, the group differences were specific to signal enhancement (figure 11.4, left).

In a related line of research, we examined the neural mechanisms of selective attention in children from different socioeconomic backgrounds. Previous behavioral studies indicated that children from lower socioeconomic backgrounds experience difficulty with selective attention, particularly in tasks of executive function and tasks that require filtering irrelevant information or suppressing prepotent responses (Farah et al., 2006; Lupien, King, Meaney, & McEwen, 2001; Mezzacappa, 2004; Noble et al., 2005; Noble, McCandliss, & Farah, 2007). Using the same selective auditory attention ERP task described earlier, we observed differences in the neural mechanisms of selective attention in children from different socioeconomic backgrounds (Stevens, Lauinger, & Neville, in press). Specifically, children whose mothers had lower levels of education (no college experience) showed reduced effects of selective attention on neural processing compared to children whose mothers had higher levels of education (at least some college) (figure 11.5). These differences were related specifically to a reduced ability to filter irrelevant information (i.e., to suppress the response to ignored sounds) (figure 11.4, right) and could not be accounted for by differences in receptive language skill. Thus the mechanism implicated in attention deficits in children from lower socioeconomic backgrounds (i.e., distractor suppression) was not the same as the mechanism implicated in children with SLI, who showed a deficit in signal enhancement of stimuli in the attended channel (Stevens, Sanders, & Neville, 2006). Similar results have been reported by other research groups (D'Angiulli, Herdman, Stapells, & Hertzman, 2008). Taken together, these studies point to the two sides of the plasticity of early mechanisms of attention, which show both enhancements and vulnerabilities in different populations.

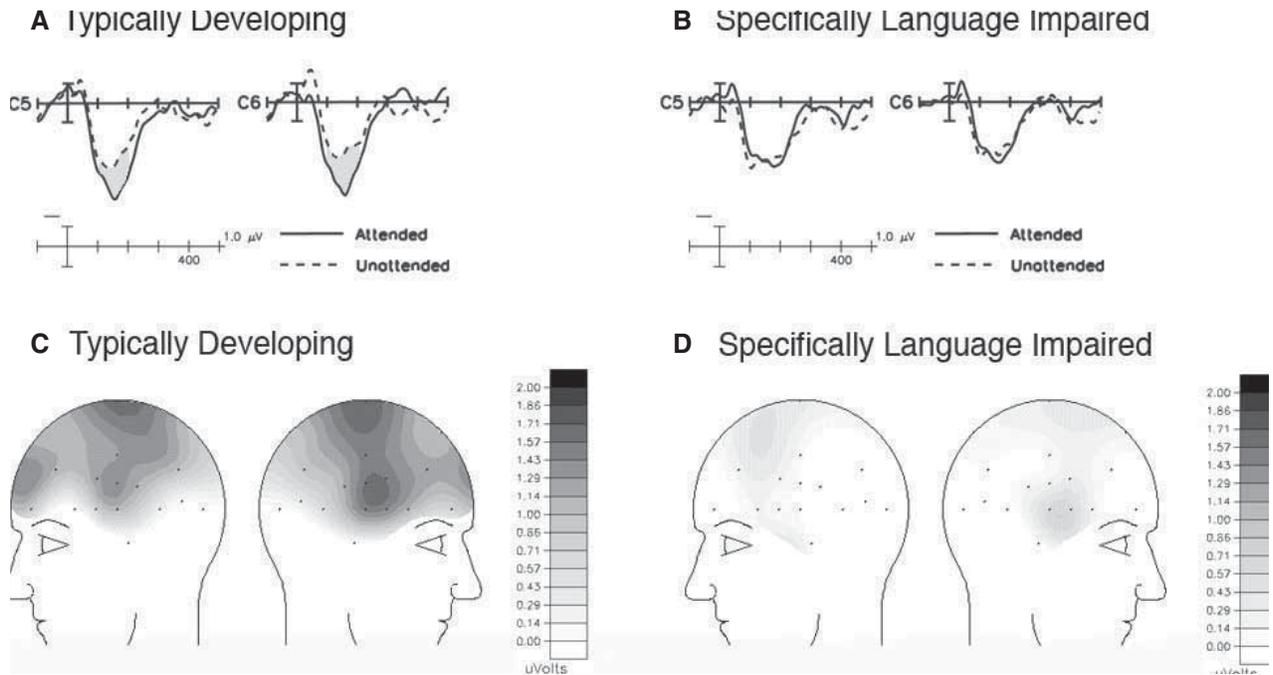

FIGURE 11.3 Grand average event-related potentials (ERPs) for attended and unattended stimuli (*A*) in typically developing children ($P = .001$) and (*B*) in children with specific language impairment ($P > 0.4$). Voltage map of the attention effect (Attended-Unattended) shows (*C*) in typically developing children a large,

broadly distributed effect and (*D*) in children with specific language impairment no modulation with attention. (Data from Stevens, Sanders, & Neville, 2006. Image reproduced with permission from *Brain Research*.)

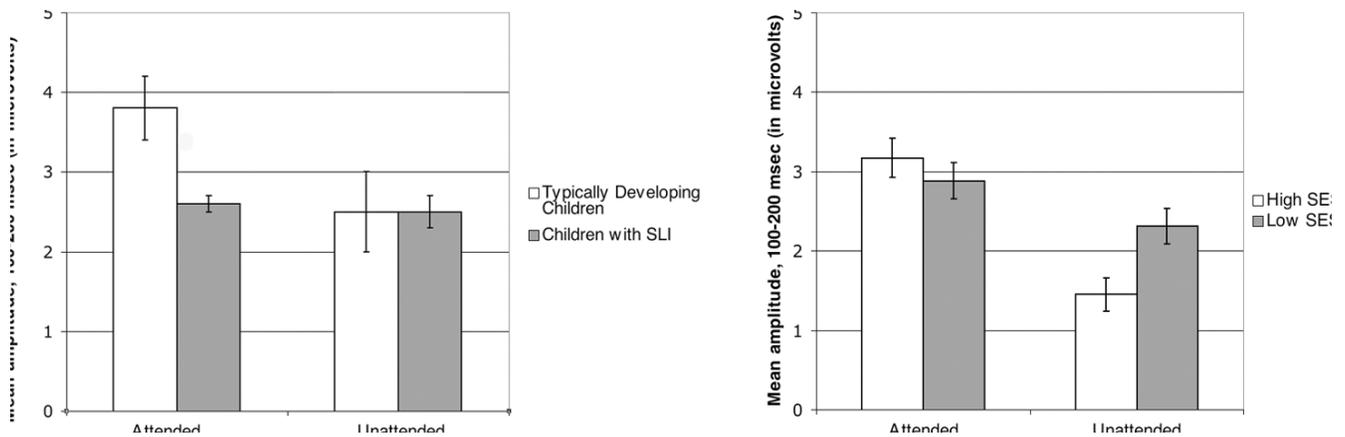

FIGURE 11.4 Mean amplitude of the ERP from 100 to 200 ms of responses to unattended and attended probes. Error bars represent standard error of the mean. Left panel shows data from typically developing children (TD) and children with specific language impairment (SLI). The two groups did not differ in the magnitude of response to unattended stimuli. However, typically developing children showed a larger amplitude response (i.e., better signal enhancement) than children with SLI to attended stimuli. Right

panel shows data from children from higher versus lower socioeconomic backgrounds. Children from different socioeconomic backgrounds did not differ in the magnitude of response to attended stimuli. However, children from lower socioeconomic backgrounds showed a larger response (i.e., poorer filtering) to unattended stimuli compared to children from higher socioeconomic backgrounds. (Data from Stevens, Sanders, & Neville, 2006, *Brain Research*, and Stevens, Lauinger, & Neville, in press, *Developmental Science*.)

Several mechanisms might underlie the plasticity of attention. Whereas the research described previously focused on sustained, selective attention, research in cognitive science and cognitive neuroscience has also identified several different subsystems, or components of attention

(Coull, Frith, Frackowiak, & Grasby, 1996; Raz & Buhle, 2006; Shipp, 2004). These components of attention depend upon different neural substrates and neurotransmitters (Bush, Luu, & Posner, 2000; Gomes, Molholm, Christodoulou, Ritter, & Cowan, 2000; Posner & Petersen, 1990) and

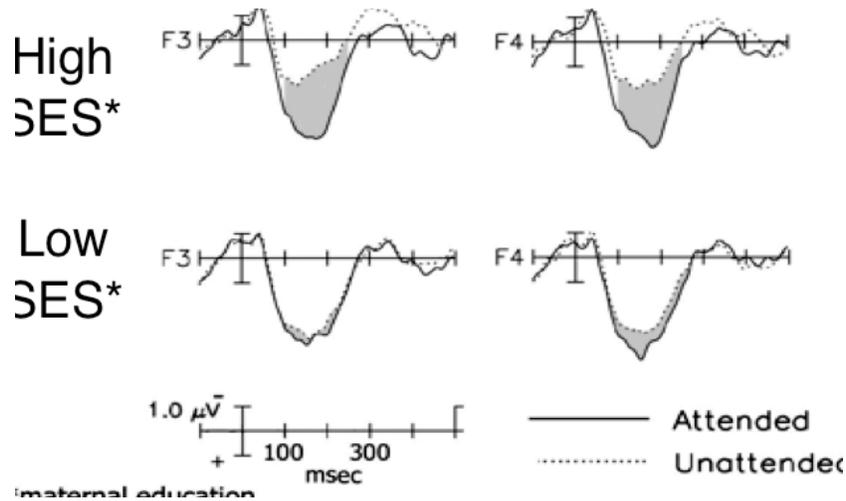

FIGURE 11.5 Grand average evoked potentials for attended and unattended stimuli in children from higher socioeconomic backgrounds (upper panel) and lower socioeconomic backgrounds (lower panel). The effect of attention on sensorineural processing

was significantly larger in children from higher socioeconomic backgrounds ($P = .001$). (Data from Stevens, Lauinger, & Neville, in press, *Developmental Science*.)

mature along different timetables (Andersson & Hugdahl, 1987; Doyle, 1973; Geffen & Wale, 1979; Hiscock & Kinsbourne, 1980; Pearson & Lane, 1991; Rueda, Fan, et al., 2004; Rueda, Posner, Rothbart, & Davis-Stober, 2004; Schul, Townsend, & Stiles, 2003). Sustained, selective attention shows a particularly long time course of development. The abilities both to selectively attend to relevant stimuli and to successfully ignore irrelevant stimuli improve progressively with increasing age across childhood (Cherry, 1981; Geffen & Sexton, 1978; Geffen & Wale, 1979; Hiscock & Kinsbourne, 1980; Lane & Pearson, 1982; Maccoby & Konrad, 1966; Sexton & Geffen, 1979; Zukier & Hagen, 1978). Further, there is some evidence that background noise creates greater interference effects for younger children than for adolescents or adults (Elliott, 1979; Ridderinkhof & van der Stelt, 2000). In a review of both behavioral and ERP studies of the development of selective attention, Ridderinkhof and van der Stelt (2000) proposed that the abilities to select among competing stimuli and to preferentially process more relevant information are essentially available in very young children, but that the speed and efficiency of these behaviors and the systems contributing to these abilities improve as children develop. Additionally, since the key sources of selective attention within the parietal and frontal lobes constitute parts of the dorsal pathway, similar chemical and anatomical factors noted in the section on vision may contribute to the plasticity of attention in a similar way. In addition, recent evidence suggests that there are considerable genetic effects on attention (Bell et al., 2008; Fan, Fossella, Sommer, Wu, & Posner, 2003; Posner, Rothbart, & Sheese, 2007; Rueda, Rothbart, McCandliss, Saccamanno, & Posner, 2005) and that these may also be modified by environmental input epigenetically

(Bakermans-Kranenberg et al., 2008; Sheese et al., 2007; unpublished observations from our lab).

Interventions

As described in the preceding section, selective attention influences early sensory processing across a number of domains. In our most recent research, we have been investigating the possibility that attention itself might be trainable, and that this training can impact processing in a number of different domains. Indeed, in his seminal work *Principles of Psychology*, William James raised the idea of attention training for children, proposing that this would be “*the education par excellence*” (James, 1890, italics in original). While James went on to say that such an education is difficult to define and bring about, attention training has recently been implemented in curricula for preschool and school-age children (Bodrova & Leong, 2007; Chenault, Thomson, Abbot, & Berninger, 2006; Diamond, Barnett, Thomas, & Munro, 2007; Rueda et al., 2005). These programs are associated with improvements in behavioral and neurophysiological indices of attention, as well as in measures of academic outcomes and nonverbal intelligence. Furthermore, one program showed that attention training translated to increased benefits of a subsequent remedial writing intervention for adolescents with dyslexia (Chenault et al., 2006).

Recent proposals suggest that some interventions designed to improve language skills might also target or train selective attention (Gillam, 1999; Gillam, Loeb, & Friel-Patti, 2001; Gillam, Crofford, Gale, & Hoffman, 2001; Hari & Renvall, 2001). We have tested this hypothesis in a series of intervention studies. In this research, we have documented changes in the neural mechanisms of selective attention following

training in typically developing children, as well as children with language impairment or at risk for reading failure (Stevens, Coch, Sanders, & Neville, 2008; Stevens, Harn, et al., in press). In all cases, increases in the effects of attention on sensorineural processing were accompanied by behavioral changes in other domains that were also targeted by the training programs, including language and preliteracy skills. These data suggest that modifications in behavior can arise alongside changes in the early neural mechanisms of attention.

In one study, we examined whether six weeks of high-intensity (100 min/day) training with a computerized intervention program designed to improve language skills would also influence neural mechanisms of selective auditory attention previously shown to be deficient in children with SLI (Stevens, Coch, et al., 2008). Before and after training (or a comparable delay period for a no-treatment control group), children completed standardized language assessments and the ERP measure of selective auditory attention described earlier. Relative to the no-treatment control group, both children with SLI and typically developing children receiving training showed increases in standardized measures of receptive language. In addition, children receiving training showed larger increases in the effects of attention on neural processing following training relative to the control group, and these changes were specific to changes in signal enhancement of attended stimuli (figure 11.6).

In a second study, we examined the neural mechanisms of selective attention in kindergarten children who were

either on track in preliteracy skills or at risk for reading failure. They were studied at the beginning of and following the first semester of kindergarten (Stevens, Currin, et al., 2008; Stevens, Harn, et al., in press). The at-risk group also received supplemental instruction with a previously validated reading intervention (Simmons, Kame'enui, Stoolmiller, Coyne, & Harn, 2003; Simmons et al., 2007). Behaviorally, the at-risk group showed improved performance on several preliteracy measures, raising their performance close to the on-track group by the end of the year. At the start of kindergarten, the at-risk group displayed reduced effects of attention on sensorineural processing compared to the on-track group. Following training, this difference between groups disappeared, with the at-risk group showing increased effects of attention on sensorineural processing (figure 11.7).

Functional MRI data from the same kindergarten children further supported the role of attentional changes in successful language or reading interventions (Yamada et al., 2008; Yamada, Stevens, Harn, Chard, & Neville, under review). Hemodynamic responses to visually presented letters or false-font stimuli (presented in separate blocks) were examined. Participants indicated when the same letter or false-font stimulus was repeated in two successive trials (i.e., a 1-back task). Consistent with previous research on reading-related networks in fluent readers, adults recruited a left temporoparietal region during this task (figure 11.8A). At the start of kindergarten, on-track children recruited bilateral temporoparietal regions, whereas children at risk for reading

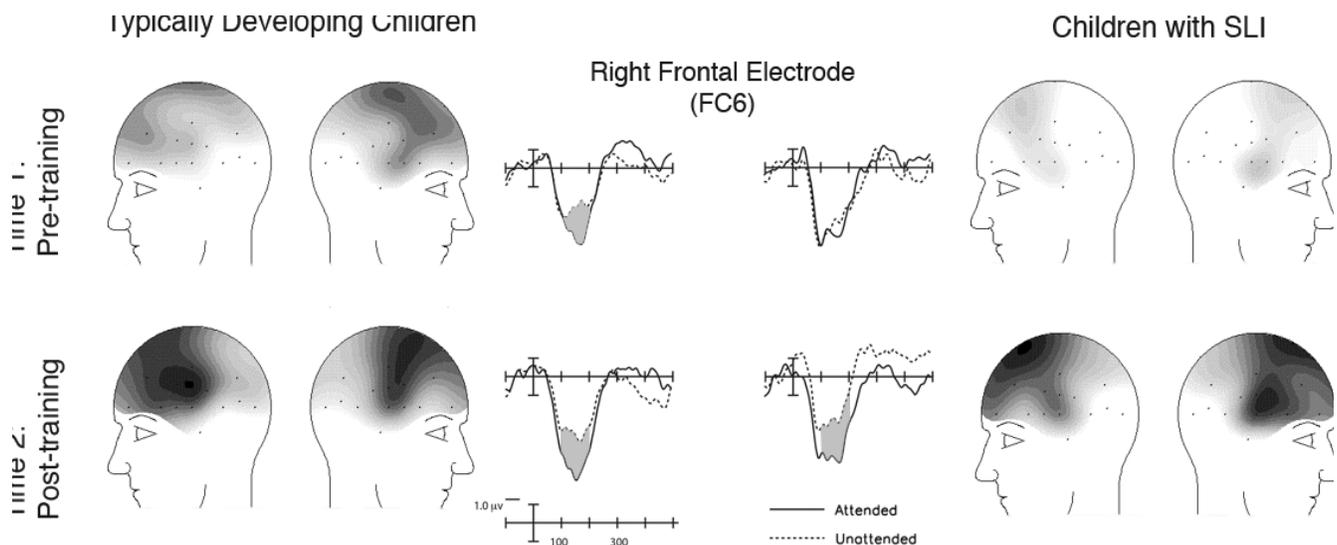

FIGURE 11.6 ERP responses to attended and ignored auditory stimuli in typically developing (TD) children and children with specific language impairment (SLI) before and after six weeks of daily, 100-minute computerized language training. Grand average evoked potentials for attended and unattended stimuli are collapsed across linguistic and nonlinguistic probes. Voltage maps show magnitude and distribution of the attention effect (attended-unattended)

during the 100–200-ms time window. Following training, both children with SLI ($P < .05$) and typically developing children ($P < .1$) showed evidence of increased effects of attention on sensorineural processing. These changes were larger than those made in a no-treatment control group ($P < .01$), who showed no change in the effects of attention on sensorineural processing when retested after a comparable time period ($P = .96$).

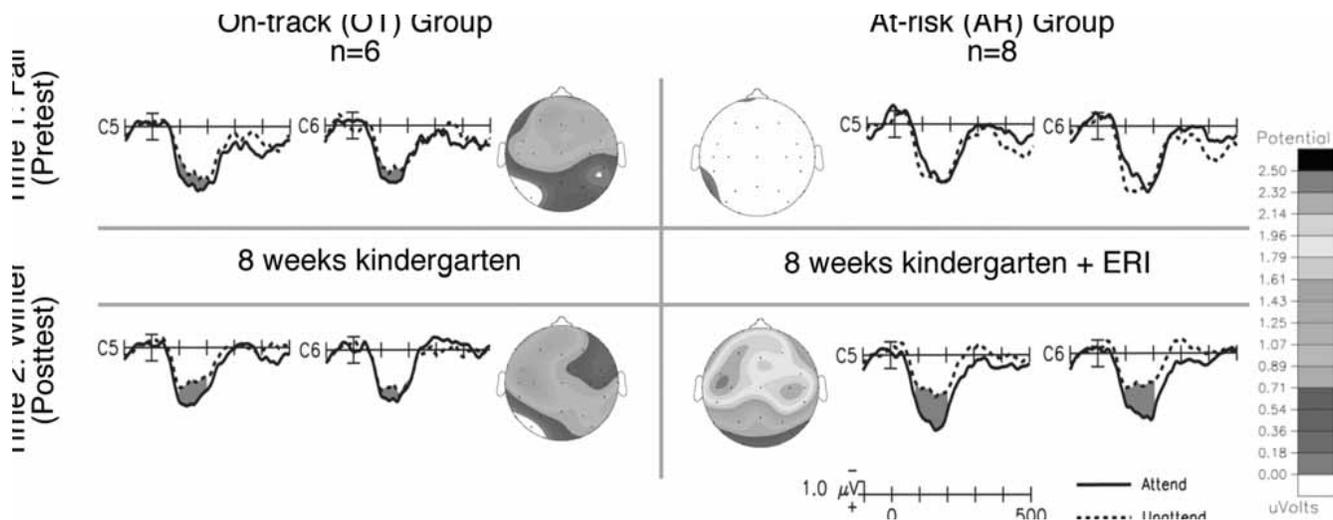

FIGURE 11.7 Grand average ERP waveforms from the selective auditory attention paradigm show the effects of attention on sensorineural processing in kindergarten children of diverse early reading ability across the first semester of kindergarten. Top row shows data from pretest, and bottom row shows data from posttest for five-year-old kindergarten children on track (OT) in early literacy skills or at risk (AR) for reading difficulty. The OT group received eight weeks of kindergarten between pretest and posttest. The AR group received eight weeks of kindergarten with 45 minutes of daily, supplemental instruction with the Early Reading

Intervention (ERI). Voltage map indicates the magnitude and distribution of the attention effect (Attended-Unattended). Changes in the effects of attention differed from pretest to posttest in the two groups ($P < .05$), with the OT group showing no change ($P = .92$) and the AR group showing a significant increase in the attention effect ($P < .01$). At pretest, the OT group tended to have a larger attention effect than the AR group ($P = .06$). At posttest, the AR group had a nonsignificantly larger attention effect than the OT group ($P = .17$). (See color plate 12.)

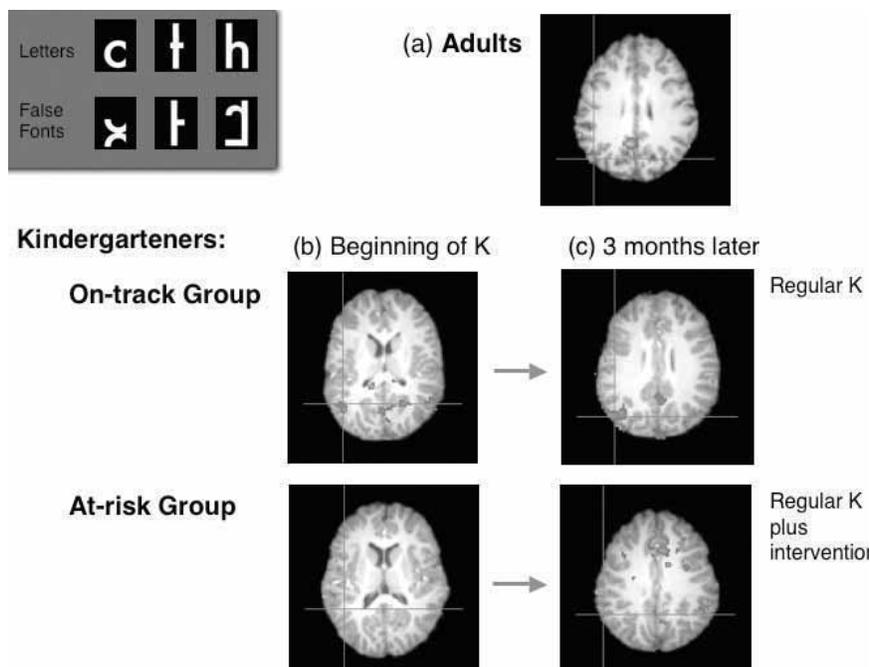

FIGURE 11.8 Functional MRI activations for letter > false font while performing a 1-back task in adults and kindergarten children of diverse reading ability across the first semester of formal reading instruction. (A) Adults performing the task displayed activation in classic left temporoparietal regions. (B) In contrast, at the beginning of kindergarten, children on track in early literacy skills (upper panel) showed bilateral temporoparietal activation, and children at risk for reading difficulty (lower panel) showed no regions of greater

activation. (C) Following one semester of kindergarten and, for children in the at-risk group, daily supplemental instruction with the Early Reading Intervention, on-track children showed left-lateralized activation in temporoparietal regions, and at-risk children showed bilateral temporoparietal activation and large activation of frontal regions, including the ACC. The left hemisphere is displayed on the left. In the upper left corner are example stimuli. (See color plate 13.)

failure did not show greater recruitment of any brain regions for letters versus false-font stimuli (figure 11.8B). Following 3 months of kindergarten and, for children at risk for reading failure, supplemental reading instruction, both groups showed changes in reading circuits toward more adultlike patterns, though the at-risk group showed a less mature pattern of activation (figure 11.8C). Interestingly, following a semester of kindergarten, the at-risk group showed greater activation than the on-track group of supplemental frontal regions, including the anterior cingulate cortex (figure 11.8). This suggested that changes in the neural circuits for reading in response to intervention also involved the recruitment of additional neural resources related to attention.

In a related line of research, we have also begun studies that train parents of children from lower socioeconomic backgrounds. Across eight weekly, small-group sessions, parents learn evidence-based strategies to improve communication with their children, promote children's critical thinking skills, and decrease family stress. We have compared the pre- to posttraining changes in this group of parents and their children to changes in a matched control group randomly assigned not to receive the intervention. To date the parent training appears very promising (Fanning, 2007; Fanning, Paulsen, Sundborg, & Neville, 2008; Fanning, Sohlberg, & Neville, under review). Relative to the control group, parents in the intervention group show larger decreases in self-reported stress related to parenting challenges. When interacting with their children, their language becomes more child directed (e.g., they allow more opportunities for the child to talk and to guide the interaction). In addition, there are large changes in the children themselves. Children whose parents completed the training show large and significant increases in standardized measures of language, nonverbal IQ, memory, and attention compared to children whose parents are randomly assigned not to receive the intervention. We are continuing to assess the parent-training program by looking at the effects of the training on attention and language-related ERPs. We are following children longitudinally to see whether improvements persist and generalize school performance. In addition, we are adapting the parent-training program to include a stronger focus on developing children's attention and self-regulation skills.

Finally, recent studies have linked variability in polymorphisms of genes that influence the production, metabolism, and transport of neurotransmitters important in attention to variability in behavioral, ERP, and fMRI indices of attention (Bell et al., 2008; Fan et al., 2003; Greenwood & Parasuraman, 2003). For example, the 3 repeat allele of the MAOA gene is associated with reductions in language and cognition, including executive attention, and with reductions in our ERP attention effects and activation of ACC on fMRI compared to the 4 repeat allele (Bell et al.; Fan et al.). The long-

long allele of the serotonin transporter gene and the 7 repeat allele of the DRD4 gene are associated with increased rates of ADHD and reduction of our ERP attention effects (Bell et al.; Fan et al.; Parasuraman, Greenwood, Kumar, & Fosella, 2005; Rueda et al., 2005; Savitz, Solmes, & Ramesar, 2006). However, recent studies suggest that such genetic effects display plasticity that is dependent on and modified by environmental input including parenting quality, parental interventions, and small group interventions (Bakermans-Kranenberg & Van Ijzendoorn, 2006; Bakermans-Kranenberg et al., 2008; Sheese et al., 2007; and our unpublished observations). Thus gene \times environment interactions and epigenetic mechanisms similar to those operating in animal studies (Kondo et al., 2008; Suomi, 2003, 2006) likely play a role in determining the different profiles of human neuroplasticity as well.

Conclusions

The research described in this chapter has illustrated the variable degrees and time periods of neuroplasticity in the human brain and likely mechanisms whereby experience influences different subsystems within perceptual and cognitive domains. Additionally, this research has highlighted the bidirectional nature of plasticity—those aspects of neural processing and related cognitive functioning that show the greatest capability for enhancement also display the greatest susceptibility to deficits under different conditions. Researchers are entering an exciting frontier of neuroplasticity research that takes the results of basic research on the profiles and mechanisms of neuroplasticity as a point of departure in the development of training and intervention programs. Our growing understanding of the limits and mechanisms of plasticity contributes to a basic understanding of human brain development and function and can also inform and guide efforts to harness neuroplasticity both to optimize and to protect the malleable and vulnerable aspects of human development.

Introduction

STEVEN J. LUCK AND GEORGE R. MANGUN

THE TERM “ATTENTION” has a broad set of meanings in everyday language, but they are all related in some way to the concept of focusing mental processes. Focusing on one task to the exclusion of others is often called “concentration” in everyday language. This kind of attention is typically studied under the heading of executive control. A good example is the Stroop task, in which the challenge is to perform a relatively unpracticed task (saying the name of a color) while suppressing interference from a highly practiced task (reading a word). This variety of attention is discussed in part IX, on higher cognitive functions (chapters 69–76).

Focusing on one source of sensory inputs to the exclusion of others is termed selective attention or, as a shorthand, simply “selection.” A good example is the visual search task, in which the challenge is to find a target object while suppressing interference from distractor objects that may be perceptually similar to the target. This is the variety of attention that is the focus of this section. Although selective attention plays a key role in many sensory modalities, the largest body of work has been in the visual system because our detailed knowledge of the anatomy and physiology of this sensory system provides solid footing for the study of the more ephemeral topic of attention. Visual attention is therefore the main focus of the chapters in this section.

Perhaps the most fundamental distinction in the study of attention is between the control of attention and the implementation of attention. Attentional control processes are responsible for taking general task instructions (e.g., find a grapefruit on the left side of this photograph) and converting these into a bias toward an appropriate set of features (e.g., colors, shapes, locations, etc.). Once a set of potentially relevant features, objects, or locations has been found, attentional implementation processes are responsible for ensuring that these features, objects, or locations receive preferential

processing. In the context of the classic spotlight metaphor, control processes are responsible for directing the attentional beam, and attention is implemented by means of the illumination of objects by the beam.

As discussed in Treisman's chapter on the basic behavioral phenomena of attention, early research on attention focused on the implementation of attention (chapter 12). This research initially asked whether attention operates at an early, perceptual stage or a late, postperceptual stage, but cognitive neuroscience research has shown that these are not mutually exclusive alternatives. Instead, attention can operate at different stages depending on the nature of the stimuli and task. Moreover, recent research has moved beyond coarse distinctions between perceptual and postperceptual stages and is now examining how attention operates in different ways within the dozens of different areas of the visual processing pathway. This new research is reviewed by Kastner, McMains, and Beck in chapter 13, on neuroimaging research, and by Maunsell in chapter 19, on single-unit recordings.

Research on the implementation of attention has also become more precise in identifying the nature of attentional modulations of visual sensory responses. Two major principles have now been supported by many forms of converging evidence. First, attentional selection depends strongly on the degree of competition. As described in the chapters by Kastner, McMains, and Beck and by Maunsell, attention has its strongest effects when task-irrelevant information competes with the processing of task-relevant information. For example, attention effects are often observed to increase as information moves into higher stages of the visual processing pathway, where receptive fields are larger and are therefore likely to contain task-irrelevant objects as well as task-relevant objects. A second major principle is that attention often operates as a gain control, increasing the effective contrast for attended stimuli without changing sensory tuning curves. This point has been made most clearly in the psychophysical and single-unit studies reviewed by Maunsell and in the event-related potential (ERP) studies reviewed in chapter 15 by Hopf, Heinze, Schoenfeld, and Hillyard. We are also now beginning to understand how these effects may arise from the microcircuitry and temporal dynamics of visual cortex, as reviewed in chapter 20 by Womelsdorf and Fries on the role of neural synchronization in attention.

The control of attention is also described in considerable detail in this section. Much of this work takes place within the concept of a network of frontal, parietal, and superior temporal areas that control the operation of attention. The chapters in this section make the case for specializations in attentional control within these interconnected brain regions. In chapter 17, Karnath describes the detailed anatomy of a network of areas surrounding the Sylvian fissure involved in the control of attention, noting an interesting correspon-

dence between right-hemisphere areas that are involved in attentional control and left-hemisphere areas that are involved in language and imitation. Chapter 14 by Corbetta, Sylvester, and Shulman complements this, describing how attentional control networks receive information from subcortical systems involved in affect and motivation and how different dorsal and ventral frontal-parietal networks are involved in the control of sensory and motor systems. Mangun, Saron, and Walsh describe how frontal and parietal attentional control networks interact with frontal cortical systems, such as the anterior cingulate cortex, that are involved in conflict detection, error monitoring, and online behavioral adjustments (chapter 16).

Research on the control of attention has also focused on the elementary "units" of selection. That is, does attention select spatial locations, nonspatial features, or whole objects? As reviewed in Treisman's chapter, this topic has been the source of much dispute in the cognitive literature for more than two decades, but cognitive neuroscience research has shown that these are not mutually exclusive alternatives. Attention can be allocated to the features of objects, to the locations occupied by objects, and directly to the objects themselves. This finding can be seen in neuroimaging studies (as described by Beck and Kastner and by Corbetta et al.), in single-unit studies (as described by Maunsell), and in ERP studies (as described by Hopf et al.). Perhaps the most impressive evidence, however, comes from the lesion patients described by Robertson in chapter 18. When spatial processing is severely disrupted in these patients, it is still possible to see clear evidence of intact feature-based and object-based attention.

Now that we have reviewed the major themes discussed by the chapters in this section, we would like to highlight three areas in which substantial progress has been made since the last edition of this book. First, although we have known for decades that a broad set of frontal, parietal, and subcortical areas play a role in the control of attention, the chapters in this section provide a much more detailed description of how these areas work both independently and in concert to control attention. New research is also looking at the microcircuitry of attention, revealing how different subclasses of neurons within an area are modulated by the operation of attention.

Second, the new research described in this section is beginning to reveal the details of how frontal and parietal areas can control the operation of attention within sensory areas. Top-down control signals have now been measured in a broad variety of attention tasks, and stimulation techniques have been used to show that activity within control areas can directly modulate sensory responses within visual cortex. A major unknown, however, is how these signals lead to the changes in neural synchrony that now appear to play an important role in the implementation of selection.

Finally, the chapters in this section describe new insights into the allocation of attention to nonspatial features, such as color and direction of motion. Recent studies have shown that attention can be directed to specific feature values across the visual field, and not just at attended locations. Indeed,

the operation of feature-based attention sometimes precedes and guides the allocation of space-based attention. We expect that the next five years will lead to new insights into how these different varieties of attention work together in the service of perception and behavior.

12 Attention: Theoretical and Psychological Perspectives

ANNE TREISMAN

ABSTRACT This chapter reviews research on attention using behavioral and psychological methods. It attempts to illustrate what was learned through these tools alone and what is gained when tools from cognitive neuroscience are added. The psychological approaches defined many of the theoretical issues, such as the nature of the overloads that make attention necessary, the level of selection, the method of selection (enhancement of attended stimuli or suppression of unattended ones), the targets of selection (locations, objects, or attributes), the ways in which attention is controlled, and the role of attention in solving the feature-binding problem. Psychology also developed many of the paradigms used to probe the underlying mechanisms that are now being confirmed by converging evidence from brain imaging and from studies of brain-damaged patients. Theories of attention have evolved from the early sequential “pipeline” model of processing to a more flexible and interactive model with parallel streams specializing in different forms of perceptual analysis, iterative cycles of processing, and reentry to earlier levels. Attentional selection takes many forms and applies at many levels. We learn as much from exploring the constraints on flexibility—what cannot be done—as from discovering what can.

While watching a movie of a basketball game and counting the passes made by one of the teams, participants completely miss seeing a large black gorilla walk through the game, even though it is clearly visible if attended to (Simons & Chabris, 1999; see also Neisser & Becklen, 1975). Why should we still be interested in purely psychological studies like this one? If, as Minsky said, the mind is what the brain does, then that is what, as psychologists, we are interested in, and it would be foolish not to use the tools from neuroscience. However, brain-imaging data and findings with neurological patients depend critically for their interpretation on the designs of the behavioral tasks being performed. We can directly observe actions, or we can measure brain activation, but by putting them together we further constrain the possible theories. This chapter is intended to set the scene, both historically and conceptually, for the subsequent chapters exploring neuroscientific approaches to attention in more detail.

The traditional questions in attention research mostly started as di- or trichotomies: “Is it x , or y , or z ?” For

example, does attention select the relevant stimuli early or late in perceptual processing? The answer typically proves to be “both or all the above.” Simplistic questions have evolved into attempts to specify *when* each answer applies and *why*. I select eight such issues to discuss here, using mostly psychological methods and bringing in neural evidence where it can decide questions that otherwise could not be answered. I also introduce many experimental paradigms that have been used to study attention. The goal has been to “bottle” the wide range of everyday phenomena encompassed by the label “attention” and bring them into the controlled conditions necessary for scientific study.

Why is attention limited?

As the gorilla example that opened this chapter suggests, attention seems to be severely limited. Other examples abound, as we show in later sections. We typically see only four items in a brief visual flash (Woodworth, 1938). We can follow the content of only one auditory message at a time (Broadbent, 1958). We can track only four moving circles among other identical circles moving in random directions (Pylyshyn & Storm, 1988). Why do these limits arise? There are three general ideas about their nature, and all could play a part.

STRUCTURAL INTERFERENCE One hypothesis is that limits arise only when two concurrent tasks use the same specialized subsystems. Proponents compared the interference between tasks that seemed likely to share common mechanisms and tasks that did not—for example, both were speech shadowing or one was piano playing (Allport, Antonis, & Reynolds, 1972), both were visual or one was auditory (Treisman & Davies, 1973), both used verbal rehearsal or one used imagery (Brooks, 1968). The results clearly showed more interference between tasks that were more similar. When they were sufficiently different, they were sometimes combined without impairment.

Different attributes like color, motion, and shape are processed by at least partially separate systems (e.g., Corbetta, Miezin, Dobmeyer, Shulman, & Petersen, 1991). Thus the structural interference view predicts little difficulty

ANNE TREISMAN Psychology Department, Princeton University, Princeton, New Jersey

in registering different properties of the same object, and this is what is found. Interference may still arise at the response level if the different attributes evoke conflicting responses, as in the task of naming the colored inks in which different color names are written (Stroop, 1935). The reason why attention is ineffective in tasks like the Stroop may be that the brain is forced to use whatever discriminative systems it has available *unless* these are fully occupied with other stimuli (Treisman, 1969).

Certain stimuli may have privileged access to attention, bypassing the structural limits: In a dichotic listening task, participants' own names sometimes broke through from the unattended message (Moray, 1959). Emotional stimuli, like a snake (Ohman, Flykt, & Esteves, 2001) or an angry face, are more likely to be seen than neutral stimuli (Eastwood, Smilek, & Merikle, 2001; for a review see Vuilleumier, 2005). The advantage extends also to guns and other nonevolutionary stimuli, suggesting that attention can be drawn to learned categories of fearful stimuli (Blanchette, 2006). Emotional stimuli may directly activate a separate pathway to the ventral prefrontal cortex and the amygdala (e.g., Yamasaki, LaBar, & McCarthy, 2002), although, contrary to some prior claims, some attentional resources are still needed for their detection (Pessoa, Kastner, & Ungerleider, 2002).

GENERAL RESOURCES There are also more general limits to attention. Kahneman (1973) argued for a limited pool of resources or "effort." He showed that a secondary task (monitoring a stream of visual letters) was impaired when combined with a primary task of adding one to each of a string of auditory digits, although these two tasks are unlikely to share the same brain systems. Kahneman used the size of the pupil as an online index of effort, having previously shown that it correlates closely with difficulty across a wide range of tasks. Interference with visual letter detection was maximal when the memory load was highest and effort, as indexed by the pupil, was at a peak (see figure 12.1).

Purely psychological studies are handicapped in determining what information is extracted from unattended messages by the fact that observable responses are needed as evidence, so that limits could arise from our inability to carry out simultaneous actions or to remember stimuli that we did in fact observe. Brain imaging allows us to monitor the incidental processing of unattended stimuli as they are presented, and it may give us more sensitive indications of where the limits arise. Results have cast additional doubt on claims that only structural interference matters. Rees, Frith, and Lavie (1997) observed fMRI activity in area MT produced by irrelevant moving dots surrounding a central, task-relevant word. Two tasks differing in difficulty were used to assess the effects of load in processing the central word: case discrimination (easy) or detecting a bisyllabic word (more

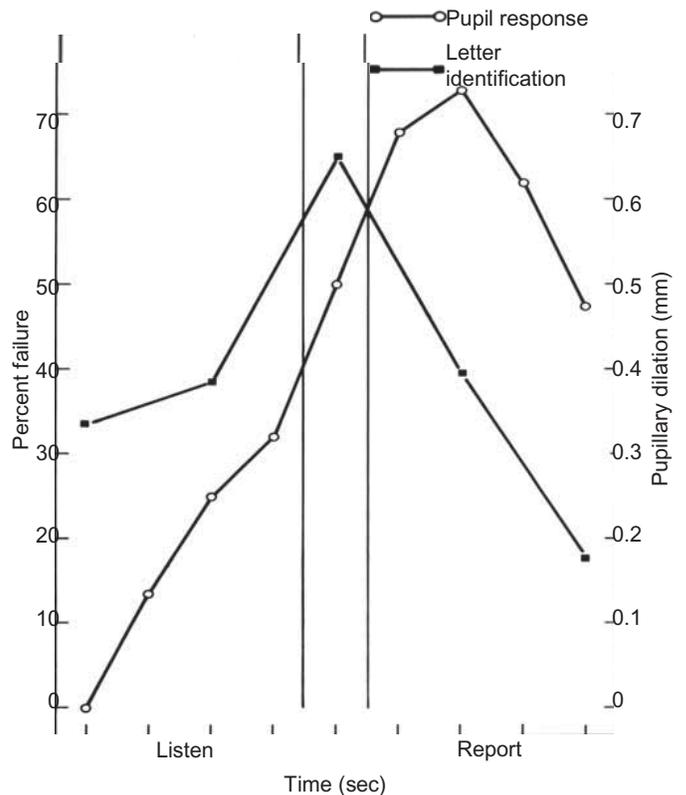

FIGURE 12.1 A measure of perceptual deficit and the pupillary response to a digit-transformation task. Black symbols show percent missed letters in a rapid visual sequence while participants listened to four digits, adding one to each and reporting the results (at rate of 1 per second). Errors increase with each extra digit at intake; they are highest at the time when participants are doing the mental addition; and they decrease as each transformed digit is reported. Open symbols show the size of the pupil, reflecting the amount of effort or resources being used. Note that the pupil index has about a 2-second lag behind the mental processing. (Modified with permission from Kahneman, 1973.)

difficult). Discriminating phonology is unlikely to involve area MT, yet fMRI activation to the irrelevant dots was reduced during the more difficult word task. Thus attention limits appear between two very different forms of visual perception. However, when auditory words replaced the visual ones, task difficulty in the auditory word task had no impact on visual activation of area MT. Psychological tests provided converging evidence: With visual words, the difficult task reduced the motion aftereffect generated by the irrelevant dots, whereas with auditory words it was unaffected. Resources are at least partly shared across very different tasks within vision, suggesting resource limits rather than structural interference within the visual modality, but may be separate across different modalities. An interesting exception concerns spatial coding, where a shared representation of space may create some overlap in resources (e.g., Spence & Driver, 1996).

BEHAVIORAL COHERENCE The premotor theory of attention suggests that attention is simply a preparation for response, selecting the goal of an intended action (Rizzolatti, Riggio, Dascola, & Umiltà, 1987). Attention is facilitated when the actions afforded by the stimulus are compatible with the response required (e.g., Craighero, Fadiga, Rizzolatti, & Umiltà, 1999; Tucker & Ellis, 1998). Hand location can facilitate detection of targets near the hand (Reed, Grubb, & Steele, 2006). Spatial attention normally follows a saccadic eye movement and can be triggered by subliminal stimulation of neurons that control that saccade (Moore & Armstrong, 2003). Attentional systems differ for space that is within reach and space that is beyond it (Ladavas, 2002). Actions may themselves affect the way attention is deployed. If a salient target like a unique color need only be detected, it “pops out” of the display; but if the goal is to touch the object, focused attention is required (Song & Nakayama, 2006). Although motor performance clearly interacts with attention, it seems unlikely that intended actions are the only limits to attention. Even when we passively watch stimuli go by (e.g., at the movies), we do select a subset of the information that reaches the senses.

WHEN LIMITS DISAPPEAR Attention limits are typically found in unpracticed tasks, but most attention-demanding tasks can, with extensive practice, be automatized—made independent of attention. Search for target letters among other random letters initially demands attention and gives steep slopes of latencies against display size. But after weeks of practice with consistent target-distractor mapping, the slopes become flat (Schneider & Shiffrin, 1977). Two verbal tasks that are both similar and demanding (reading for comprehension and writing to dictation) can initially be done only in alternation, but after weeks of practice, they are efficiently combined (Spelke, Hirst, & Neisser, 1976). The only remaining constraint is between tasks that required combining words in sentences, for example, deciding whether the passage makes sense semantically. Theories of attention limits must also account for how these limits can, in many cases, disappear with practice.

What does attention select?

Traditionally the debate has centered on three possible goals of selection—locations, objects, and attributes. To these, we can add selection of scale and selection of moments of time. The answer again seems to be “all the above.” Spatial selection is implied when facilitation spreads to separate, unrelated objects in the neighborhood of an attended target, shown by behavioral improvement (Hoffman & Nelson, 1981), ERPs (Mangun & Hillyard, 1988), and fMRI activation (Downing, Liu, & Kanwisher, 2001). For example, Downing and colleagues showed that attending to one of

two separately located colored ovals increased the fMRI activation produced by either a house or a face stimulus that shared the same location.

A number of findings also favor object selection. When overlapping objects share the same general location, like the basketball game and the gorilla described earlier, attention can still be very efficient. Selection may be guided by properties of the attended object, perhaps a color or a range of spatial frequencies, or simply by the collinearity and spatial continuity of its contours. Attention spreads more easily within than between objects (Duncan, 1984; Egly, Driver, & Rafal, 1994; Tipper & Behrmann, 1996; see figure 12.2). Patients with neglect due to parietal damage who are oblivious to the left side of space often also neglect the left side of objects (e.g., Halligan & Marshall, 1994). A dramatic

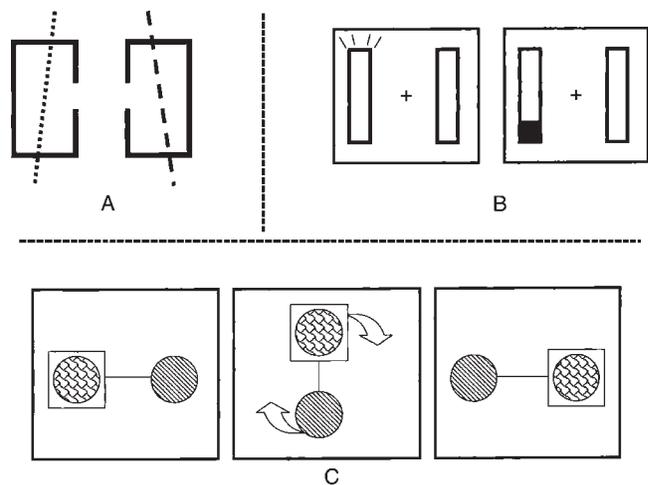

FIGURE 12.2 Three experiments suggesting that attention is allocated to perceptual objects. (A) Two examples of stimuli used in the experiment. Only one was presented on any trial. Participants were better at making two decisions on a single object (e.g., the orientation and texture of the line) than on two objects (e.g., the orientation of the line and the gap side of the rectangle), even though the two objects share the same location. (From Duncan, 1984, with permission.) (B) Two bars are presented, and one end of one bar brightens temporarily. Then a target (indicated by the black area) is presented either at the cued end of the cued object, or at the opposite end (as in the example shown), or in the other object at the same spatial distance from the cue. Responses are fastest at the cued end, but they are also faster at the other end of the cued object than in the other object, indicating that a within-object shift of attention is faster than a between-objects shift. (Modified with permission from Egly, Driver, & Rafal, 1994.) (C) Schematic illustration of the impact of left-sided neglect in the rotating objects experiment. When shown two objects, neglect patients with right parietal damage often see the one on the right and fail to see the one on the left. If they watch the objects rotate, however, they may continue to neglect the one that was originally on the left, even when it moves into the right field, suggesting that attention is allocated to the object rather than to its location. The shaded area reflects the part of the display neglected by the patients. (Modified with permission from Tipper & Behrmann, 1996.)

demonstration of object-based selection with *no* distinguishing properties involves tracking a subset of identical moving dots (Pylyshyn & Storm, 1988). Participants are shown, for example, eight identical dots, of which four briefly brighten, indicating that they are the targets. All eight dots then move on random, independent paths, and participants attempt to track the four targets. Selection here must be based exclusively on spatiotemporal continuity, since after the initial cues nothing else differentiates targets from distractors. Scholl, Pylyshyn, and Feldman (2001) further defined what counts as a selectable object, showing that the ends of lines whose other ends are to be ignored are impossible to track. Pylyshyn proposed that selection is maintained through preattentive indices (FINSTs) attached to the cued targets. These give direct access to the objects to which they are attached, and finding them should therefore not need attention. However, the task is clearly subject to attention limits, showing a decrement with dual tasks (Treisman, 1993). Wilson and I showed that tracking was impaired when participants were also asked to note changes in binding of color and texture in the borders around the display.

Attributes may also be units of attentional selection. For example, we may attend to motion and ignore color and shape (Corbetta et al., 1991). However, selection of one attribute within an object is often less efficient than other forms of selection. There is a strong bias to attend to objects as wholes. The Stroop task illustrates a failure to reject a word while attending to its color. Can we further narrow attention to select a particular feature within an attribute (e.g., red within the attribute of color)? Serences and Boynton (2007) showed that facilitation of a particular feature could spread across the visual field, even in the absence of a stimulus. Observers can track one feature of an object as it changes over time, so long as the changes are gradual (Blaser, Pylyshyn, & Holcombe, 2000). However, they could track two changing features at once only if these characterized the same object. Again feature selection was mediated by attention to an object as a whole.

When irrelevant attributes produce no behavioral interference with the relevant task, brain imaging is needed to test whether they are truly suppressed. O'Craven, Downing, and Kanwisher (1999) used overlapping face and place stimuli and asked participants to report either the direction of the moving picture or the location (slightly shifted from center) of the static one. The picture with the relevant attribute produced increased activation in the brain area specialized for its (irrelevant) category—PPA for houses and FFA for faces. Selection of one attribute here also resulted in enhanced attention to the object as a whole. The picture that emerges is that attention can be biased to select any of the three candidates, locations, objects, and attributes, but that object selection either takes precedence over feature selection or mediates it.

Selection of scale with hierarchically organized stimuli (e.g., global letters made of local letters) shows many similar attentional phenomena. For example, it can take time to reset attention from one level to another (Ward, 1982), and performance at one level deteriorates when attention is cued to the other (Bulakowski, Bressler, & Whitney, 2007). Navon (1977) found faster responses to the global level (“global precedence”), although this preference is modulated by the density and size of the local elements (Kimchi, 1992). Ivry and Robertson (1998) suggest that the attentional bias is relative rather than absolute, selecting the *higher* or the *lower* spatial frequencies in any given display. They link it to a cerebral asymmetry favoring higher frequencies in the left hemisphere and lower in the right. Data from neurological patients support this specialization (Robertson & Lamb, 1991).

Finally selection of moments in time is demonstrated by comparing performance with and without a temporal warning. In Posner's typology of attention, measured by his Attention Network Test (ANT; Fan, McCandliss, Sommer, Raz, & Posner, 2002), this is one of the three components of attention—alerting, orienting, and executive control. Alerting, cued by a temporal warning, considerably speeds reaction times.

How does attention select?

Does attention enhance relevant items, inhibit irrelevant items, or change the tuning of selected neurons? This question is difficult to answer because it is unclear what the baseline should be. We cannot be in a state of *no* attentional deployment. The alternatives to focused attention are inattention (i.e., focused attention to another object) or divided attention to two or more objects, which allows only a relative measure of facilitation. Probing unattended objects behaviorally is self-defeating, although an indirect measure of reduced interference can suggest inhibition. Another solution is to use neural measures of response to unattended stimuli.

FACILITATION Focused attention is generally found to facilitate the processing of selected signals relative to the divided attention baseline, improving the accuracy or latency of response (Posner, 1980). There is some disagreement about the form the facilitation takes—an increase in signal-to-noise ratio, a narrower tuning to sharpen discrimination, or a shift in criterion (see chapter 19 by Maunsell, this volume, for evidence from neural recordings). Prinzmetal, Nwachuku, Bodanski, Blumenfeld, and Shimizu (1997) and Prinzmetal, Amiri, Allen, and Edwards (1998) investigated the phenomenology of attention, showing that it reduces the variance but leaves the perceived intensity unchanged. Signal detection theory separates effects on sensitivity (d')

and on decision criteria. Shaw (1984) found that in detection of luminance increments, attention load affected only the criterion, but in a letter localization task it also affected d' . However, Hawkins and colleagues (1990) found that spatial cuing affected both d' and criterion in a luminance detection task.

A related question, best answered with neural measures, is whether attention produces a multiplicative effect on the signal (gain control) or simply changes the baseline activity on which the signal is superimposed. Hillyard, Vogel, and Luck (1998) concluded that the gain control model fits best in early spatial selection. But there is also evidence in some conditions for changes in baseline activity (Kastner, Pinsk, De Weerd, Desimone, & Ungerleider, 1999; Chawla, Rees, & Friston, 1999).

INHIBITION Whether inhibition is invoked in an attention task may depend on how distracting the irrelevant stimuli would otherwise be. More active suppression is needed when the target and distractors are superimposed rather than spatially separated. Participants name one of two superimposed pictures more slowly when the currently relevant picture was the irrelevant one on the previous trial, suggesting that it was inhibited when it was irrelevant and the inhibition then had to be removed (Tipper, 1985). Thus this negative priming paradigm may show aftereffects of inhibition. A reduction in Stroop interference demonstrates the online inhibition of an irrelevant object, not just the aftereffects of inattention (Wühr & Frings, 2008; see figure 12.3).

Inhibition may also be used to prevent rechecking the same locations or stimuli that have already proved fruitless. Thus responses are slower at locations that have previously received attention, an effect known as inhibition of return

(Posner & Snyder, 1975). Probe items in search get slightly slower responses when they appear in locations previously occupied by nontarget items (Cepeda, Cave, Bichot, & Kim, 1998; Klein & MacInnes, 1999). In the Marking Paradigm (Watson & Humphreys, 1997), a subset of distractors is shown in advance of the full search display. This procedure eliminates their contribution to search latencies, producing efficient feature search of just the items that appear in the final display instead of what would otherwise be a slower search for a conjunction target.

Functional MRI measures offer more direct evidence of inhibition, suggesting that attention to a stimulus at the fovea strongly suppresses baseline activity in brain areas responding to other spatial locations (Smith, Singh, & Greenlee, 2000). Event-related potential (ERP) differences between attended and unattended items show both inhibition of irrelevant items (shown in the P1 ERP component) and facilitation of relevant ones (shown in the N1 component) (Luck et al., 1994). When participants must bind features to identify the target, both a P1 and an N1 are shown, whereas when the presence of a color is sufficient, only the N1 (facilitation) effect remains (Luck & Hillyard, 1995). Again, inhibition is used only when distractors would otherwise cause interference.

CHANGES OF TUNING OR SELECTIVITY Receptive field sizes can change, shrinking with attention to give finer selectivity (Moran & Desimone, 1985). Selectivity to particular features can also be sharpened. For example, when participants attended to the direction in which objects were rotated, the selectivity of fMRI in area LOC to orientation differences was increased relative to when they attended to the color of a central dot (Murray & Wojciulik, 2004). (Again, see chapter 19 by Maunsell for evidence from neural recordings.)

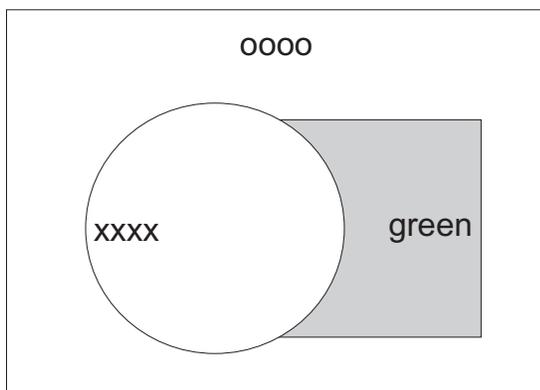

FIGURE 12.3 The task is to name the color of the square shape (which was yellow). Stroop interference is greater from the word “green” inside the relevant object than it is if the word is presented in the background where the *O*’s are shown, and it is reduced further when presented in the irrelevant red circle, where the *X*’s are shown in the figure. (Modified with permission from Wühr & Frings, 2008.)

Does attention act early or late?

In the early days of attention research, information processing was seen as a pipeline of successive stages, the output of each becoming the input of the next, with information of increasing complexity abstracted at each level. Attention could potentially select between outputs at any level to determine which should be passed on to the next. This model has been replaced by a more interactive system with reentry to early levels and extensive lateral communication between separate parallel streams of analysis, dealing with different types of information—“what?” in the ventral versus “where?” in the dorsal areas (Ungerleider & Mishkin, 1982), or objects and events for conscious representation in the ventral pathway and the online control of actions in the dorsal pathway (Milner & Goodale, 1995). Within each pathway, selection can occur at various levels, depending on the task,

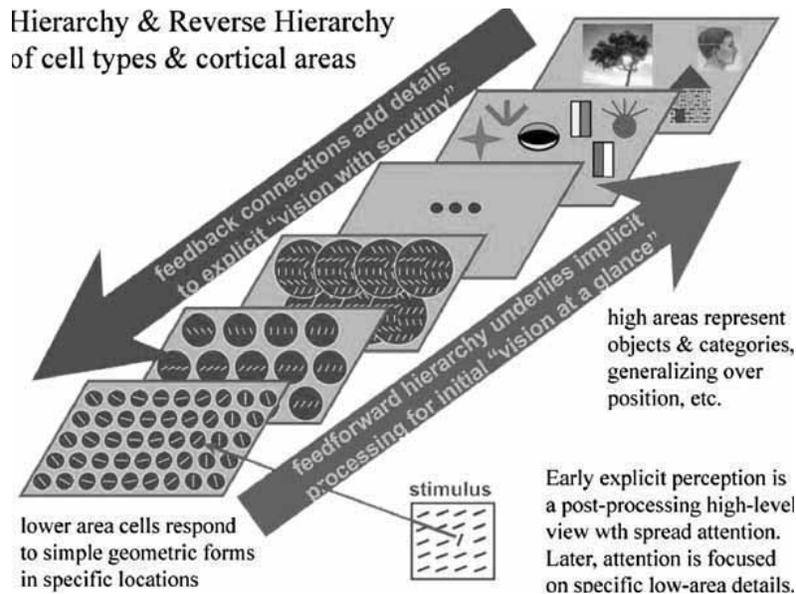

FIGURE 12.4 The reverse hierarchy theory. An initial fast-forward sweep through the visual hierarchy yields early access to high-level properties from large receptive fields. This can be followed by reentry to earlier areas, as required by the task. (Reprinted from Hochstein & Ahissar, 2002.)

the load, and the degree to which concurrent tasks engage the same subsystems. A recent framework that captures this flexibility is the reverse hierarchy theory of Hochstein and Ahissar (2002), in which an initial feedforward sweep through the sequence of visual areas takes place automatically, followed by optional controlled processing that may return to lower areas as required by the task (see figure 12.4). Access to awareness is initially at the highest levels of representation where receptive fields are large and discrimination is categorical.

Without assuming that the two must be correlated in a fixed order, we can still ask about either the level or the time at which selection is made. The early-late dichotomy was actually always a “straw” question. Proponents of early selection did not deny that selection could also occur late. The real question was “*Can* attention act early (Broadbent, 1958), or is all perceptual processing automatic, with attention selecting only at the level of memory and response?” (Deutsch & Deutsch, 1963). On one hand, proponents of late selection argued that attention limits are determined by decision effects alone: More stimuli lead to increased uncertainty and increased chances that noise will exceed a response criterion (e.g., Bundesen, 1990; Kinchla, 1974; Palmer, 1995). On the other hand, behavioral tests showed that selection based on properties that are processed early (simple physical characteristics like location, color, auditory pitch) was more efficient than selection based on properties presumably processed only later (semantic content, abstract categories). This conclusion was true even when the load on responses and memory was minimized (e.g., Treisman & Riley, 1969).

In the so-called psychological refractory period, attention limits seem to arise late. When separate speeded responses are required to two stimuli presented in close succession, the response to the second is typically delayed, reflecting an attentional bottleneck (Welford, 1952). Pashler (1993, 1994) used evidence of underadditivity of factors contributing to the two reaction times to locate the point at which overlap in processing becomes impossible. He found convincing evidence that the bottleneck arises not in perception but in central decision and response selection (see figure 12.5). The fact that attention limits *can* and sometimes do arise at late stages does not refute the claim that they can also act early.

A coherent account relates the level of selection to the level at which the potential overload occurs. If perception is demanding, selection needs to be early, whereas if the perceptual load is low, early selection may be not only unnecessary but actually impossible. Lavie and Tsal (1994) and Lavie (1995) showed that interference from a flanking distractor decreased, and, by inference, early selection efficiency increased, as the attended task became more difficult (see figure 12.6). But if the load arises in the control systems that direct attention, high load may *reduce* the efficiency of early selection and increase the effects of irrelevant stimuli. Using a dual task where participants were to remember the order of four digits, presented either in random orders (high working memory load) or in a fixed regular order (low load), while classifying famous names printed over irrelevant distractor faces, de Fockert, Rees, Frith, and Lavie (2001) found that incongruent faces produced more interference in the *high* load condition, presumably because working memory

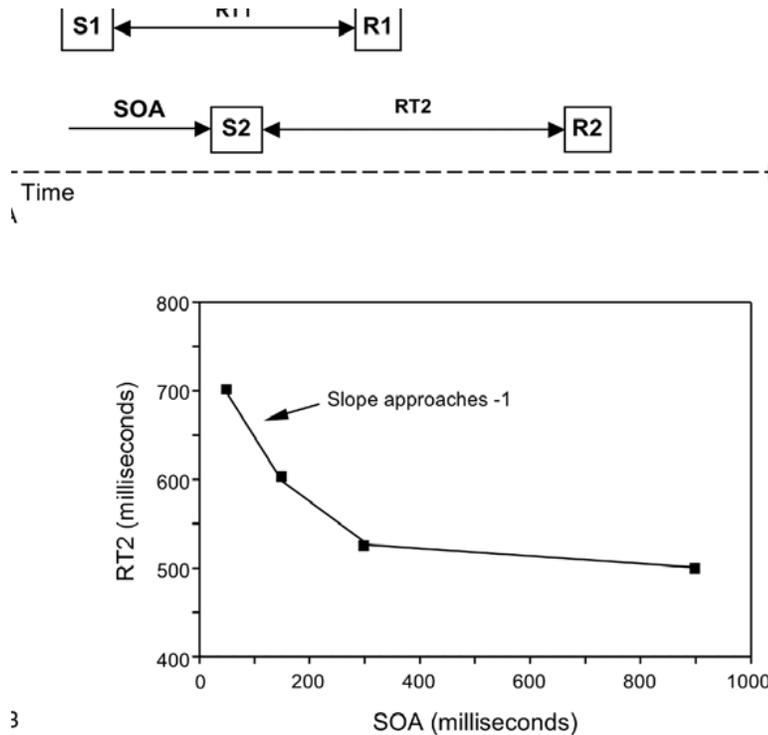

FIGURE 12.5 Psychological refractory period (A) Objective sequence of events (S1, stimulus 1; R1, response 1; SOA, stimulus onset asynchrony). (B) Observed reaction time to second stimulus is delayed as the interval between the tasks is reduced. The slope approaches -1 , indicating that (on average) the second response cannot be produced until a certain time after S1. (C) Hypothesized

stages of mental processing: A, perceptual processing; B, central decision time; C, response programming time. Stage B forms a bottleneck where two separate decisions cannot overlap with each other. Other stages can operate in parallel. (From Pashler, 1994, with permission.)

involves the same frontal lobe executive system as attentional selection. Brain imaging provided converging evidence: Activation in the fusiform face area was higher when working memory load was high, making selection inefficient.

IMPLICIT PROCESSING In distinguishing the level at which selection is made, we must also distinguish implicit processing from explicit accessibility. In the 1960s and 1970s, it was often assumed that perceptual processing was fully reflected in conscious experience and that behavioral responses were a reliable guide to the information available. This assumption was challenged by an early finding (Corteen & Dunn, 1974): Shock-associated words in an unattended message produced a galvanic skin response without also being consciously detected. Since then, other examples of implicit processing have been documented, using both indirect behavioral

evidence, such as priming, interference, or emotional responses, and direct neural measures of responses to unattended stimuli.

Patients with unilateral neglect due to a right parietal lesion often show indirect evidence that they have identified stimuli that they are unable to report (e.g., McGlinchey-Berroth, 1997). There are also many instances of implicit perception in normal participants. When participants judged the relative length of the arms of a cross, an additional unexpected stimulus was often simply not seen (Mack & Rock, 1998). Yet a subsequent word-completion task showed priming from visual words to which the participant was “inattentionally blind” (see figure 12.7). A smiling face and the participant’s own name were among other stimuli that were also detected, presumably because of their subjective importance. Implicit processing of surprising complexity and

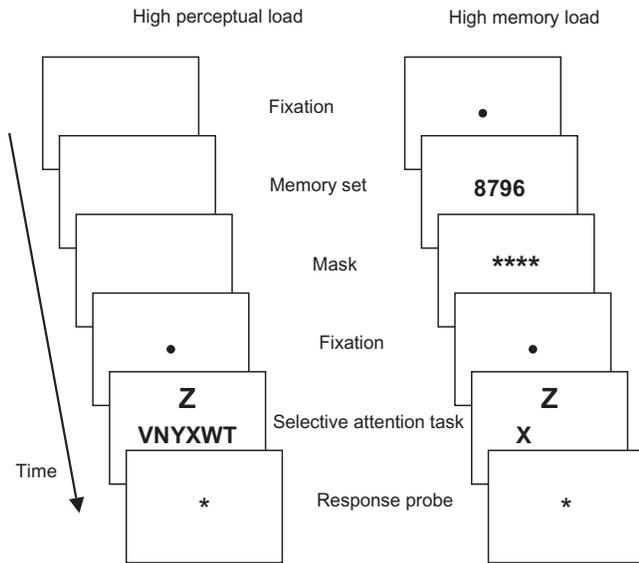

FIGURE 12.6 Two forms of attention load with different effects on performance. The task is to find the *X* or *Z* in the foveal letter string or single letter. On the left, the irrelevant flanking *Z* causes more interference when the relevant task involves a single letter (low load) relative to a string. On the right, there is always just one central letter, but there is an additional memory task with either a high load (4 random digits to remember) or a low load (4 digits in sequential order, e.g., 6789). Interference from the irrelevant flanker is higher in this case when the load on working memory is high. The reason suggested is that the control of attention depends on the same areas as working memory. (Modified with permission from Lavie & DeFockert, 2003.)

persistence was shown in a negative priming experiment (DeSchepper & Treisman, 1996). We found a slight delay in responding to novel, previously unattended nonsense shapes when they subsequently became relevant, even though explicit recognition memory was at chance (see figure 12.8). This negative priming, which sometimes lasted for days or weeks, was established in a single trial and was specific enough to discriminate between 260 different unfamiliar shapes.

Neural measures can show implicit processing even when behavioral responses do not. The attentional blink is shown when rapid serial visual presentation of two targets embedded in a string of distractors results in a reduced probability of detecting the second target within the following few items, as if the first occupies attention for several hundred milliseconds, blocking processing of the second (Shapiro & Raymond, 1994; see figure 12.9). Yet unexpected words presented during this “attentional blink” triggered an N400 ERP component, implying that they were identified at least to the level of semantic analysis (Luck, Vogel, & Shapiro, 1996). Yi, Woodman, Widders, Marois, and Chun (2004) presented a sequence of faces in the center and places in the surround. While attempting to detect a one-back repetition of a face, participants failed to notice repetitions of the unattended places, suggesting early selection. However, fMRI showed

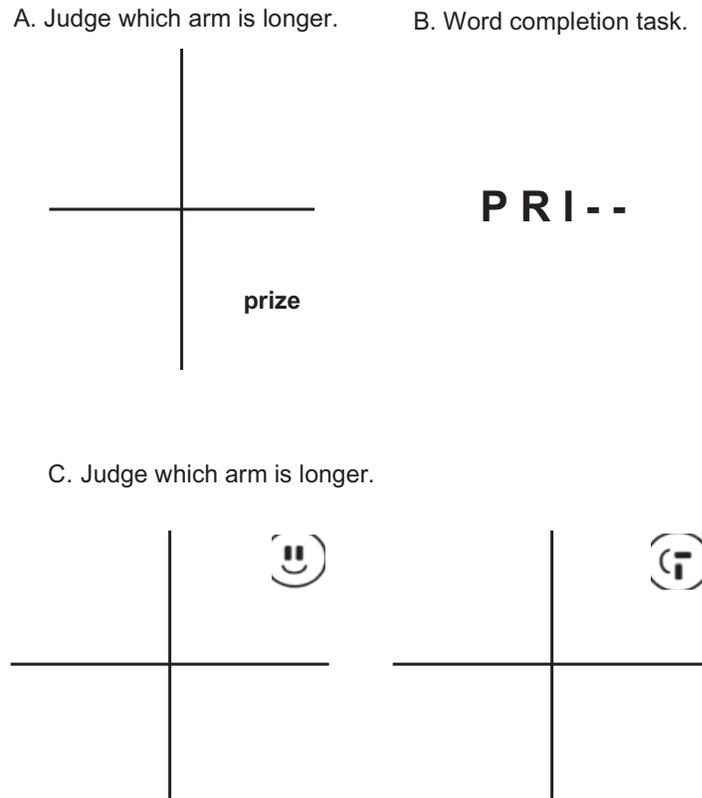

FIGURE 12.7 Inattention blindness. (A, B) An experiment showing implicit processing of unattended words. On the first three trials participants are shown only a plus sign and they judge which arm is longer. On the fourth trial a word appears in one of the quadrants and is often not seen. However, in a subsequent word-completion task participants are more likely to respond with the unseen word, showing implicit priming from an unattended and undetected word. (C) A similar experiment in which the unexpected stimulus is a face. The smiling face is much more likely to be seen than the scrambled one or than a sad face, showing effects of meaning and emotion on implicit processing of unattended stimuli. (Modified from Mack & Rock, 1998.)

decreased activation to the repeated scenes in the parahippocampal place area. Adaptation to specific scenes implies that representations were formed and matched across trials despite never reaching conscious awareness. Again the fMRI effect was weaker than when the scenes received full attention, suggesting some reduction in early processing when attention is focused elsewhere.

Neural changes can specify the timing of attention effects. Functional MRI activation and single-unit changes occurring in anticipation of the stimulus have proved that attention can affect the baseline activity in specialized extrastriate areas even before the stimulus is presented—“early” indeed! (Chawla et al., 1999; Hopfinger, Buonocore, & Mangun, 2000; Kastner & Ungerleider, 2000). Early attenuation of unattended stimuli also appeared in ERP responses as early as 70–100 ms after stimulus onset (Van Voorhis & Hillyard, 1977). Anatomically low-level effects in an fMRI study

showed attention effects as early in the ascending visual pathways as the lateral geniculate (O'Connor, Fukui, Pinsk, & Kastner, 2002). Because of the multiple connections back from higher areas and the low temporal resolution of fMRI, it is ambiguous here whether attention affects a first pass through the visual hierarchy or acts only through reentrant

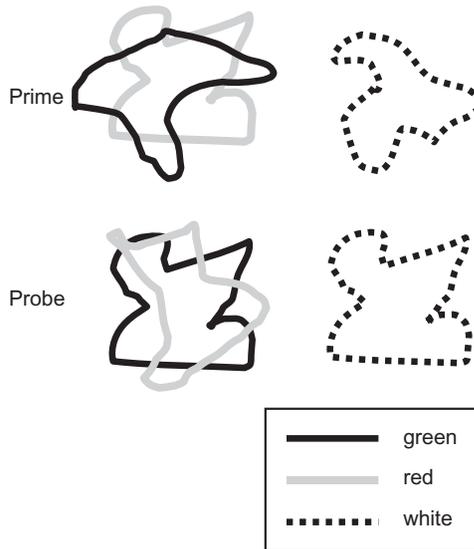

FIGURE 12.8 Negative priming. Participants judge whether the green shape on the left matches the white shape on the right while ignoring the red shape on the left. They have no explicit memory for the unattended shapes, yet when one reappears as the shape to be attended, responses are slightly slowed, as though it had previously been inhibited or labeled “irrelevant” and the label had to be cleared when the shape became relevant. This negative priming effect can last across hundreds of intervening trials and days or weeks of delay. (After DeSchepper & Treisman, 1996.)

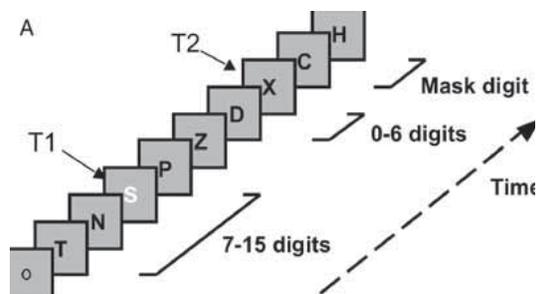

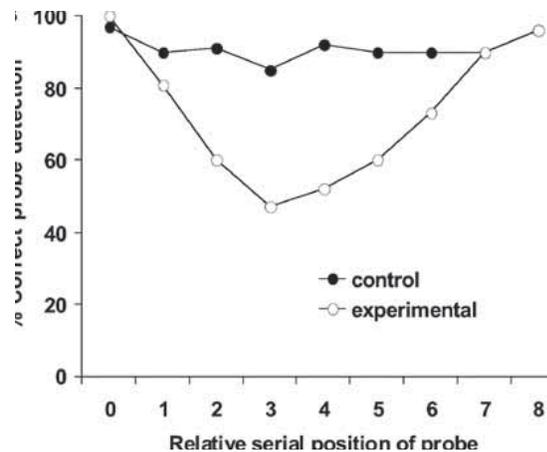

FIGURE 12.9 The attentional blink. (A) Participants monitor a rapid visual sequence for two different targets. For example, T1 might be a white letter in a black string, and T2 might be a letter X. (B) The open circles give the detection rates when participants do both tasks, and the black circles show performance on T2 in the control condition in which they ignore the first target. In the com-

connections. However, combined with temporal evidence from ERPs and single-neuron recordings, both reflecting early cortical activity, the occurrence of early, short-latency attentional modulation is now clearly established.

Implicit processing of unattended items complicates the attentional story, suggesting that attention can block access to consciousness without blocking all forms of perceptual processing. The fact that this result can occur does not imply that it always does. The perceptual load was low in most experiments that showed implicit effects, and when it was raised, the implicit effects disappeared (Neumann & Deschep- per, 1992; Rees et al., 1997). But we still need to explain why attention should limit conscious access when the perceptual load is low. Interference may be greater from consciously perceived objects than from implicitly distinguished stimuli.

The role of attention in feature binding

The visual system comprises many specialized areas coding different aspects of the scene. This modularity poses the binding problem—to specify how the information is recom- bined in the correct conjunctions—red shirt and blue pants rather than an illusory blue shirt. Behavioral results (Treisman & Gelade, 1980) suggest that we bind features by focusing attention on each object in turn. Evidence includes findings that when attention is prevented, binding errors or illusory conjunctions are frequently perceived (Treisman & Schmidt, 1982); a spatial precue helps detection of a conjunction much more than of a feature target (Treisman, 1988); boundaries between groups defined only by conjunctions are hard to detect, whereas those between features are easy (Treisman & Gelade, 1980); visual search depends on focused

bined tasks, T2 is very likely to be missed if it occurs within a few hundred milliseconds of T1, suggesting that detecting a first target makes the participant refractory to detecting a second for the next few hundred milliseconds. (From Shapiro & Raymond, 1994, with permission.)

attention when the target is defined only by a conjunction of features (e.g., a green *T* among green *X*'s and brown *T*'s), whereas search for either of two disjunctive features (e.g., blue *or* curved) among the same distractors allows parallel search. In some cases, conjunction search for a known target with salient features can bypass the serial check, suggesting an additional mode of selection through feature grouping and guidance (Nakayama & Silverman, 1986; Treisman & Sato, 1990; Wolfe, Cave, & Franzel, 1989).

The theory was generally interpreted as predicting parallel search whenever a unique feature is available to mediate performance. This conclusion was correct, but the interpretation of "feature" as "any unidimensional difference" was not. When target and distractors differ on a single dimension, so that both activate the same detectors to different degrees, they can produce a wide range of search rates (Treisman & Gormican, 1988). Features are defined relative to a background: they are properties that activate neural detectors not also activated by surrounding elements. Converging tests include the following: Features are elements that can migrate to form illusory conjunctions, that mediate effective grouping and boundary detection, and that can be separately attended. Neural evidence from single units may also confirm candidates derived from behavioral criteria. There is evidence that new feature detectors can be established through learning (e.g., Freedman, Riesenhuber, Poggio, & Miller, 2002).

Support for feature integration theory came from a patient studied by Robertson, Treisman, Friedman-Hill, and Grabowecky (1997). RM had bilateral parietal damage from two successive strokes, showing the classic symptoms of Balint's syndrome: a failure to localize visual stimuli and an inability to see more than one object at a time—simultanagnosia. The theory predicted that he should also have difficulty binding features, since doing so requires focused attention to their shared location. Even with long exposures, when two letters were present, RM frequently saw the shape of one letter in the color of another. He was unable to search for conjunction targets, although, despite his severe simultanagnosia, he had no difficulty with feature search, detecting the presence of red in a display of blue letters, or a *Q* among *O*'s, with very few errors.

Further evidence from neuroimaging (Corbetta, Shulman, Miezin, & Petersen, 1995) showed that the same parietal areas were active in spatial attention switching and in binding, but not in feature search. Transcranial magnetic stimulation (TMS) to the parietal lobes selectively disrupts conjunction but not feature search (Ashbridge, Walsh, & Cowey, 1997). Luck and Hillyard (1995) showed ERP suppression specific to conjunction search. Recent studies comparing conjunction search with difficult feature search gave mixed results (Donner et al., 2002; Leonards, Sunaert, Van Hecke, & Orban, 2000; Wojciulik & Kanwisher, 1999).

However, these are of questionable relevance, since the theory suggests that feature discrimination can also require focused attention when discriminability is low.

How is attention controlled?

Attention can be "captured" "bottom-up" by salient sensory events, particularly when they signal the onset of a new object (Yantis & Jonides, 1996). It may be attracted by events with emotional significance. But attention can also be endogenously controlled. Two general accounts have been proposed. One suggests a specialized attention network, controlling perceptual processing from the outside by amplifying relevant signals and/or attenuating irrelevant ones (Mesulam, 1981; Posner & Dehaene, 1994). The existence of such a control system is supported by several fMRI studies. D'Esposito and colleagues (1995) found that the dorsolateral prefrontal cortex and the anterior cingulate were activated only when two tasks were performed concurrently and not for either alone. Hopfinger and colleagues (2000), Corbetta, Kincade, Ollinger, McAvoy, and Shulman (2000), and Kastner and Ungerleider (2000) identify a network of areas, including FEF, SPL, SEF, IPL and MFG, involved in the external control of attention. Corbetta and colleagues additionally distinguish between voluntary control of attention in advance of the stimulus and the reorienting of attention when a target has been detected. The former seems to be controlled by the intraparietal sulcus, and the latter by the right temporoparietal junction (Corbetta et al.).

An alternative account sees selection as the emergent outcome of competition between neighboring objects within receptive fields. Reynolds, Chelazzi, and Desimone (1999) showed competitive interactions between single units in monkey ventral areas. The biased competition theory (Desimone & Duncan, 1995) combines the two accounts: top-down inputs from the control network bias the competition by adding to local activation of one of the competing objects. Different brain systems responding to the same object cooperate, ensuring that one object becomes dominant across multiple areas. It is not clear that purely behavioral evidence could distinguish biased competition from structural interference, which makes similar predictions about the specificity of interference. Thus the supporting evidence is mainly neural. Functional MRI studies showed weaker activation when four pictures were shown together for 250 ms than when they were shown successively for 250 ms each (Kastner & Ungerleider, 2000). Differences in stimulus duration were subsequently eliminated by presenting one picture in the upper visual field, either alone or together with three others in the lower field (Kastner et al., 2001). The added pictures reduced the activation produced by the target, but when attention was directed to the upper picture, full activation was restored. Competition arises

mainly within receptive fields. Since these increase in size with the level in the hierarchy, the further apart the stimuli, the higher the level of processing at which they compete (Kastner et al.). However, there may also be attention limits outside the classical receptive field. The early ERP effects of attention reflect selection between stimuli in different visual hemifields and therefore hemispheres of the brain (Van Voorhis & Hillyard, 1977). Another issue for the biased competition theory is to specify how local neurons “know” whether their activity is produced by parts of the same object, which should cooperate, or by different objects that should compete. This “knowledge” may require substantial top-down control of local competition.

Focused versus distributed attention

There is a paradox in attention research: Many studies show sharp limits such that only three or four objects can be tracked through space (Pylyshyn & Storm, 1988) or identified at a glance (Woodworth, 1938); change detection in an alternating pair of otherwise identical scenes is surprisingly difficult (Rensink, O’Regan, & Clark, 1997); and accurate binding depends on focused attention. Yet natural scenes can be rapidly and effortlessly monitored for semantic targets (Potter, 1975). While doing an attention-demanding task at the fovea, participants failed to discriminate which side of a peripheral circle was red, yet they easily detected an unknown animal target in a peripheral natural scene (Li, VanRullen, Koch, & Perona, 2002). This finding raises the question whether attention limits apply primarily to simplified laboratory stimuli, while in the natural world information is easily absorbed and understood. Can these contradictions be resolved?

Using natural scenes, Oliva and Torralba (2006) showed that the gist can be inferred from a combination of statistical properties. Chong and Treisman (2003) suggested that the global deployment of attention generates a statistical mode of processing. We confirmed a finding by Ariely (2001) that observers can accurately estimate the mean size of elements and showed that such estimating happens automatically when attention is distributed over the display (see figure 12.10). Combining these findings with the idea that the parallel intake of sets of diagnostic features could mediate detection of familiar objects even before those features are bound may resolve the paradox (Treisman, 2006). Participants, shown rapid sequences of natural scenes, were able to detect target animals quite well, while often being unable to specify which animal or where in the picture it appeared (Evans & Treisman, 2005). If two successive targets had to be identified, a severe attentional blink was incurred, but when the targets could simply be detected, the blink disappeared. If features must be bound to identify or locate a target, focused attention is required, but when only the gist

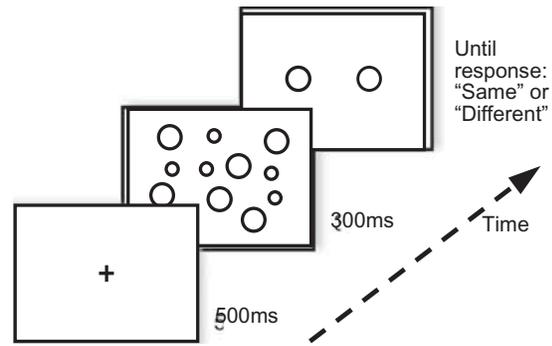

FIGURE 12.10 Implicit priming from the mean size of the pre-viewed display. The task is to judge whether the two circles in the final display are the same size or different. Participants respond a little faster if one or both matches the mean size of the preceding prime display, and faster even than when they match one of the presented sizes. It seems that participants automatically compute the mean size of an array of circles. (Experiment described in Chong & Treisman, 2001.)

is needed, statistical processing and parallel feature detection may provide sufficient information about most redundant natural scenes.

How does attention relate to consciousness?

Some theories equate attention and consciousness. This approach is probably misleading. Not everything that receives attention reaches awareness. We look at an ambiguous figure and experience only one interpretation. We may attend to a spatial location and show implicit priming without becoming aware that anything was there (Marcel, 1983a). Attention can facilitate unconscious perception in blindsight patients (Kentridge, Heywood, & Weiskrantz, 2004) and in normal participants (Kentridge, Nijboer, & Heywood, 2008). Attention limits appear even in unconscious perception: Kahneman and Chajczyk (1983) found “dilution” of interference when a neutral word was presented together with the irrelevant color name in a Stroop color-naming task. Bahrami, Lavie, and Rees (2007) found that load effects in a foveal task modulated V1 activation produced by unseen pictures of tools in the periphery.

Thus attention is not *sufficient* to ensure consciousness. Is it *necessary*? Can we be conscious of something that was not attended? There is an ambiguity here. I can be conscious of an unattended voice, without identifying the words that are spoken. Am I conscious of the stimulus? We are probably never conscious of every property, even of fully attended stimuli—for example, that this cat is smaller than the Eiffel tower. We become explicitly aware of just a small fraction of the possible propositions that could be formulated about an object or event that we are observing. With unattended objects, we lose those aspects for which capacity was overloaded, but we may retain some information.

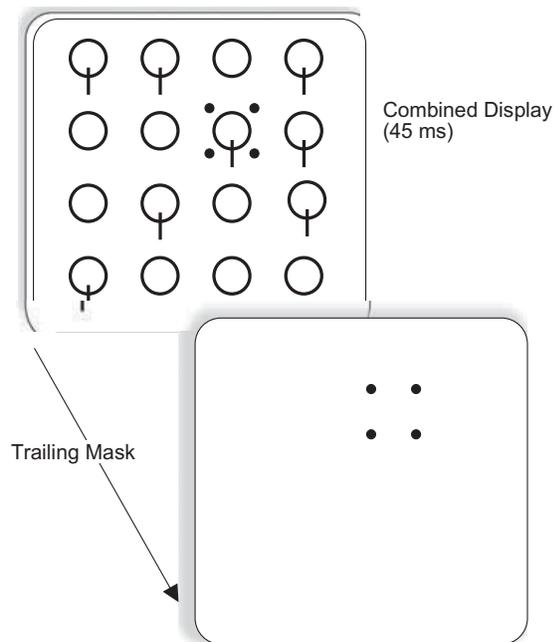

FIGURE 12.11 Object substitution masking. The display contains up to 16 rings, half of which have a vertical bar across the bottom. The target is singled out by four dots, as shown, which also serve as the mask. Observers indicate whether the target contains the vertical bar. The sequence begins with a combined display of the target, mask, and distractors for 45 ms and continues with a display of the mask alone for durations of 0, 45, 90, 135, or 180 ms. The four dots produce no masking if they end with the display, but if they continue after it disappears, they render the stimulus that they surround invisible. The suggestion is that visual processing will not reach conscious awareness unless a reentry check confirms the information extracted on a first pass through the visual system. In the case illustrated, the dots remain alone in the location of one of the *Q*'s and are substituted for it in conscious perception, whereas in the other locations there are no alternative stimuli to compete. (From Di Lollo, Enns, & Rensink, 2000.)

Attention, then, seems to be neither necessary nor sufficient for conscious awareness, although the two are normally highly correlated. What *is* necessary for conscious experience? The idea of reentry is much in the air these days. Several authors propose that the initial registration of stimuli consists of a rapid feedforward sweep through the visual areas without conscious awareness, then a possible return back to the early levels to check a tentative identification for selected elements against the sensory data (Damasio, 1989; Hochstein & Ahissar, 2002; Lamme & Roelfsema, 2000; Marcel, 1983b). Binding may also depend on reentry to early visual areas to ensure fine spatial resolution (Treisman, 1996). We become conscious of objects or events only if the initial match is confirmed. Supporting evidence comes from “object substitution” masking, in which a mask that begins at the same time as the target but outlasts it can render a stimulus invisible in a search array, even with

no overlap of contours (Di Lollo, Enns, & Rensink, 2000; see figure 12.11). When the reentry check is made, only the mask remains, and it replaces the target in conscious experience. Related evidence comes by using TMS to V1 to erase the stimulus before the reentry check can be made, around 80 ms after onset (Walsh & Cowey, 1998; Lamme & Roelfsema, 2000).

Conclusions

Psychological studies posed many of the relevant questions, outlined possible mechanisms, and developed experimental paradigms to capture different aspects of what is meant by attention. The data provide constraints, ruling out many possible accounts. Neuroscience has added powerful tools to cast votes on issues that remained controversial, or sometimes to reframe the questions in ways that more closely match the way the brain functions.

Some suggest that attention acts primarily through biases on intrinsic competitive local interactions. Others see it arising primarily or only at the decision level, following parallel perceptual processing. Still others (myself included) suggest that conscious perception, detailed localization, and binding of features may depend on focused attention through reentrant pathways. An initial rapid pass through the visual hierarchy provides the global framework and gist of the scene and may prime target objects through the features that are detected. Attention is then focused back to early areas to allow a serial check of the initial rough bindings and to form the representations that are consciously experienced. The impact of neuroscience is obvious in these developments, but so is the ingenious and careful use of psychological paradigms to tease apart the mechanisms controlling our perception and action.

13 Mechanisms of Selective Attention in the Human Visual System: Evidence from Neuroimaging

SABINE KASTNER, STEPHANIE A. McMAINS, AND DIANE M. BECK

ABSTRACT In this chapter, we review evidence from functional brain imaging revealing that attention operates at various processing levels within the visual system including the lateral geniculate nucleus of the thalamus and the striate and extrastriate cortex. Attention modulates visual processing by enhancing neural responses to attended stimuli, attenuating responses to ignored stimuli, and increasing baseline activity in the absence of visual stimulation. These mechanisms operate dynamically on spatial locations, entire objects, or particular features, which constitute the units of selection. At intermediate cortical processing stages such as areas V4 and MT, the filtering of unwanted information is achieved by resolving competitive interactions among multiple simultaneously present stimuli. Together, these mechanisms allow us to select relevant information from the cluttered visual world in which we live to guide behavior.

Natural visual scenes are cluttered and contain many different objects. However, the capacity of the visual system to process information about multiple objects at any given moment in time is limited (e.g., Broadbent, 1958). Hence, attentional mechanisms are needed to select relevant information and to filter out irrelevant information from cluttered visual scenes. Selective visual attention is a broad term that refers to a variety of different behavioral phenomena. Directing attention to a spatial location has been shown to improve the accuracy and speed of subjects' responses to target stimuli that occur in that location (Posner, 1980). Attention also increases the perceptual sensitivity for the discrimination of target stimuli (Lu & Doshier, 1998), increases contrast sensitivity (Cameron, Tai, & Carrasco, 2002; Carrasco, Marie Giordano, & McElree, 2004), reduces the interference caused by distracters (Shiu & Pashler, 1995), and improves acuity (Carrasco, Loula, & Ho, 2006; Yeshurun & Carrasco, 1998).

SABINE KASTNER and STEPHANIE A. McMAINS Department of Psychology, Princeton Neuroscience Institute, Princeton University, Princeton, New Jersey

DIANE M. BECK Department of Psychology, University of Illinois, Urbana-Champaign, Champaign, Illinois

The two most common behavioral paradigms employed to study visual attention are the spatial cuing paradigm that probes attention to a single location or stimulus (Posner, 1980) and the visual search task that probes attention in the presence of distracters (Treisman & Gelade, 1980; Wolfe, Cave, & Franzel, 1989). In the spatial cuing paradigm, subjects are instructed to maintain fixation and to direct attention covertly, that is, without shifting their gaze, to a peripheral target location, which is indicated by a cue. After a variable delay, a target stimulus, which subjects are required to detect, is presented briefly. On some trials, known as valid trials, the target appears at the cued (i.e., attended) location, and on other trials, known as invalid trials, the target appears at an uncued (i.e., unattended) location. The typically observed response difference in detecting stimuli on valid and invalid trials is thought to reflect the effects of attention on selected locations in space. In visual search tasks, subjects are given an array of stimuli (e.g., circles of different colors) and asked to report if a particular target stimulus (e.g., a red circle) is present in the array. Several factors affect performance in this task, such as the number of features that the target shares with other elements in the array. If the target (e.g., red circle) has a unique feature, such as being a different color from the distracters (e.g., green circles), the search is completed quickly, regardless of the number of elements in the array. This phenomenon is known as pop-out or efficient search. For other search arrays, where the target is defined by a conjunction of features (e.g., red horizontal line) that are shared by the distracters (e.g., red vertical and green horizontal lines), search time increases as a function of the number of elements in the array. This phenomenon is known as inefficient search, and the increase in search times is thought to reflect a serial search through the array for the target. However, under some circumstances, only a subset of the array needs to be searched. Simple features, such as color, can be used to *guide* search to just those elements that share a particular target feature (Wolfe et al., 1989). Visual search tasks have a clearer relationship than spatial cuing paradigms with our everyday

experience, where we typically face cluttered scenes with many objects that exceed our processing capacity. In this chapter, we will outline the neural basis that underlies attentional operations in these two tasks in the visual system, as they have been studied in humans using functional brain imaging and in nonhuman primates using electrophysiological techniques.

The units of selection

Attention is a highly flexible mechanism that can operate on regions of space, such as attending to a park on the right side of the road as you walk by, on particular features of an object, such as attending to the green leaves on a tree, or on entire objects, such as attending to the entire tree. Since the neural mechanisms mediating space-, object-, and feature-based attention have different characteristics, we will discuss each of them separately.

SPACE-BASED ATTENTION The spatial cuing paradigm is an example of a space-based selection process. In a typical fMRI study, the effects of space-based selection on neural responses have been investigated by presenting simple stimuli that activate the visual system well, such as flickering checkerboards to the left or right visual hemifield, while subjects directed attention to the stimulus (attended condition) or away from the stimulus (unattended condition) (e.g., O'Connor, Fukui, Pinsk, & Kastner, 2002). In the unattended condition, attention was directed away from the stimulus by having subjects count letters at fixation. The letter-counting task ensured proper fixation and effectively prevented subjects from covertly attending to the checkerboard stimuli. In the attended condition, subjects were instructed to covertly direct attention to the checkerboard stimulus and to detect luminance changes that occurred randomly in time at a peripheral stimulus location. Relative to the unattended condition, the mean fMRI signals evoked by a high-contrast checkerboard stimulus increased significantly in the attended condition in the lateral geniculate nucleus (LGN) and in visual cortex (figure 13.1A,D). In particular, attentional response enhancement was found in striate cortex, as well as in each extrastriate area along the ventral and dorsal pathways (figure 13.2A). Similar attentional response enhancement was obtained with activity evoked by a low-contrast checkerboard stimulus (figure 13.1A,D). Notably, these attention effects were shown to be spatially specific in other studies, in which identical stimuli were presented simultaneously to the right and left of fixation, while subjects were instructed to direct attention covertly to one or the other side (Brefczynski & DeYoe, 1999; Heinze et al., 1994; O'Connor et al.; Tootell et al., 1998). Taken together, these findings suggest that selective attention facilitates visual processing at thalamic and cortical stages by enhancing

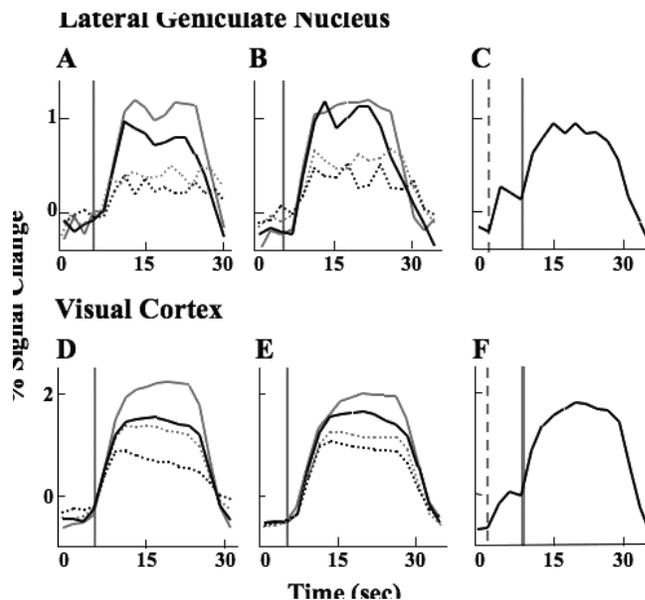

FIGURE 13.1 Attentional response enhancement, suppression, and increases in baseline activity in the LGN and in visual cortex. Group analysis ($n = 4$). Time series of fMRI signals in the LGN and visual cortex were combined across left and right hemispheres. Activity in visual cortex was pooled across areas V1, V2, V3/VP, V4, TEO, V3A, and MT/MST. (A, D) Attentional enhancement. During directed attention to the stimuli (gray curves), responses to both the high-contrast stimulus (100%, solid curves) and low-contrast stimulus (5%, dashed curves) were enhanced relative to an unattended condition (black curves). (B, E) Attentional suppression. During an attentionally demanding “hard” fixation task (black curves), responses evoked by both the high-contrast stimulus (100%, solid curves) and low-contrast stimulus (10%, dashed curves) were attenuated relative to an easy attention task at fixation (gray curves). (C, F) Baseline increases. Baseline activity was elevated during directed attention to the periphery of the visual hemifield in expectation of the stimulus onset; the beginning of the expectation period is indicated by the dashed vertical line. Gray vertical lines indicate the beginning of checkerboard presentation periods. (From O'Connor, Fukui, Pinsk, & Kastner, 2002.)

neural responses to an attended stimulus relative to those evoked by the same stimulus when ignored. Attentional response enhancement may be a neural correlate for behavioral attention effects such as increased accuracy and response speed or improved target discriminability (e.g., Posner, 1980; Lu & Doshier, 1998).

Spatial attention affects not only the processing of the selected information, but also the processing of the unattended information, which is typically the vast majority of incoming information. The neural fate of unattended stimuli was investigated in an fMRI experiment in which the attentional load of a task at fixation was varied (O'Connor et al., 2002). According to attentional load theory (Lavie & Tsai, 1994), the degree to which ignored stimuli are processed is determined by the amount of attentional capacity that is *not* dedicated to the selection process. This account predicts that

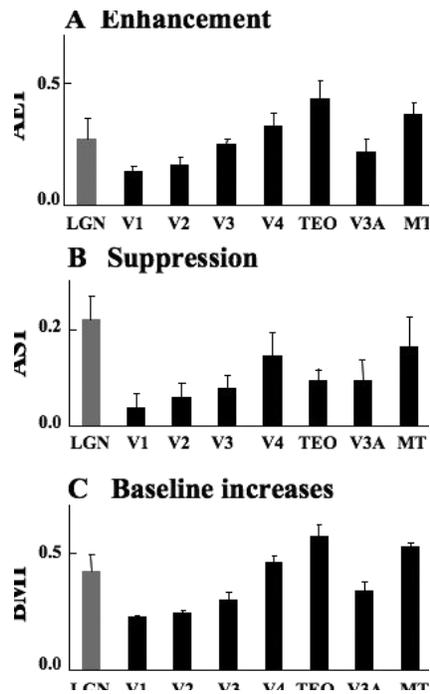

FIGURE 13.2 Attentional response modulation in the visual system. Attention effects that were obtained in the experiments presented in figure 13.1 were quantified by defining several indices: (A) attentional enhancement index (AEI), (B) attentional suppression index (ASI), (C) baseline modulation index (BMI). For all indices, larger values indicate larger effects of attention. Index values were computed for each subject based on normalized and averaged signals obtained in the different attention conditions and are presented as averaged index values from four subjects (for index definitions, see O'Connor et al., 2002). In visual cortex, attention effects increased from early to later processing stages. Attention effects in the LGN were larger than in V1. Vertical bars indicate standard error of the mean across subjects. (From O'Connor et al., 2002.)

neural responses to unattended stimuli should be attenuated depending on the attentional load necessary to process the attended stimulus. This idea was tested by using the checkerboard paradigm described earlier while subjects performed either an easy (low-load) attention task or a hard (high-load) attention task at fixation and ignored the peripheral checkerboard stimuli. Relative to the easy-task condition, mean fMRI signals evoked by the high-contrast and by the low-contrast stimuli decreased significantly in the hard-task condition across the visual system with the smallest effects in early visual cortex and the largest effects in LGN and extrastriate cortex (figure 13.1B,E). Taken together, these findings suggest that neural activity evoked by ignored stimuli is attenuated at several stages of visual processing as a function of the load of attentional resources engaged elsewhere (O'Connor et al., 2002; Rees, Frith, & Lavie, 1997; Schwartz et al., 2005). Attentional-load-dependent suppression of unattended stimuli may be a neural correlate for behavioral effects such as reduction of interference caused by distracters (Shiu & Pashler, 1995). Further, there is evi-

dence that the enhancement of activity at an attended location and the suppression of activity at unattended locations operate in a push-pull fashion and thus represent codependent mechanisms (Pinsk, Doniger, & Kastner, 2004; Schwartz et al., 2005).

An important component of the Posner task is the cuing period during which subjects deploy attention to a location in space at which visual stimuli are expected to occur. A neural correlate of cue-related activity has been found in physiology studies demonstrating that spontaneous (baseline) firing rates were 30–40% higher for neurons in areas V2 and V4 when the animal was cued to attend covertly to a location within the neuron's receptive field (RF) before the stimulus was presented there—that is, in the absence of visual stimulation (Lee, Williford, & Maunsell, 2007; Luck, Chelazzi, Hillyard, & Desimone, 1997; but see McAdams & Maunsell, 1999). This increased baseline activity has been interpreted as a direct demonstration of a top-down signal that feeds back from higher-order to lower-order areas. In the latter areas, this feedback signal appears to bias neurons representing the attended location, thereby favoring stimuli that will appear there at the expense of those appearing at unattended locations.

To investigate attention-related baseline increases in the human visual system in the absence of visual stimulation, fMRI activity was measured while subjects were cued to covertly direct attention to the periphery of the left or right visual hemifield and to expect the onset of a stimulus (Kastner, Pinsk, De Weerd, Desimone, & Ungerleider, 1999; O'Connor et al., 2002; Sylvester, Shulman, Jack, & Corbetta, 2007). The expectation period, during which subjects were attending to the periphery without receiving visual input, was followed by attended presentations of a high-contrast checkerboard. During the attended presentations, subjects counted the occurrences of luminance changes. Relative to the preceding blank period in which subjects maintained fixation at the center of the screen and did not attend to the periphery, fMRI signals increased during the expectation period in the LGN and the striate and extrastriate cortex (figures 13.1C,F, 13.2C). This elevation of baseline activity was followed by a further response increase evoked by the visual stimuli (figure 13.1C).

Similar to response modulation, the magnitude of increases in baseline activity depends on several variables, including the expected task difficulty (Rees, Backus, & Heeger, 2000) or the expected presence or absence of distracter stimuli (Serences, Yantis, Culbertson, & Awh, 2004). Early studies have found evidence that baseline increases are feature specific; that is, they are stronger during the expectation of a preferred compared to a nonpreferred stimulus feature in areas that preferentially process a particular stimulus feature (e.g., color in area V4 or motion in area MT) (Chawla, Rees, & Friston, 1999; Shulman et al., 1999). However, more

recent studies have not confirmed these initial findings (McMains, Fehd, Emmanouli, & Kastner, 2007), and therefore the feature specificity of baseline increases is still an open question. The baseline increases found in human visual cortex may be subserved by increases in spontaneous firing rate similar to those found in the single-cell recording studies (Luck et al., 1997), but summed over large populations of neurons. The increases evoked by directing attention to a target location in anticipation of a behaviorally relevant stimulus at that attended location are thus likely to reflect a top-down feedback bias in favor of a preferred stimulus at an attended location.

Comparison of space-based attention effects across the visual system With fMRI, neural responses can be investigated at the population level and across a wide range of different processing stages, allowing for quantitative comparisons of attentional modulatory effects across the visual system. For example, the attention effects of enhancement, suppression, and baseline increases described in the last section can be quantified in each visual area by calculating an index value. Large index values indicate large effects of attention (for further details, see O'Connor et al., 2002). As shown in figure 13.2, the magnitude of all attention effects increased from early to more advanced processing stages along both the ventral and dorsal pathways of visual cortex (figure 13.2A–C; Cook & Maunsell, 2002; Kastner, De Weerd, Desimone, & Ungerleider, 1998; Martinez et al., 1999; Mehta, Ulbert, & Schroeder, 2000). This finding is consistent with the idea that attention operates through top-down signals that are transmitted via corticocortical feedback connections in a hierarchical fashion. Thereby, areas at advanced levels of visual cortical processing are more strongly controlled by attentional mechanisms than are early processing levels. This idea is supported by single-cell recording studies, which have shown that attentional effects in area TE of inferior temporal cortex have a latency of approximately 150 ms (Chelazzi, Duncan, Miller, & Desimone, 1998), whereas attentional effects in V1 have a longer latency, approximately 230 ms (Roelfsema, Lamme, & Spekreijse, 1998). According to this account, one would predict smaller attention effects in the LGN than in striate cortex. Surprisingly, it was found that all attention effects tended to be larger in the LGN than in striate cortex (figure 13.2A–C). This finding raises the possibility that attentional modulation in the LGN may not be exclusively attributable to corticothalamic feedback from striate cortex, but may also reflect additional modulatory influences from other sources. In addition to corticothalamic feedback projections from V1, the LGN receives inputs from the superior colliculus, which is part of a distributed network of areas controlling eye movements, and the thalamic reticular nucleus (TRN), which has long been implicated in theo-

retical accounts of selective attention (Crick, 1984; Sherman & Guillery, 2001).

OBJECT-BASED ATTENTION In addition to selecting regions of space, attention can also be directed to entire objects. Object-based attention signals have been investigated in human neuroimaging studies, in which subjects were asked to attend to a particular feature of an object, while signals evoked by the unattended features of the attended object were measured (McMains et al., 2007; O'Craven, Downing, & Kanwisher, 1999). In one such study, Kanwisher and colleagues used stimuli that consisted of overlapping images of houses and faces (O'Craven et al., 1999; figure 13.3A). On any given trial, one of those images moved. Subjects attended to and performed a task on either the house, the face, or the motion, resulting in increased activity in regions specialized for processing the attended feature or object, that is, the fusiform face area, parahippocampal place area, or MT, respectively. Interestingly, activity also spread to the unattended feature of the attended stimulus. For instance, when the face stimuli were moving and subjects attended to the faces, increased activity was observed in MT as compared to when subjects attended to stationary house stimuli (figure 13.3B). Thus attentional biasing signals appear to spread to the unattended features of the attended object, resulting in enhanced signals in regions specialized for processing the unattended feature. These studies demonstrate that processing can be biased in favor of an attended object, with all features of the attended object receiving some amount of enhanced processing. In addition, when attention is directed to only a portion of an object, attention has been found to spread throughout the entire object (Muller & Kleinschmidt, 2003; Roelfsema et al., 1998). In a physiology study by Roelfsema and colleagues, monkeys were presented with two curved lines, one of which was the target curve. Small changes in the stimulus close to fixation determined which line was the target, while neuronal responses were measured in V1 neurons with RFs centered over distant points on one of the lines. Responses were increased when the line segment in the RF was part of the target curve compared to when it was part of the distractor curve. Together, these results suggest that when attention is directed to an object, all features of the attended object are enhanced along with the entire spatial extent of the attended object. These findings may provide a neural correlate for classical behavioral studies showing that subjects perform worse at reporting two attributes that belong to different objects as compared to two attributes belonging to the same object (Duncan, 1984).

FEATURE-BASED SELECTION In addition to biasing processing in favor of a spatial location or an entire object,

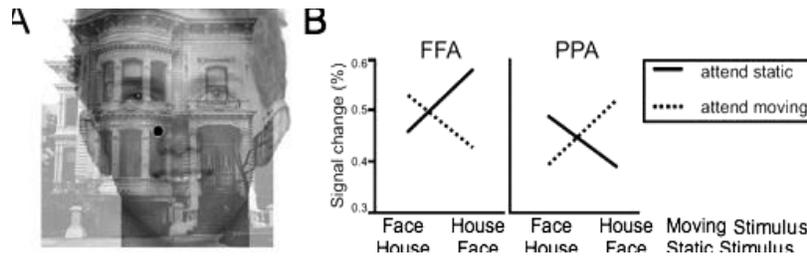

FIGURE 13.3 Object-based attention in visual cortex. (A) Example stimulus from experiment 2 of the study by O’Craven, Downing, and Kanwisher (1999) demonstrating object-based attention. The stimuli consisted of overlapping house and face stimuli. On each trial either the house or the face stimulus moved while subjects performed a consecutive repetition-detection task on either the direction of motion of the moving stimuli or the position of the stationary object, which was offset slightly from trial to trial. (B) Averaged fMRI signals ($n = 4$), computed as percent signal change, for the

fusiform face area (FFA) and the parahippocampal place area (PPA). Solid lines represent activity when subjects attended to the static stimulus, and dotted lines represent trials during which subjects attended to the moving stimulus. Activity was higher in the FFA when “faceness” was the irrelevant property of the attended object (Attend Moving, Face Moving) than when it was a property of the unattended object (Attend Moving, House Moving). The response pattern of the PPA was identical for “houseness.” (Modified figure 42.1, Freiwald & Kanwisher, 2004.)

attention can also bias processing in favor of a particular stimulus attribute, or feature. In experiments investigating feature-based attention, stimuli are typically composed of multiple stimulus features (e.g., colored shapes moving in different directions), and subjects are cued to attend to a particular feature dimension (e.g., the color red) while ignoring the other dimensions. In monkey physiology studies, neural responses increased when the feature in the RF matched the cued feature regardless of where the animal was attending. Feature-based attention effects have been observed in area V4 for several feature dimensions (for a review see Maunsell & Treue, 2006) including color (Motter, 1994), luminance (Motter, 1994), and orientation (Haenny, Maunsell, & Schiller, 1988), and in MT for direction of motion (Martinez-Trujillo & Treue, 2004; Treue & Martinez-Trujillo, 1999). In addition, the temporal characteristics of feature-based and space-based attention were investigated in area V4 (Hayden & Gallant, 2005). Feature-based attention effects were found to be sustained throughout the visual evoked responses, whereas space-based attention effects were more transient, peaking in the later portion of the response. These findings suggest that space- and feature-based attention effects rely on different neural mechanisms.

In human neuroimaging studies, where activity is measured at the level of entire areas within neural networks, researchers have taken advantage of the functional specialization of visual cortex in studying feature-based attention (Beauchamp, Cox, & DeYoe, 1997; Buechel et al., 1998; Clark et al., 1997; Corbetta, Miezin, Dobmeyer, Shulman, & Petersen, 1991; McMains et al., 2007; O’Craven, Rosen, Kwong, Treisman, & Savoy, 1997; Serences & Boynton, 2007; Sohn, Chong, Pappathomas, & Vidnyanszky, 2005). In one such study, Corbetta and colleagues investigated attention to shape, color, or speed and observed enhanced activity in visual regions specialized for processing the attended

feature, including enhanced activity in the posterior fusiform gyrus for attention to shape, area V4 for attention to color, and area MT for attention to motion.

Feature-based attention mechanisms have also been investigated in the presence of distracters. The observation that neural responses to a selected feature increase regardless of where the animal attends has led to the hypothesis that feature-based attention may operate globally throughout the visual field (Bichot, Rossi, & Desimone, 2005; Martinez-Trujillo & Treue, 2004; McAdams & Maunsell, 2000; Saenz, Buracas, & Boynton, 2002; Serences & Boynton, 2007). If one considers a visual search task where subjects are looking for a red circle in an array of colored shapes, it will certainly be advantageous from a computational point of view to increase neural responses to any red items, thereby marking the candidate target stimuli and restricting the remaining search to the subset of red shapes to ultimately find the circle. This approach is opposed to space- and object-based attention, which are both inherently tied to a spatial location. This hypothesis has been tested in a physiology study where monkeys performed a visual search task (Bichot et al., 2005). Neuronal responses were enhanced when the stimulus inside the RF was the same color or shape as the target stimulus. This result occurred throughout the search period, regardless of where the monkey was attending.

A similar effect has been observed in humans in an experimental design with two stimuli, one presented in each visual hemifield (Saenz et al., 2002). The attended stimulus consisted of two overlapping dot patterns, one moving upward and the other moving downward. The stimulus in the unattended hemifield always moved in the same direction (e.g., downward). Functional MRI signals were measured in the retinotopic representation of the unattended stimulus while subjects alternated between attending to the same direction as the distracter (i.e., downward) or to the opposite direction

(i.e., upward). As in the physiology studies, signals evoked by the distracter stimulus were greater in V1, V2, V3, V3A, V4, and MT when it matched the attended direction. In addition, it has been shown that enhanced responses to the attended feature spread to regions of the visual field that are not stimulated (Serences & Boynton, 2007). Taken together, these results suggest a mechanism for feature-based attention that operates globally and biases processing throughout the visual field by enhancing the population response to attended features. This type of global attention mechanism might be important in guiding spatial attention to regions of the visual field that contain behaviorally relevant stimuli and may be one of the mechanisms that underlie guided visual search (Wolfe et al., 1989).

SUMMARY Mechanisms for the selection of behaviorally relevant information operate flexibly in the visual system on spatial locations, features of objects, or entire objects by enhancing responses evoked by attended stimuli, by suppressing responses evoked by unattended stimuli, and by increasing neural baseline activity to facilitate the processing of expected stimuli. These different effects of attention provide a framework for the neural basis of simple attentional operations such as orienting to a spatial location, as tested in the spatial cuing paradigm. In the next section, we will explore the effects of attention when multiple stimuli are present, such as in visual search tasks.

Selection among multiple competing objects

One of the key aspects of the visual search paradigm, and indeed what makes it relevant to our everyday behavior, is that a target must be found among a field of other objects. The defining role of selective attention in this case is to mediate the selection of a subset of the available information for further processing. As such, in order to understand selective attention, it is necessary to understand first how the brain processes multiple stimuli simultaneously present in the visual field.

NEURAL BASIS OF COMPETITION A large body of evidence from both single-cell physiology and neuroimaging suggests that multiple stimuli present at the same time within a neuron's RF are not processed independently, but interact with each other in a mutually suppressive way. In physiology studies (Miller, Gochin, & Gross, 1993; Recanzone, Wurtz, & Schwarz, 1997; Reynolds, Chelazzi, & Desimone, 1999; Snowden, Treue, Erickson, & Andersen, 1991), the responses to paired stimuli were found to be smaller than the sum of the responses evoked by each stimulus individually. In particular, the response evoked by a pair of stimuli was a weighted average of the individual responses (Luck et al., 1997; Reynolds et al.). Suppressive interactions such as

these among multiple stimuli have been found in several visual areas in the monkey brain, including V2, V4, MT, MST, and IT (Miller et al.; Recanzone et al.; Reynolds et al.; Snowden et al.), and have been interpreted as the neural substrate of an ongoing competition among multiple simultaneously present stimuli for representation in visual cortex.

In the human brain, evidence for neural competition has been found using an fMRI paradigm (Beck & Kastner, 2005, 2007; Kastner et al., 2001), in which four colorful and patterned visual stimuli that optimally activate ventral visual cortex were presented in four nearby locations to the periphery of the visual field, while subjects maintained fixation (figure 13.4A). Critically, these stimuli were presented under two different presentation conditions, sequential and simultaneous. In the sequential presentation condition, each stimulus was presented alone in one of the four locations, one after the other. In the simultaneous presentation condition, the same four stimuli appeared simultaneously in the four locations. Thus, integrated over time, the physical stimulation parameters were identical in each of the four locations in the two presentation conditions. However, competitive interactions among stimuli could take place only in the simultaneous and not in the sequential presentation condition.

Consistent with the physiology literature, simultaneous presentations evoked weaker responses than sequential presentations in areas V1, V2/VP, V4, TEO, V3A, and MT. The response differences were smallest in V1 and increased in magnitude toward ventral extrastriate areas V4 (figure 13.4D) and TEO, and dorsal extrastriate areas V3A and MT. In other words, the suppressive interactions among the four stimuli scaled with the increasing RF sizes across visual cortex, consistent with the idea that the stimuli were competing for representation at the level of the RF.

The idea that suppressive interactions are scaled to RF size was tested directly by varying the spatial separation among the stimuli (Kastner et al., 2001). If stimuli are competing at the level of the RF, then increasing the spatial separation among stimuli should decrease the level of competition within the RF, and decreasing the array size should increase competitive interactions in areas with smaller RFs. In keeping with both of these predictions, suppressive interactions were twice as strong in V1 and V2 with a $2 \times 2^\circ$ display as compared to those induced with a $4 \times 4^\circ$ display, and separating the stimuli in the $2 \times 2^\circ$ display by 4° abolished suppressive interactions in V2 and reduced them in V4, but did not affect them in TEO. Separating the stimuli by 6° led to a further reduction of suppression effects in V4, but again had no effect in TEO. Taken together, monkey physiology and human brain imaging studies have begun to establish a neural basis for competitive representations of stimuli in the visual system.

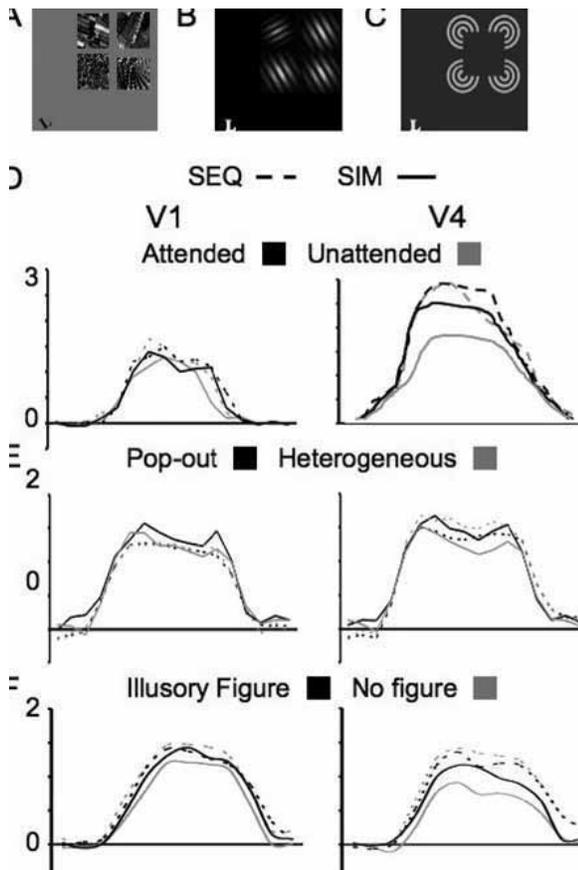

FIGURE 13.4 Top-down and bottom-up biases in resolving neural competition in visual cortex. In three experiments, competitive interactions among stimuli were assessed in the presence of top-down and bottom-up biases. Competition was measured by comparing fMRI responses to four stimuli presented either simultaneously (potentially competing; SIM) or sequentially (noncompeting; SEQ). (A) In the study investigating top-down attention biases (Kastner, De Weerd, Desimone, & Ungerleider, 1998), the four stimuli were complex colored images. In the attended conditions, subjects monitored the lower left location for the appearance of a target stimulus, whereas in the unattended condition they ignored the colorful stimuli and instead detected targets at fixation. (B) In the bottom-up pop-out study (Beck & Kastner, 2005), the stimuli were four Gabor patches that either all differed in color and orientation (heterogeneous condition; not shown) or in which one Gabor differed in color and orientation from the rest (pop-out condition; shown here without color). (C) In the illusory contour study (McMains & Kastner, 2007), four “Pacman” images were aligned to form an illusory square (shown) or rotated such that no square was perceived. (D–F) Dashed curves indicate activity evoked by sequential presentations and solid curves indicate activity evoked by simultaneous presentations for attention (D), pop-out (E), and illusory contour (F) studies. Black lines represent the conditions in which a top-down or bottom-up bias was probed, and gray lines represent conditions during which stimuli were competing without any bias. For all three studies, competition was partially overcome in V4 when a bias was present (black curves), resulting in smaller differences in responses evoked by sequential and simultaneous presentations (dashed and solid curves). These effects were smaller (F) or nonexistent in V1 (D, E).

It is important to note that the suppressive (competitive) interactions across visual cortex discussed thus far occurred automatically and in the absence of attentional allocation to the stimuli. In fact, in these paradigms, participants were engaged in an attention-demanding task at fixation. Thus neural competition would appear to be pervasive in the representation of cluttered visual scenes. In order to overcome this less than optimal representation of objects within a visual scene, there need to be mechanisms by which this ongoing competition among multiple stimuli can be resolved. The allocation of top-down attention is one such mechanism.

TOP-DOWN INFLUENCES ON COMPETITION Single-cell recording studies have shown that spatially directed attention represents one top-down mechanism that can bias the competition among multiple stimuli in favor of the attended stimulus by modulating competitive interactions. When a monkey directed attention to one of two competing stimuli within an RF, the responses in extrastriate areas V2, V4, and MT to the pair of stimuli were as large as those to that stimulus presented alone (Recanzone & Wurtz, 2000; Reynolds et al., 1999). A similar mechanism appears to operate in the human visual cortex. Kastner and colleagues (1998) studied the effects of spatially directed attention on multiple competing visual stimuli in a variation of the paradigm described earlier. In addition to the two different presentation conditions, sequential and simultaneous, two different attentional conditions were tested, attended and unattended. During the unattended condition, attention was directed away from the peripheral visual display by having subjects count letters at fixation. In the attended condition, subjects were instructed to attend covertly to the peripheral stimulus location in the display closest to fixation and to count the occurrences of a target stimulus. Directing attention to this location led to greater activity increases for simultaneously presented stimuli than for sequentially presented stimuli in areas V4 and TEO, but not in early visual areas such as V1 (figure 13.4D). Like the competition effects, the magnitude of the attentional effects scaled with RF size, with the strongest reduction of suppression occurring in ventral extrastriate areas V4 and TEO (see also Bles, Schwarzbach, De Weerd, Goebel, & Jansma, 2006). It is important to note that the stage at which these attention mechanisms will operate in the visual system is flexibly determined by the spatial scale of the displays, similar to the spatial scaling of competition mechanisms to RF size. For example, targets in displays of large spatial scale will engage areas with larger RFs and will shift the locus of attentional selection to more anterior extrastriate areas relative to targets in displays of smaller spatial scale (Buffalo, Bertini, Ungerleider, & Desimone, 2005; Hopf et al., 2006). Together, these findings support the idea that directed attention

enhances information processing of stimuli at the attended location by counteracting suppression induced by nearby stimuli. This may be an important mechanism by which unwanted information is filtered out from nearby distracters.

BOTTOM-UP INFLUENCES ON COMPETITION RELATED TO VISUAL SALIENCE Top-down attention, however, is not the only mechanism that can resolve competition in visual cortex. Properties of the stimulus—that is, bottom-up stimulus-driven mechanisms—have also been shown to modulate competition (Beck & Kastner, 2005, 2007; McMains & Kastner, 2007; Reynolds & Desimone, 2003). For example, Beck and Kastner (2005) found that competition could be influenced by visual salience, a bottom-up stimulus-driven mechanism that does not depend on the focus of attention. Instead of the complex images used in the previous studies, in which the sequential/simultaneous paradigm was investigated, they used four Gabor patches of different colors and orientations. These Gabor patches could be presented in two display contexts: pop-out displays, in which a single item differed from the others in color and orientation (figure 13.4*B*), and heterogeneous displays, in which all items differed from each other in both dimensions. As has been shown with the heterogeneous displays used in previous experiments, the heterogeneous displays produced robust suppressive interactions among multiple stimuli in areas V2/VP and V4 (figure 13.4*E*). However, this suppression was eliminated when the same stimuli were presented in the context of pop-out displays, consistent with the prediction that visual salience can bias competitive interactions among multiple stimuli in intermediate processing areas (figure 13.4*E*).

As in previous studies, no evidence of competitive interactions was found in area V1, presumably because of the small RF sizes in that area. However, an effect of display context was evident in this early visual area: simultaneously presented pop-out displays evoked more activity than any of the other three conditions, consistent with both physiology studies and computational models suggesting that pop-out may be computed as early as in area V1 (Kastner, Nothdurft, & Pigarev, 1999; Knierim & Van Essen, 1992; Li, 1999; Nothdurft, Gallant, & Van Essen, 1999). Taken together, these data suggest that V1 may be the source of the signal that biases neural competition in extrastriate cortex when salient stimuli are present in the visual scene, a finding which further distinguishes this bottom-up bias from top-down biases that are thought to have their source in frontoparietal cortex (Kastner et al.; T. Moore & Armstrong, 2003).

BOTTOM-UP INFLUENCES ON COMPETITION RELATED TO SCENE SEGMENTATION Both top-down attention and bottom-up visual salience constitute a spatial bias that results

in a single item dominating the response of the neuron. However, as described in the section “The units of selection,” attention not only selects a location or feature, but can also select whole objects, including all the features that comprise the object. The existence of object-based selection argues against competition among the features within an object and instead argues for mechanisms that bind the features of an object together across multiple areas prior to competition among objects. Indeed, there are a number of factors that are thought to influence how the components of a scene are structured into larger units such as objects and groups of objects. The first of these *principles of perceptual organization* were proposed by the Gestalt psychologists (e.g., Wertheimer, 1923; Rubin, 1958). For instance, visual stimuli may be perceptually grouped according to their similarity, proximity, common fate (Wertheimer, 1923), and other stimulus properties (Palmer & Rock, 1994; Palmer, 1992), thereby linking elements of a scene that are likely to belong together, segmenting the scene into a more limited number of objectlike perceptual units. There is growing evidence that some forms of perceptual organization do not require top-down control, but rather represent automatic bottom-up processes (Altmann, Bulthoff, & Kourtzi, 2003; Driver, Baylis, & Rafal, 1992; Duncan, 1984; Kastner, De Weerd, & Ungerleider, 2000; Lamy, Segal, & Ruderman, 2006; Marcus & Van Essen, 2002; C. Moore & Egeth, 1997; Qiu, Sugihara, & von der Heydt, 2007; Russell & Driver, 2005; but see also Ben-Av, Sagi, & Braun, 1992; Han, Jiang, Mao, Humphreys, & Gu, 2005; Mack, Tang, Tuma, Kahn, & Rock, 1992; Roelfsema, 2006). Therefore, perceptual organization principles may represent bottom-up stimulus-driven processes by which features within an object are grouped, allowing competition to occur among objects and not among features within an object (Desimone & Duncan, 1995). According to this view, any principle of perceptual organization that produces a bottom-up bias may modulate competition.

Evidence in favor of this prediction was found in a series of studies that used variants of the sequential/simultaneous fMRI paradigm to investigate effects of perceptual organization on competition. In one study, suppressive interactions among four identical items (homogeneous display) were compared to those induced by four stimuli that differed in both color and orientation (heterogeneous display). Because identical or similar items that are present in nearby locations tend to form perceptual groups by the Gestalt principle of similarity, the prediction was tested that competitive interactions should be minimal with identical stimuli in the display (homogeneous condition) as compared to the heterogeneous condition. In accordance with previous data, simultaneous presentation of four heterogeneous visual stimuli evoked significantly less activity in areas V2, VP, and V4 than the same stimuli presented sequentially. However, when the four

stimuli were identical, the suppression was considerably reduced relative to the heterogeneous conditions. This result suggests that grouping by similarity represents a bottom-up bias that may influence or even determine the amount of competition among items.

Although grouping is arguably the most well-known of the perceptual organization processes, there are a number of other processes critical to our ability to segment and organize a scene. Before objects can be grouped together, the visual system must decide what regions in the scene constitute potential objects; that is, it must segment figure from ground (Rubin, 1958). Further complicating this process is the fact that some potential objects may be partially occluded from view, requiring the visual system to infer the presence of objects on the basis of the information present in the scene; that is, it must rely on visual interpolation mechanisms (Palmer, 1999). Both of these processes were probed in a second study (McMains & Kastner, 2007), using the Kanizsa illusion (Kanizsa, 1976). In the Kanizsa illusion, four circular “Pacman” items, also called inducers, are aligned to form an illusory square (figure 13.4C) that is perceived as a single foreground element with the inducers lying behind it. When the four inducers are rotated inward, the illusion occurs as a result of the assignment of the L-shaped borders to a common object, but does not occur when they are rotated outward. Based on the hypothesis that the degree of perceptual organization in a visual display should determine the degree of competition, it was predicted that when the four inducers were rotated inward giving rise to the illusion and were thus part of a single object, they should not compete with each other. Alternatively, if the four inducers were rotated outward, thereby disrupting the illusion, they would be treated as four separate objects, which compete for neural representation independently. As predicted, the competitive interactions were significantly reduced across visual cortex when the four inducers formed a single foreground object, but not when they were rotated outward representing four separate items (figure 13.4F). Thus far, a number of perceptual organization processes, such as grouping by the Gestalt factor of similarity and figure-ground segmentation and visual interpolation processes related to illusory contour formation, have been shown to affect the outcome of competitive interactions, thereby suggesting that any form of perceptual organization might influence the ongoing competition (Beck & Kastner, 2007; McMains & Kastner, 2007).

The relationship between perceptual organization principles and competition can be interpreted in at least two ways. Competition may be influenced by mechanisms that mediate perceptual organization from elsewhere in the cortex. These mechanisms could boost the activity related to the set of stimuli as it enters V4, effectively counteracting any competition that may have occurred between stimuli. Such a

perspective is consistent with effects of Gestalt grouping and figure-ground segmentation found in early visual cortex (Kapadia, Ito, Gilbert, & Westheimer, 1995; Kastner et al., 2000; Lamme, 1995; Nothdurft et al., 1999; Qiu et al., 2007; Zhou, Friedman, & von der Heydt, 2000). Alternatively, the degree to which perceptual organization occurs may be a consequence of competitive interactions. As mentioned, the response of V4 neurons to a pair of stimuli is best described as a weighted average of the responses to the two stimuli when presented alone (Luck et al., 1997; Reynolds et al., 2000). If the two stimuli that comprise the pair are identical, as in the grouping-by-similarity study, then the weighted-average model would predict that the response to the pair should be indistinguishable from the response to each of the individual stimuli (Reynolds et al.). Thus there may not be any need to appeal to additional grouping mechanisms to explain these findings. Instead, the reduced competition present in the displays with identical items, relative to the one with different stimuli, may simply be the result of the averaging procedure performed by the neurons in areas such as V4. If less competition is evoked by items that are perceptually organized, then there is no need to select or filter any one of them, and instead the items are processed as a group. Importantly, these are not mutually exclusive possibilities. Further, it is unlikely that these interactions can be explained by a unified neural mechanism. Rather, the variety of perceptual organization principles may rely on a variety of underlying neural processes.

RELATION OF BOTTOM-UP AND TOP-DOWN MECHANISMS

The studies described thus far suggest that both top-down and bottom-up processes can bias competitive interactions in visual cortex. How might these processes interact? Evidence comes from a physiology study (Qiu et al., 2007) in which the effects of attention on image segmentation processes were probed in V2 neurons. Neurons in V2 have previously been found to integrate contextual information from beyond their small RFs in order to signal when a border in their RF belongs to an attended object, an effect termed border ownership (Zhou et al., 2000). Consistent with previous studies (Driver et al., 1992; Kastner et al., 2000; Lamy, Segal, & Ruderman, 2006; C. Moore & Egeth, 1997), V2 neurons signaled border ownership for both attended and unattended figures, suggesting that attention is not necessary for figure-ground segmentation (Qiu et al.). When the interaction of attention and border ownership was investigated, the magnitudes of the attention effects were found to be predicted by the neurons’ border ownership responses, such that attention effects were larger when the object that owned the border in the RF was attended to compared to when a different figure of equal distance away from the RF was attended to (figure 13.5E). These results were interpreted using a novel framework, the “interface

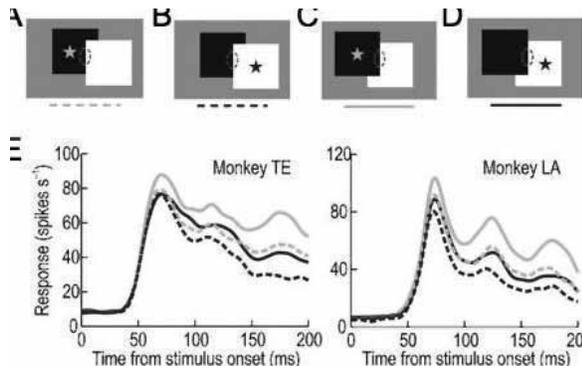

FIGURE 13.5 Responses of neurons influenced by border ownership and attention. (A–D) Example stimuli for the different experimental conditions. Asterisks indicate the location of attention, and the ellipses symbolize the RF of the neuron that was recorded from. (A–B) The right figure was in front, with the nonpreferred side of the object in the RF. (C–D) The left figure was in front, with the preferred side of the object in the RF. (E) Firing rates as a function of time for the population of neurons influenced by border ownership and attention for each of two monkeys. The solid lines represent preferred border ownership, and dashed lines indicate nonpreferred border ownership; gray indicates attention to the left side, and black indicates attention to the right side. Attention effects were always greater when the animals attended to the left, that is, to the preferred object side ($A > B$ and $C > D$). However, attention effects were largest when the animals attended to the preferred object side (left) and the border in the RF was “owned” by the object on the left (C). (Modified from figure 5 of Qiu, Sugihara, & von der Heydt, 2007.)

hypothesis of attention.” This hypothesis suggests that the correlation between border ownership responses and attentional effects may be explained by assuming that the same circuits underlie both processes and that the circuit that mediates border ownership provides an interface for attentional mechanisms. Thus top-down mechanisms might operate on intrinsic local circuits within V2 or on a local V2–V4 feedback network that mediates border ownership during the selection of object information.

The effects of attention on local circuits related to figure-ground segmentation in early visual cortex may represent one example in support of the interface hypothesis. A similar account may explain selection processes operating on neural competition at intermediate processing stages such as V4. As described earlier, when a stimulus is selected for further processing among multiple items, top-down processes appear to counteract the suppressive influences induced by nearby stimuli, thereby strengthening the neural representation of the attended stimulus. It is possible that the local intrinsic circuit engaged during competition within these areas provides an interface for the selection mechanisms to operate on. Consistent with this idea, local interneurons in V4, which are thought to subserve local circuits, receive stronger attentional modulation than other cell classes (Mitchell, Sundberg, & Reynolds, 2007). Thus the interface hypothesis

may be a useful novel framework for the interpretation of a number of empirical findings in the attention field.

SUMMARY One of the primary roles of attention is to select a small set of items among many, as when searching for an object in a cluttered visual scene. The need for such a mechanism becomes clearer when we consider the mutually suppressive interactions among multiple stimuli in visual cortex. Directed attention has been shown to bias this competition in favor of an attended stimulus, thus restoring a more optimal representation of that stimulus. Similarly, competitive interactions can be modulated by bottom-up factors such as salience and factors related to perceptual organization. Although these bottom-up factors represent qualitatively different biases from top-down directed attention, it also appears that the two factors interact to organize and ultimately select relevant aspects of a visual scene.

Conclusion

Evidence from functional brain imaging reveals that attention operates at various processing levels within the human visual system and beyond. These attention mechanisms appear to be controlled by a distributed network of higher-order areas in frontal and parietal cortex, which generate top-down signals that are transmitted by way of feedback connections to the visual system (see chapter 14 by Corbetta, Sylvester, & Shulman). Together, these widely distributed brain systems cooperate to mediate the selection of behaviorally relevant information that can be further utilized in other cognitive networks to ultimately guide goal-directed action.

14 The Frontoparietal Attention Network

MAURIZIO CORBETTA, CHAD M. SYLVESTER, AND GORDON L. SHULMAN

ABSTRACT This chapter is concerned with the attentional mechanisms that ensure that behavior is directed toward important stimuli in the environment. We review the evidence for a coherent neural network in dorsal parietal and frontal cortex that sends top-down signals, reflecting both the location and features of task-relevant objects, that bias processing in sensory regions such as occipital cortex. Top-down signals for location aid selection of an object by changing neural activity throughout an occipital retinotopic map, not just at the attended location, resulting in a relative increase in activity at that location in the map. The overall behavioral goals that determine which objects are selected are not set within the frontoparietal network, but reflect the interaction of networks involved in reward, memory, and executive control. These networks may provide inputs to dorsal frontoparietal regions that are transformed into biasing signals.

“Attention” broadly refers to a set of mechanisms that allow people to selectively perceive and respond to events that are relevant to their behavioral goals. Because of the importance of this function for many aspects of human behavior, discussions of attention crop up in treatments of such diverse topics as language, memory, emotion, perception, and motor control. Here we concentrate on the selection of objects in the environment for action. Chapter 13 in this book (Kastner, McMains, & Beck) discussed how attending to an object biases sensory evoked activity in sensory cortex and how these biases are thought to result in selective processing of the object (Desimone & Duncan, 1995).

Because complex goal-directed behaviors reflect the interaction of many different brain systems, it is not possible to speak of a single attentional control system. Different brain networks may be recruited when formulating behavioral goals, assessing those goals with respect to current knowledge of the environment, retrieving relevant information from memory, and integrating all of these influences into specific biasing signals that can be sent down to sensory and motor systems (hence the term “top-down” biases). In this review, we suggest that a set of dorsal frontoparietal regions

constitute a *dorsal frontoparietal attention network* that performs this final integration step. While this network operates irrespective of the criteria used to select stimuli (e.g., location, features) or responses (e.g., effector), subregions may show specializations for particular attributes, as we will discuss. We will also briefly review the coordination of this network with other networks involved in assessing value, generating and maintaining goals, accessing information in working memory, and retrieving information from long-term memory (figure 14.1).

The dorsal frontoparietal attention network

DEFINITION: FUNCTIONAL CONNECTIVITY AND ANTICIPATORY SIGNALS While the involvement of different brain regions in different functions is not controversial, it may not seem justified to segregate sets of regions into coherent brain networks, such as a dorsal frontoparietal network. However, an important development over the last decade has been the refinement of physiological techniques for identifying related sets of brain regions. One such technique, called functional connectivity magnetic resonance imaging (fcMRI), measures the temporal correlation of the blood-oxygenation-level dependent (BOLD) signal across multiple regions (Biswal, Yetkin, Haughton, & Hyde, 1995). Related regions show strong low-frequency (< 0.1 Hz) correlations over time, even when the subject is lying at rest with no task or stimulation (resting-state fcMRI). The origin of these correlations is still controversial, but they are thought to reflect both anatomical and functional factors. Several studies in the last five years have identified a number of resting-state networks that correspond to regions that are coactivated when subjects perform a task (Damoiseaux et al., 2006; Fox, Corbetta, Snyder, Vincent, & Raichle, 2006; Fox et al., 2005; Fransson, 2005; Greicius, Krasnow, Reiss, & Menon, 2003; Hampson, Peterson, Skudlarski, Gatenby, & Gore, 2002). Relevant to this discussion is the strong correlation between the frontal eye field (FEF) at the intersection of superior frontal sulcus and precentral sulcus, and regions within the intraparietal sulcus (IPS). IPS and FEF represent the core regions of the dorsal attention network (figure 14.2). These regions show spontaneous correlation also with visual areas like

(B) Wire diagram. Dorsal attention network feeds top-down and receives bottom-up biases to/from sensory cortices for stimulus and response selection. Other networks bias sensory processing via interaction with dorsal attention network. (See color plate 14.).

MT+ and V7. Other networks involved in regulation of attention are shown in figure 14.2 and will not be further considered in this chapter. A right-hemisphere-dominant ventral frontoparietal attention network, with core regions in right temporoparietal junction and ventral frontal cortex, is involved in stimulus-driven reorienting and resetting task-relevant networks; its physiological properties have been recently reviewed (Corbetta, Patel, & Shulman, 2008). A bilateral “default” network is consistently deactivated during goal-directed behavior (Mazoyer et al., 2001; Raichle et al., 2001; Shulman et al., 1997) and may be important in filtering information from internal task-irrelevant processes.

Perhaps the most direct method for observing sensory biases in isolation is to provide subjects with a cue telling them to attend to a specific location in space or a visual feature and to measure the resulting physiological signals prior to the onset of a target stimulus (Corbetta, Kincade, Ollinger, McAvoy, & Shulman, 2000; Hopfinger, Buonocore, & Mangun, 2000; Kastner, Pinsk, De Weerd, Desimone, & Ungerleider, 1999; N. Muller, Bartelt, Donner, Villringer, & Brandt, 2003; Serences, Yantis, Culbertson, & Awh, 2004; Sylvester, Shulman, Jack, & Corbetta, 2007). Cuing experiments in humans have routinely observed preparatory or endogenous activations—that is, activations not

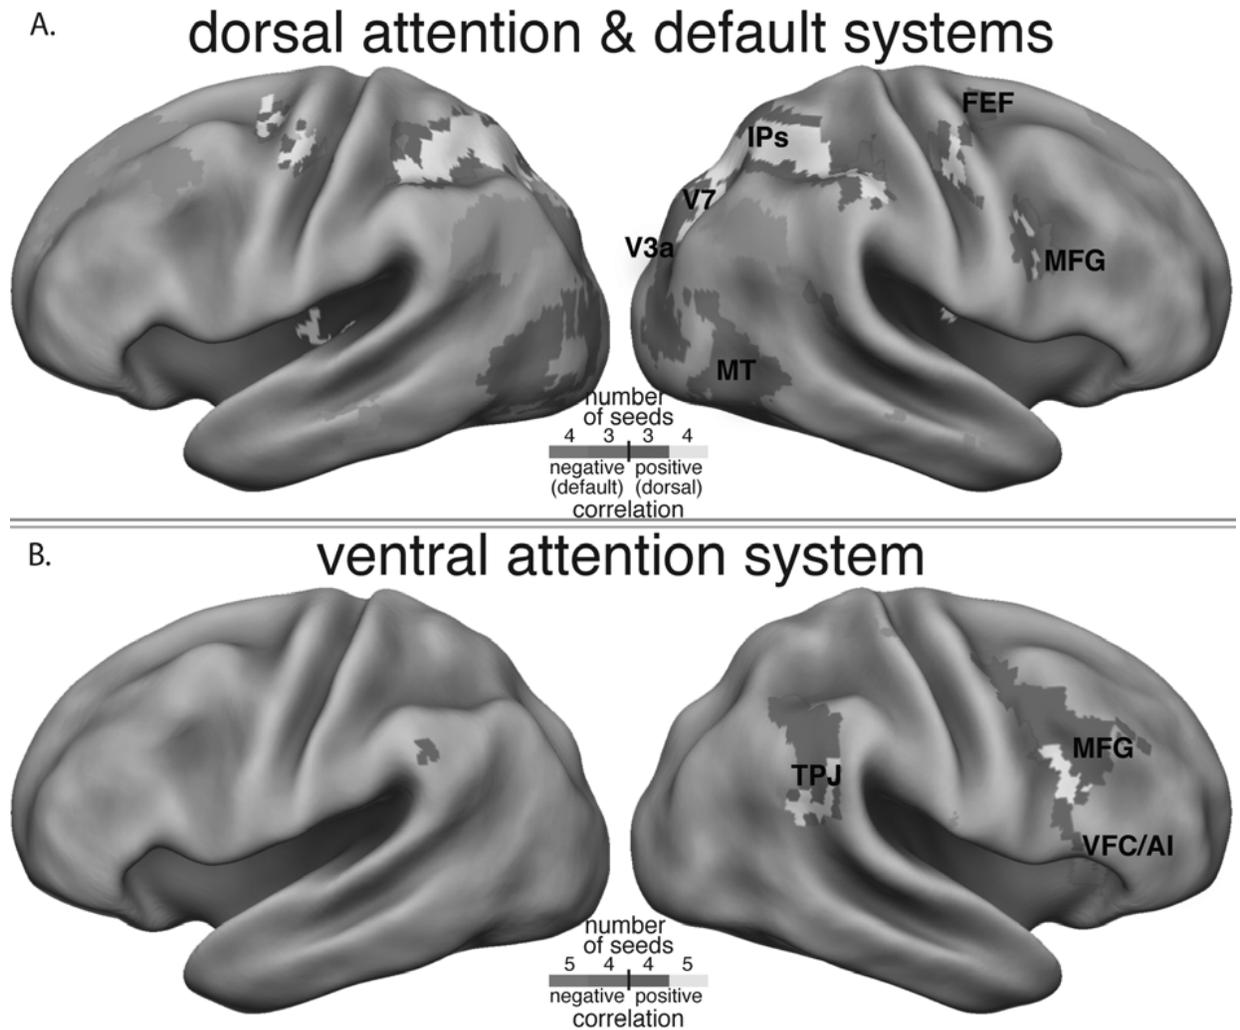

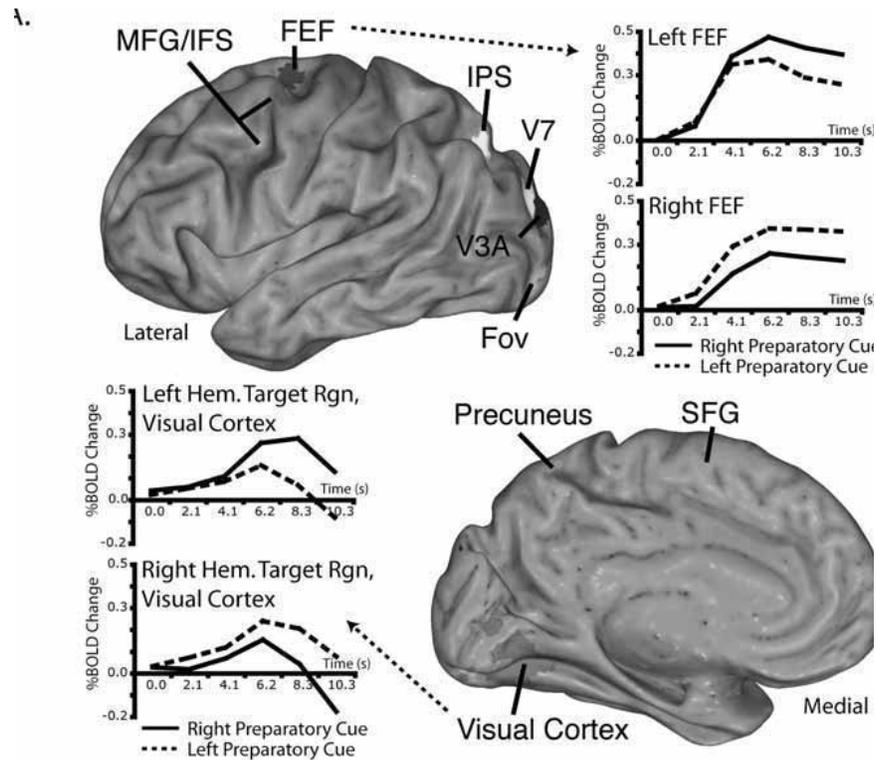

FIGURE 14.2 Functional connectivity by fMRI (fcMRI) defines separate dorsal and ventral networks. (A) Dorsal attention and default networks. The map indicates regions that showed significant positive correlations with three (red) or four (yellow) of the seed regions in the dorsal attention network (IPS, FEF, V7, MT+). The dorsal network is largely reproduced in the resting state FC maps. Regions that show significant negative correlations with three (green) or four (blue) of the seed regions are also shown and

roughly reproduce the default network, possibly indicating a push-pull relationship between the two networks. (B) Ventral attention network. Five ventral regions (R TPJ, R VFC, R MFG, R PrCe) were used as seeds for an FC analysis. Regions showing consistent positive correlations largely reproduce the ventral network, but negative correlations in default regions are not observed. The posterior MFG near the inferior frontal sulcus appears to be connected to both networks. (He et al., 2007.) (See color plate 15.)

driven by a sensory stimulus—in dorsal parietal regions of IPS, extending medially into superior parietal lobule, and in dorsal precentral sulcus at the intersection with the superior frontal sulcus (FEF; figure 14.3A). As noted earlier, these regions also show strong resting-state fcMRI. Dorsal frontoparietal activations are observed whether the cue stimulus is visual (Corbetta et al., 2000; Hopfinger et al.; Kastner et al.) or auditory (Sylvester et al.) and are sustained as attention is maintained over extended durations (Corbetta, Kincade, & Shulman, 2002). Subtle but consistent topographic differences have been reported between regions that encode a cue and maintain attention (Woldorff et al., 2004). Preparatory

activations in parietal and other regions predict performance on subsequent targets (Pessoa & Padmala, 2005; Sapir, d’Avossa, McAvoy, Shulman, & Corbetta, 2005). Finally, purely endogenous activations in dorsal frontoparietal regions are spatially selective, with greater activity following a cue in contralateral FEF and IPS (Sylvester et al.), as expected if these regions control the spatial selection of information.

In some studies of spatial cuing, endogenous cue-related responses in dorsal frontoparietal regions are accompanied by spatially selective endogenous activation of retinotopic occipital cortex (Kastner et al., 1999; Sylvester et al., 2007),

3.

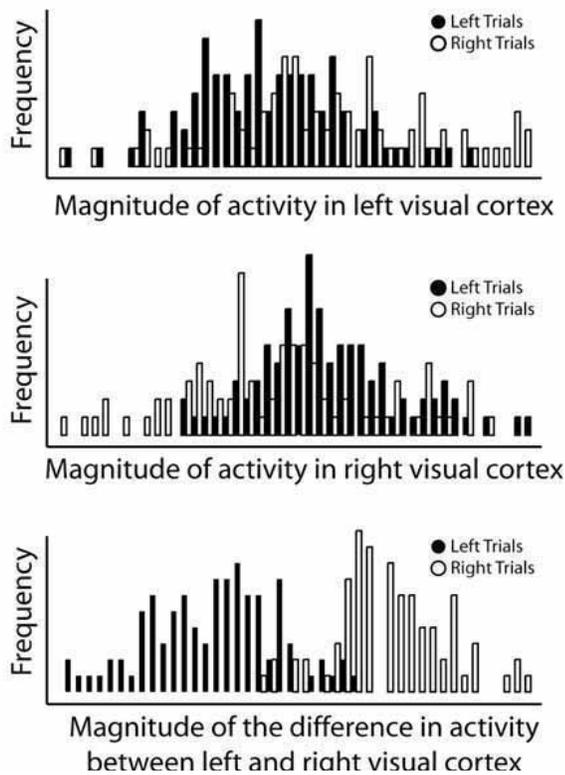

FIGURE 14.3 (A) Frontoparietal areas and visual cortex modulated by anticipatory signal for spatial attention. Areas with spatially selective preparatory signals following an auditory cue directing attention to a left or right location. MFG/IFS: middle frontal gyrus/inferior frontal sulcus; FEF: frontal eye field; IPS: intraparietal sulcus; Fov: foveal region of V1–V3; SFG: superior frontal gyrus. BOLD signal time series following spatial auditory cues show anticipatory signals that are stronger for cue directing attention to contralateral visual field locations. (See color plate 16.) (B) Relative activity predicts locus of attention in visual cortex. Top: single-trial

response magnitude of anticipatory activity in left visual cortex for directing spatial attention to left or right visual location. Note slightly higher activity for contralateral attention (right trials), but also strong overlap in the two populations of trials. Therefore readout of activity from only attended visual cortex does not provide a good prediction of the locus of spatial attention. Middle: same for right visual cortex. Bottom: the difference in activity between left and right visual cortex provides a strong trial-to-trial prediction of the locus of spatial attention by subtracting out common noise in the two maps. (From Sylvester et al., 2007.)

but not in other studies (Corbetta, Tansy et al., 2005; figure 14.3A). Although the reasons for this variation are not well understood, it may reflect the degree to which selection of an object or stimulus is limited by perceptual factors, which may be associated with endogenous modulation of visual cortex, as opposed to factors related to memory or stimulus-response translation.

Therefore dorsal frontal and parietal regions in IPS and FEF that are coactivated by cues to attend to a visual object form a distinct network in resting-state fMRI studies (Fox et al., 2006, 2005) and can be considered a separate functional network. Interestingly, consistent with the activation results, this network is not correlated under resting conditions with regions in the occipital lobe, except for human MT+. The interaction of dorsal frontoparietal cortex with occipital cortex is highly task contingent. In a later section, we discuss a possible mechanism for flexibly changing the effects of signals in one area (e.g., FEF) on those in another (e.g., V4). These human imaging studies of preparatory and resting-state activity in dorsal frontoparietal regions in humans are complemented by monkey single-unit studies showing anticipatory signals for spatial attention in FEF (Kodaka, Mikami, & Kubota, 1997) and LIP (Bisley & Goldberg, 2003), as well as resting-state functional connectivity between FEF and LIP in anesthetized monkeys (Vincent et al., 2007).

CAUSALITY OF TOP-DOWN BIASES FROM DORSAL ATTENTION NETWORK ONTO VISUAL CORTEX Physiological studies are generally correlational, demonstrating a relationship between a spatial or temporal pattern of neural activity and some task or behavioral parameters. Although cues to attend can produce endogenous signals in both dorsal frontoparietal and sensory cortex, and these signals may be predictive of behavioral performance, these results do not imply a causal influence of control regions on data-processing regions. Several recent studies, however, have provided evidence for this proposition. Moore and colleagues showed in monkey that stimulation of R FEF modulated sensory-evoked activity in V4 neurons whose receptive fields matched the movement field of the stimulated FEF site (Moore & Armstrong, 2003). Stimulation also changed the psycho-

physical threshold for detection of a low-contrast stimulus presented within the movement field of the stimulated site in FEF (Moore & Fallah, 2001). In humans, Ruff and colleagues showed that TMS of human FEF produced BOLD activation in peripheral V1–V4, independently of whether a stimulus was present (Ruff et al., 2006; figure 14.4A). Correspondingly, stimulation enhanced the perceived contrast of peripheral stimuli. These studies show that activity in FEF can produce the physiological changes in occipital cortex and the changes in behavioral performance that are expected for a brain region involved in top-down control of spatial attention.

However, these results were not obtained under physiological conditions, and more importantly they do not demonstrate an asymmetry in the interaction between occipital and dorsal frontoparietal regions. A recent study using Granger causality analysis meets both these objections (Bressler, Tang, Sylvester, Shulman, & Corbetta, 2008). The authors compared the degree to which endogenous preparatory signals in occipital cortex temporally predicted signals in dorsal frontoparietal regions over and above the prediction based on the dorsal frontoparietal regions themselves, and vice versa. They found that signals in dorsal frontoparietal regions strongly predicted occipital signals (top-down direction), and this prediction was significantly greater than that from occipital signals to dorsal frontoparietal signals (bottom-up direction). In fact, the latter predictability did not exceed a baseline level of predictability between any two voxels in the brain. These results support the hypothesis that under physiological conditions, following a cue to attend to a location, dorsal frontoparietal regions modulate occipital regions (figure 14.1).

TOPOGRAPHIC ORGANIZATION OF MAPS IN DORSAL ATTENTION NETWORK To understand how control is implemented, a helpful hint is the functional organization of an area or system, that is, the parameters that are coded in the pattern of neural activity. Recent studies have begun to detail the organization of the spatially selective neurons in frontal and parietal cortex that may be the source of top-down biases to visual cortex. Human parietal and frontal cortex appears to contain topographic maps of contralateral

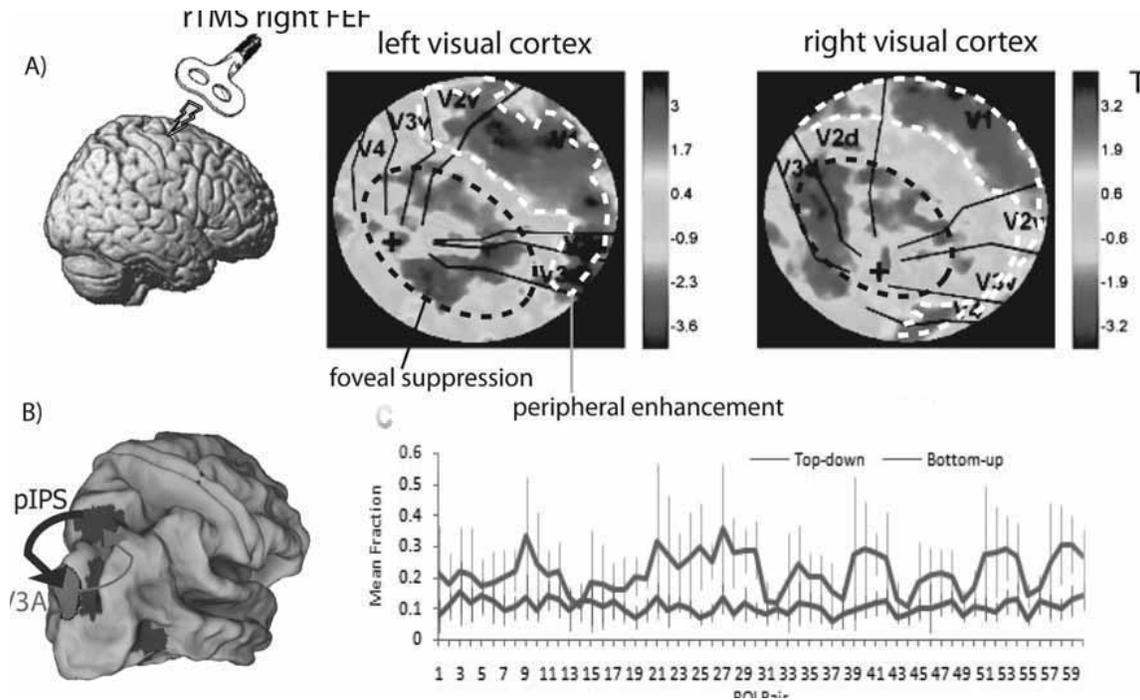

FIGURE 14.4 (A) Top-down activation of visual cortex from frontal eye field. Repetitive transcranial magnetic stimulation (rTMS) of right FEF causes bilateral activation in peripheral retinotopic visual cortex (V1–V4) (dotted white line) and corresponding deactivation in foveal representation (dotted black line). (Courtesy of Ruff & Driver; Ruff et al., 2006.) (B) Granger causality of BOLD signal time series during anticipatory spatial attention.

Left: “Control” area pIPS top-down modulates visual area V3A. The strength of top-down control trial-by-trial correlates with higher accuracy on a difficult visual discrimination task. *Right:* During anticipatory spatial attention the strength of top-down influences is stronger from control to visual areas than bottom-up influences from visual areas to control areas. (From Bressler, Tang, Sylvester, Shulman, & Corbetta, 2008.) (See color plate 17.)

visual space. The initial report of a single topographic map of the contralateral hemifield in human parietal cortex by Sereno, Pitzalis, and Martinez (2001) has been followed by several studies that have found multiple maps (Hagler, Riecke, & Sereno, 2007; Schluppeck, Glimcher, & Heeger, 2005; Silver, Ress, & Heeger, 2005), including a report of five contiguous maps along IPS (Swisher, Halko, Merabet, McMains, & Somers, 2007). Unlike early retinotopic occipital cortex, some of these regions may also show substantial nontopographic activations to ipsilateral stimuli (Jack et al., 2007). In the animal single-unit literature, the evidence for topographic maps in parietal areas such as LIP is inconsistent (Ben Hamed, Duhamel, Bremmer, & Graf, 2001; Platt & Glimcher, 1998), although a recent monkey fMRI study reported clear evidence for a hemifield map in both hemispheres (Gaurav Patel, Larry Snyder, and Maurizio Corbetta, personal communication).

Models of spatial selection propose that objects in a scene are represented in a topographically organized “salience” map and that the most activated object or location in the map is selected as part of a “winner-take-all” process (Koch & Ullman, 1985; Wolfe, 1994). The salience of an object in the map is partly determined by its sensory properties (e.g., high contrast) and by whether its features or

location are relevant to the current task and, as such, have been biased by preparatory activity. Selection is therefore based on the magnitude of an object’s activation relative to the activation of all other objects in the scene. A single-unit study in area LIP (Bisley & Goldberg, 2003), a likely homologue of human IPS regions, supports the idea that selection is based on the activity in one spatially selective set of neurons relative to that of another. The duration for which a monkey attended to the location of a flashed distracter object, presented in the opposite hemifield from an attended target location, was predicted from the duration for which LIP activity from the neurons responding to the distracter location was greater than the activity from neurons responding to the target location. In other words, the locus of attention in frontoparietal control regions may be coded by a difference signal between the level of anticipatory activity at the attended location versus unattended locations in different parts of the map.

MECHANISMS: CODING THE LOCUS OF ATTENTION BASED ON RELATIVE ACTIVITY WITHIN A MAP The importance of relative rather than absolute activity extends to top-down biases in visual cortex, where attending to a location changes activity not only at the attended location

of the retinotopic visual map but also throughout the map. While preparatory increases are observed at the attended location in an occipital retinotopic map (Hopfinger et al., 2000; Kastner et al., 1999; N. Muller et al., 2003; Serences, Yantis, et al., 2004; Sylvester et al., 2007), preparatory decreases are observed at unattended locations in the map (Silver, Ress, & Heeger, 2007; Sylvester, Jack, Corbetta, & Shulman, 2008).

Mapwide changes in occipital areas support the hypothesis that the operative spatial signal determining the locus of attention and salience is relative, such as a difference signal, but more direct evidence has recently been reported. Most studies of attentional modulations compare the activations from an object when it is attended versus unattended. The assumption is that the two situations are analogous to when attended and unattended objects are simultaneously present. However, this assumption is only correct when the activations from the two objects are uncorrelated over time. In fact, a recent fMRI study has shown that preparatory signals between homotopic locations of occipital retinotopic maps, as well as between left and right IPS and FEF, are highly correlated over trials (Sylvester et al., 2007). Correlated activity is significant but less strong at nonhomotopic locations (e.g., between fovea and periphery) or across separate areas (e.g., between FEF and V3A). Correlated neural activity across separate parts of V1 following stimulus presentation has also been reported (Chen, Geisler, & Seidemann, 2006), suggesting that the BOLD correlations reflect neural rather than or in addition to hemodynamic factors. While the neural causes of the BOLD correlations are not known, they might reflect nonspatial signals that carry information about the upcoming stimulus features or task or overall changes in arousal. As a result of the correlated signal, the absolute BOLD signal at the attended location in occipital and dorsal frontoparietal cortex is only a moderate trial-to-trial predictor of the direction of attention. Predictability in both occipital and dorsal frontoparietal areas is greatly improved by subtracting out the common “noise,” that is, taking the difference between activity at the attended location in the map and the homotopic location in the opposite hemisphere (Sestieri et al., 2008; Sylvester et al., 2007; figure 14.3*B*). The biological relevance of the difference signal is demonstrated by the fact that performance for subsequent targets is better predicted in V3A by the magnitude of the difference signal than by the magnitude of the absolute signal at the attended location.

The importance of relative rather than absolute signal levels qualifies the association of sustained BOLD activity with the maintenance of attention (Silver, Ress, & Heeger, 2007). In one fMRI study, while the absolute signal at the cued location in occipital retinotopic maps decreased over the course of the cue period, the difference between the signal at that location and at the homotopic location, as

well as the predictability of the locus of attention, increased over the same period, reflecting the larger signal decreases at the homotopic uncued location (Sylvester et al., 2007). Therefore, the maintenance of attention may be reflected in the sustained magnitude of a relative signal, not an absolute signal.

Finally, the mapwide distribution of preparatory activity in retinotopic cortex reflects not simply the location of the attended object, but also the computational demands of the task. Serences, Yantis, and colleagues (2004) demonstrated that when subjects expected a target stimulus to be surrounded by closely spaced distracter objects, preparatory signals increased, even when task difficulty remained constant. However, the relationship between the additional preparatory signal at the attended location and the suppression of distracter information at nontarget locations was unclear. A recent study (Sylvester et al., 2008) has shown that preparatory activity at nontarget locations depends on whether noise at those locations can adversely affect performance. Sylvester and colleagues compared mapwide changes in activity when subjects performed a coarse orientation discrimination on a low-contrast, near-threshold Gabor patch and an equally difficult but fine orientation discrimination on a high-contrast, suprathreshold Gabor patch. The location of the Gabor was cued, and expected contrast was blocked, allowing subjects to optimally adjust the distribution of attention to both the attended location and the nature of the discrimination. In the low-contrast condition, performance was partly limited by noise at nontarget locations that created spurious false alarms, but in the high-contrast condition, performance was only limited by noise at the target location. Even though the spatial distribution of the task stimulus was identical in the two conditions, preparatory signal decreases at nontarget locations in retinotopic occipital maps were greater when subjects expected a low-contrast than high-contrast Gabor, reflecting the need to suppress noise at these locations and “mark” the target location by creating a steep target-nontarget location gradient. No effects of expected contrast were observed at the cued location.

How are these task-dependent changes in the mapwide distribution of preparatory signals controlled? Sylvester and colleagues (2008) reported that regions in FEF and IFS (inferior frontal sulcus), but not IPS, showed additive effects of expected target location and contrast, with greater activations when contralateral locations were cued but also when low-contrast stimuli were expected at either contralateral or ipsilateral locations. The additive contrast and cue location signals in FEF and IFS were combined to produce the interacting, mapwide changes observed in retinotopic occipital cortex, although the manner in which this process occurred was unclear. Interestingly, stimulation of FEF by TMS, in the absence of a visual stimulus, decreases activity in portions of early visual cortex corresponding to the central

visual field (Ruff et al., 2006), which also showed the largest decreases in Sylvester and colleagues (2008).

In conclusion, these studies emphasize that selection of an object at a location in the visual field involves a mapwide modulation of topographic sensory representation, and that spatial sensory bias at the attended location arises from an interaction of biasing signals at both attended and unattended locations. Within dorsal frontoparietal areas, spatial biases coexist with nonspatial (feature) biases that seem to independently modulate activity in visual areas prior to stimulus presentation. The presence of correlated noise, especially among homologous locations of a map (e.g., left and right upper visual field) or regions of a network (e.g., left and right FEF) may reflect spontaneous oscillatory activity that is strongest between regions in visual cortex that are connected through the corpus callosum. In the next section we link these interhemispheric interactions in spatial selection to the functional relationship that exists between spatial attention and the control of eye movements.

MECHANISMS: RELATIONSHIP TO EYE MOVEMENTS AND FEATURE-BASED SELECTION While spatial selection can be controlled independently of eye movements (Klein, 1980), it is striking that the same set of brain regions, including IPS and FEF (and superior colliculus subcortically), have been implicated in both processes (Beauchamp, Petit, Ellmore, Ingeholm, & Haxby, 2001; Bisley & Goldberg, 2003; Bruce & Goldberg, 1985; Bushnell, Goldberg, & Robinson, 1981; Corbetta et al., 1998; Corbetta, Miezin, Shulman, & Petersen, 1993; Luna et al., 1998; Nobre et al., 1997; Perry & Zeki, 2000; Petit, Clark, Ingeholm, & Haxby, 1997; Snyder, Batista, & Andersen, 1997; Sweeney et al., 1996). Moreover, many studies have suggested that both processes are linked (Hoffman & Subramaniam, 1995; Kowler, Anderson, Doshier, & Blaser, 1995; Kustov & Robinson, 1996; Sheliga, Riggio, & Rizzolatti, 1994; Shepherd, Findlay, & Hockey, 1986; but see Klein, 1980), leading to “premotor” (Rizzolatti, Riggio, Dascola, & Umiltá, 1987) accounts of spatial selection. The basic idea is that the allocation of spatial attention in the visual field, as well as the related effects on behavioral performance and evoked responses in sensory cortex (see chapter 13), depend on the preparation of an eye movement plan to foveate the target. Since most experiments of spatial attention are conducted while subjects maintain fixation, these oculomotor plans are “covert” and do not lead to an actual eye movement. Conversely, the preparation of an eye movement plan leads to an anticipatory shift of spatial attention. This idea has been more recently supported by electrical microstimulation studies in oculomotor regions (FEF and superior colliculus) showing that stimulation with electricity below the level necessary to produce an overt eye movement still produces changes in visual field sensitivity consistent with a shift of spatial attention

at the potential saccade location (Moore & Fallah, 2001; J. Muller, Philiastides, & Newsome, 2005). The coincidence of neural systems for spatial attention and eye movements is not complete, however; at the level of single cells in FEF, visual and visuomovement cells respond during covert target selection while purely motor cells are either silent or even inhibited (Thompson, Biscoe, & Sato, 2005). Therefore, a reasonable conclusion is that spatial attention and eye movement mechanisms are functionally (even causally) related but that dissociations can occur both psychologically and neurally (Awh, Armstrong, & Moore, 2006).

The link between spatial attention and eye movements provides a potential explanation for the prominent role that interhemispheric interactions play in the allocation of attention in both visual cortex and frontoparietal regions. As earlier discussed, in both control and sensory areas the locus of spatial attention is best described by a relative balance of activity between attended and unattended parts of a topographic map, especially between homologous regions in different hemispheres (e.g., left and right upper visual field, or left and right FEF). If directing attention is akin to planning an eye movement, then it would be sensible to have mechanisms that prevent the simultaneous activation of oculomotor neurons in opposite directions. These would ensure behavioral coherence as subjects explore the environment. An inhibitory mechanism that prevents reexploration of previously attended locations or objects is well described and is also linked to eye movements (inhibition of return). Here we propose that a similar mechanism may be operative during the anticipatory deployment of attention to a location and the subsequent readout of sensory information. By using a subtraction strategy between homologous regions for coding the locus of attention, the brain prevents the generation of eye movements and selection of stimuli in opposite locations. It will be interesting to evaluate whether similar subtractive strategies are operational even when competing locations are in the same visual field or along the vertical axis.

The important link between attention and eye movements does not completely explain the broad and flexible range of selection mechanisms that are implemented in the dorsal frontoparietal attention network. Selection of visual information is based on many properties besides spatial location. People can efficiently search for an object defined by a very large number of different features (e.g., red, motion in a particular direction) in the presence of complete spatial uncertainty (Wolfe, 1994). Consistent with this observation, feature-specific modulations of sensory activity have been reported throughout the visual field, not just at the currently attended location, both in single-unit and imaging studies (Martinez-Trujillo & Treue, 2004; Saenz, Buracas, & Boynton, 2002; Treue & Trujillo, 1999). Objects containing the primed features, however, attract shifts of attention (Folk, Remington, & Johnston, 1992; Serences et al., 2005),

suggesting that feature-based selection may operate in part by biasing sensory activity to an object, which evokes shifts of spatial attention or eye movements to the object (Shih & Sperling, 1996). This interaction suggests important links between or within brain regions involved in feature-based selection and overt or covert spatial selection.

Accordingly, feature-selective selection signals have been found in parietal and FEF cortex. Fast-latency single-unit responses to a particular color, for example, have been reported in FEF following extended experience with targets defined by that color in multiobject displays (Bichot, Schall, & Thompson, 1996). Imaging studies have reported dorsal frontoparietal activity during cuing of features in addition to spatial location (Shulman et al., 1999). Explicit comparisons of the activations to cues for location and color indicate common activity in many dorsal frontoparietal regions, but also activations in subregions that are greater for location than color (Giesbrecht, Woldorff, Song, & Mangun, 2003; Slagter et al., 2007). Similarly, studies comparing motion and color cues have reported dorsal frontoparietal activations that are greater for motion than color (Mangun & Fannon, 2007; Shulman, D'Avossa, Tansy, & Corbetta, 2002), and Mangun and colleagues have suggested that the location-selective regions are similar to the motion-selective regions (Mangun, Fannon, Geng, & Saron, 2009). These studies indicate that preparing to select a visual attribute activates dorsal frontoparietal regions that generalize across visual dimensions as well as subregions that show specificity for some dimensions. Finally, during sustained attention to a visual stimulus, feature-specific attentional modulations—for example, modulations that are specific to a particular direction of motion—have been reported in parietal cortex and FEF, in addition to retinotopic occipital cortex, using multi-voxel classification techniques (Serences & Boynton, 2007).

While feature-based and location-based selection can be coordinated, as in the case of visual search discussed previously, feature-based selection need not drive an oculomotor mechanism. Selection by hierarchical scale is one example in which eye movements do not aid changes in selection, yet preparatory activations are observed in IPS, with larger preparatory activations during selection of local scales in left than right IPS (Weissman & Woldorff, 2005). Therefore, while eye movements, feature-based selection, and object-based selection sometimes operate in a coordinated fashion, premotor theories that explain selection of task-relevant visual stimuli solely in terms of the signals that drive or are observed within oculomotor mechanisms remain incomplete. Dorsal frontoparietal regions include both oculomotor-based and non-oculomotor-based selection mechanisms.

Finally, some transient neural signals appear to generalize across virtually any change in selection criteria. Transient “switch” signals are observed most strongly in medial parietal areas such as precuneus, rather than IPS, and in frontal

areas such as FEF, whether attention is switched between stimuli in different locations (Yantis et al., 2002), between superimposed objects (Serences, Schwarzbach, Courtney, Golay, & Yantis, 2004), between stimuli in different modalities (Shomstein & Yantis, 2004), or between superimposed random-dot arrays with different visual features (Liu, Slotnick, Serences, & Yantis, 2003). Switch signals have been hypothesized to enable networks to “settle” into a state appropriate to the newly attended object (Serences & Yantis, 2006).

Establishing goals in frontoparietal network

In the laboratory, instructions to direct selective attention are provided by symbolic or nonsymbolic cues (arrows, symbols, sensory cues, etc). In real life, however, selective attention is controlled by a complex combination of signals (goals, desires, memories), which sit in the background of awareness while guiding behavior and are generated in distributed brain systems that interact with the frontoparietal network.

Several classes of internal signals can drive selective attention. If we take the simple case of “reaching for a cup in the cupboard to drink some water,” orienting to the cupboard and selecting the appropriate action to reach for the cup engages over time the frontoparietal dorsal attention network. But this preparatory activity reflects the interaction of the dorsal network with other neural systems. For instance, this behavior is motivated by an error signal in the hypothalamus indicating a mismatch in the concentration of blood (or osmolarity), which we subjectively perceive as thirst. The overall organization of the behavior (“reach for the cup in the cupboard”) may be built from learned patterns that can be loaded in working memory. Signals from long-term memory indicate the kitchen’s layout and the position of the cups in the cupboard. Therefore a network controlling spatial attention and target selection should interact over time with other neural systems monitoring the internal milieu and expected reward, working memory, and long-term memory. The actual sequence of activity is currently unknown because of the lack of suitable methods for tracking the temporal evolution of neural activity in distributed neural networks. However, the available evidence does show that the spatial attention system is jointly activated with other cognitive systems (working memory/executive control; reward; long-term memory) under conditions in which these systems provide inputs for the spatial selection of objects and responses. This idea is presented in figure 14.1, and some of the evidence is presented in the following sections.

REWARD/VALUE SIGNALS AND THE LIMBIC SYSTEM
Neurons in areas involved in the control of spatial attention and eye movements carry information about the amount of

reward a monkey receives for making an instructed eye movement. Platt and Glimcher found that the activity of neurons in the lateral intraparietal (LIP) area coded not only the position of the visual stimulus or intended eye movement but also the probability that a particular eye movement response would yield a fruit juice reward and the expected amount of the reward (Platt & Glimcher, 1999). Moreover, when animals were left to make their own decision on where to look, neuronal activity varied with the probability and size of an upcoming fruit juice reward. Reward-related modulations have also been observed in several areas connected to LIP like superior colliculus (Dorris & Munoz, 1998) and prefrontal cortex (Gold & Shadlen, 2003). To the extent that LIP and related areas contain salience maps indicating locations that are likely targets for eye movements or shifts of attention, the salience map includes information concerning the expected value of the eye movement.

While activity in the dorsal attention network combines information about expected value and the physical location or attributes of the object that can guide a shift of attention or eye movement, other neural systems code only reward information. Reward-related signals involve a distributed network of brain stem and cortical regions including sensory-motor and limbic regions. Two recent reports showed that neurons in orbitofrontal cortex coded the value of two possible choices independently of their physical attributes or locations, unlike LIP (Padoa-Schioppa & Assad, 2006, 2008). Other regions that have been proposed within the limbic system as the putative source of motivational/reward signals are the nucleus accumbens and related frontal connections, amygdala, and anterior and posterior cingulate cortex.

The posterior cingulate, in particular, is strongly connected bidirectionally with both limbic areas and sensory parietal areas, and may funnel limbic influences onto regions involved in visuospatial attention, as originally proposed by Marsel Mesulam (1981). Several human brain-imaging experiments have manipulated spatial attention and reward. In one study subjects directed attention based on central cues, and in different blocks won or lost money depending on whether their response to visual targets was faster or slower than following a neutral cue (Small et al., 2005). Posterior cingulate, anterior cingulate, orbitofrontal, and parahippocampal cortex were modulated by the interaction of attention-based facilitation of performance and reward. In a second study, subjects were asked to direct spatial attention based on central cues to identify target stimuli that were either food or nonfood items (Mohanty, Gitelman, Small, & Mesulam, 2008). In one session subjects were hungry, whereas in another session they were satiated. Activity in orbitofrontal cortex, posterior cingulate, and regions of the dorsal attention system (IPS) was more correlated with performance benefits due to spatial attention during hunger

than satiety. Single-unit studies have also demonstrated reward-related modulations in posterior cingulate neurons of macaques. Activity was correlated positively and negatively, in different neurons, with the size of a reward and was also affected by the omission of an expected reward (McCoy, Crowley, Haghghian, Dean, & Platt, 2003).

TASK SETS, PREFRONTAL-CINGULAR CIRCUITS, AND WORKING MEMORY Task sets and working-memory signals also guide stimulus selection. Informally, a task set specifies the types of stimuli that should be mapped onto particular responses, although more formal definitions have been developed (Logan & Gordon, 2001). A task set can be open ended, such as “get a cup in a cupboard for drinking,” or more constrained, like “get a red cup among green and blue cups.”

Experimental evidence indicates that prefrontal cortex, through its widespread connection with other brain areas, plays a critical role in generating, maintaining, and applying a task set. Patients with prefrontal lesions have problems carrying out complex behaviors, especially when they require multiple steps, and are prone to distraction by irrelevant environmental stimuli (Fuster, 1985; Stuss & Benson, 1986). Neurons in prefrontal cortex respond to cues that instruct a task, maintain this information throughout a temporal delay in the absence of sensory stimulation, and can prospectively code for the relevant response (Miller & Cohen, 2001). Prefrontal cortex is especially important when cues guiding behavior must be flexibly changed over time (Rossi, Bichot, Desimone, & Ungerleider, 2007).

Task sets that are represented in prefrontal cortex may determine the particular stimulus-response linkages or sensory biases established by the dorsal attention network. A distinction between orienting and executive networks was originally proposed in a seminal review by Posner and Petersen (1990). Recent studies have provided more evidence for a functional separation of task control and stimulus selection systems. In a large fMRI meta-analysis, Dosenbach and colleagues isolated two different putative control networks: an anterior cingulofrontal operculum (ACC/FO) network and a frontoparietal network (Dosenbach et al., 2007, 2006). The ACC/FO network was defined based on the presence across studies of three putative control signals: (1) a sustained signal maintained throughout a block of trials (typically 30–50 seconds), possibly representing a “sustained” set signal for the task at hand; (2) a transient signal at the beginning and end of a block of trials, possibly representing the loading and unloading of task parameters; and (3) a transient signal generated by an error, possibly underlying error correction and on-line adjustments. The co-localization of these three signals across a large number of different tasks to the same cingular-opercular regions supports the hypothesis that these regions form a functional network involved in some aspect of high-

level control. Moreover, the same regions formed a network in a resting-state fMRI study that was distinct from a frontoparietal network. Dosenbach and colleagues suggested that the latter network, which only partially overlapped the dorsal frontoparietal network involved in stimulus selection, was involved in moment-to-moment task adjustments. While the functional analysis of the cingulo-opercular network is just beginning and its role in behavioral performance is not well understood, these results support a functional subdivision between a dorsal frontoparietal attention network and a high-level ACC/FO network that maintains an abstract specification of a task.

During task performance, task information is thought to be maintained in “working memory,” a short-term storage in which information can be easily manipulated and accessed. The neural structures underlying visual working memory have been investigated under conditions in which this task information is highly constrained and specific (e.g., the position of each cup in the cupboard), with parietal regions showing load-dependent activity and a correlation of this activity with memory performance (Marois, Chun, & Gore, 2004; Todd, Fougner, & Marois, 2005; Vogel, McCollough, & Machizawa, 2005). Early studies showed a substantial overlap of frontoparietal regions involved in maintaining spatial attention at a location and maintaining spatial working memory (Cabeza & Nyberg, 1997; Corbetta, Kincade, & Shulman, 2002), with behavioral results clearly showing that one is important for the other (Awh & Jonides, 2001).

More recent studies by Nobre and colleagues indicate overlapping mechanisms for orienting to objects in spatial working memory and orienting to objects in the environment (Lepsien, Griffin, Devlin, & Nobre, 2005; Nobre et al., 2004). In a “pre-cue” environment condition, a cue directed attention to a location before the onset of an array. In a working-memory “retro-cue” condition, subjects loaded the same array into working memory, and then saw a cue indicating a location in the array. In both cases subjects decided whether a test object was present in the stimulus array. Both pre- and retro-cues facilitated the identification of objects that were respectively presented in the visual field or in working memory, and correspondingly, the standard frontoparietal network was also recruited in both conditions. However, in addition, “retro-cues” activated to a greater degree medial and lateral prefrontal cortex, while “pre-cues” activated visual cortex prior to stimulus presentation. Prefrontal activation precedes posterior activation in the memory condition (Lepsien et al.). These findings suggest, as in the case of reward and motivational signals discussed earlier, that prefrontal regions putatively involved in working memory coactivate with the dorsal frontoparietal network when spatial attention is directed to a memory representation.

LONG-TERM MEMORY AND HIPPOCAMPUS Long-term memory signals also guide spatial orienting under ecological conditions. Once a goal is established, prior knowledge about the surrounding environment guides the execution of complex behavior in a nearly effortless manner. In reaching for a cup, we direct attention to the location of the cabinet based on prior knowledge about the layout of the kitchen as well as the location of a particular cup in the cabinet.

Behavioral studies have shown that implicit memory derived from previous exposure to a particular stimulus configuration can facilitate performance during visual search of a target among distractors. These results indicate influences of long-term memory on orienting as we move and act in the environment (Chun & Jiang, 2003). There is also evidence that semantic knowledge, such as the association of a word with an object, can facilitate the detection of that object (Moore, Laiti, & Chelazzi, 2003).

A recent study showed that attention can be directed to specific objects in a visual scene based on memory and that the frontoparietal attention network is recruited when attention is guided by memory similarly to the way in which it is guided by explicit visual cues (Summerfield, Lepsien, Gitelman, Mesulam, & Nobre, 2006). Summerfield and colleagues asked subjects to learn the location of a target object in several visual scenes. The next day they were asked to detect the same target object in previously learned or novel scenes. Performance was facilitated when subjects knew where to look based on prior experience or a visual cue. Interestingly, the time course of this memory-based facilitation was quite rapid (~100 ms), consistent with an automatic deployment of attention. The frontoparietal attention network was recruited similarly in the memory and visual cuing conditions, whereas in the memory condition additional regions related to memory retrieval were engaged (parahippocampal, retrosplenial, hippocampus). Interestingly, the degree of hippocampus activation across subjects correlated with the strength of the spatial facilitation in the memory condition, consistent with a large literature in rats associating the hippocampus and related structures to spatial memory (O’Keefe, Burgess, Donnett, Jeffery, & Maguire, 1998; Wilson & Tonegawa, 1997).

Physiological mechanisms for top-down influences and selection of visual objects

The preceding evidence indicates that the dorsal frontoparietal attention network for stimulus selection is recruited under different task conditions, and that correspondingly different neural systems are coactivated with that network. Although coactivation does not imply a functional interaction, it seems likely that distributed networks underlying

reward, executive control, working memory, and long-term memory all influence the biasing signals sent from the dorsal frontoparietal network to sensory cortex.

The issue of communication between distributed neural networks is a fundamental problem in neuroscience that is particularly important in discussions of attention. While there are several potential mechanisms for linking separate distant neuronal populations, one recent idea is that information is best transmitted from one group of neurons to another; that is, neural activity in one group of neurons most strongly affects activity in a second group of neurons when their neural activity is synchronized or coherent (Fries, 2005; see also chapter 20 by Womelsdorf and Fries). Therefore, synchronization could be a powerful mechanism for controlling whether signals from sensory areas are sent to higher-order areas, that is, whether an object is selected. There is now a substantial and growing body of evidence that rhythmic synchronization is not epiphenomenal. A number of studies have investigated *local* neuronal synchronization and demonstrated its relation to, for example, selective attention (Bichot, Rossi, & Desimone, 2005; Engel, Fries, & Singer, 2001; Taylor, Mandon, Freiwald, & Kreiter, 2005; Womelsdorf, Fries, Mitra, & Desimone, 2006) and working-memory maintenance (Howard et al., 2003; Pesaran, Pezaris, Sahani, Mitra, & Andersen, 2002).

Local neuronal synchronization in parietal, frontal, and occipital cortex during visual attention to a stimulus has been reported at both low (8–15 Hz) and high (40–80 Hz) frequency. A number of EEG/MEG studies in healthy subjects have shown anticipatory decreases in alpha/beta power over parieto-occipital cortex before stimulus presentation that predicts subsequent visual discrimination (Babiloni, Vecchio, Miriello, Romani, & Rossini, 2006; Sauseng et al., 2005; Thut, Nietzel, Brandt, & Pascual-Leone, 2006). Interestingly, alpha/beta power modulations have an asymmetrical topography, with greater decrements in the hemisphere contralateral to the side of attention (in the case of spatial attention), and the degree of asymmetry is more predictive of the locus of attention and performance than the absolute power modulation in either hemisphere in isolation. These asymmetrical anticipatory changes in EEG power are highly reminiscent of the asymmetrical BOLD anticipatory changes in frontoparietal and visual regions during spatial attention tasks (see the first section, “The dorsal frontoparietal attention network”). As noted earlier, the best predictor of the locus of attention and subsequent perception to targets is the difference between anticipatory activity in frontoparietal and visual regions contralateral and ipsilateral to the side of attention. Preliminary evidence indicates a functional link between BOLD and EEG signal fluctuations in the alpha/beta band at rest in the dorsal frontoparietal attention network (Laufs et al., 2003; Mantini, Perrucci, Del Gratta, Romani, & Corbetta, 2007).

Conclusions

There is now consensus in cognitive neuroscience that dorsal frontoparietal areas are the sources of top-down biases onto data-processing areas in sensory cortices. The most important anticipatory signal that these areas provide is information about the upcoming target location, but there is growing evidence for other “object”- or “identity”-related signals being coded in these regions, perhaps in conjunction with other parts of prefrontal cortex. Perhaps the most important problem for the future is to find ways to visualize and thus understand how these intermediate control regions interact with other systems involved in coding value/reward, long-term memory, and goals. Solving this problem will necessarily require higher temporal resolution methods coupled with methods like fMRI that provide enough spatial resolution to monitor neural activity at the level of single areas. Another important goal will be to find the computations or the set of transformations to which these regions contribute, given the generality of their recruitment in many forms of selection. Will higher specificity emerge when population-level activity from these areas is monitored at higher temporal/spatial resolution? The difficulty of these problems, however, should not preclude us from using functional anatomical models like the one presented here and elsewhere (Corbetta et al., 2008; Corbetta & Shulman, 2002) to begin understanding human brain diseases. A network approach to the study of disorders of attention has in fact already yielded critical information (Corbetta, Kincade, Lewis, Snyder, & Sapir, 2005; Posner, Walker, Friedrich, & Rafal, 1984) that will be used in the near future to improve human health.

15 Spatiotemporal Analysis of Visual Attention

JENS-MAX HOPF, HANS-JOCHEN HEINZE, MIRCEA A. SCHOENFELD,
AND STEVEN A. HILLYARD

ABSTRACT The fact that perception of a visual event can be improved by focusing attention upon its spatial location has been documented in numerous experiments going back more than a century. It is also well established that visual attention can be selectively allocated to nonspatial stimulus features or to entire objects as integrated feature ensembles. In the quest to identify the neural mechanisms that underlie this perceptual selectivity in human observers, neuroimaging methods, including noninvasive recordings of event-related potentials (ERPs) and event-related magnetic fields (ERMFs), have provided valuable insights. Contributions from the ERP and ERMF methodologies have been particularly important for revealing the time course and rapid coordination of the underlying selection processes. The ever-expanding body of research in this field has made it abundantly clear that visual attention does not rely upon a unitary neural mechanism, but instead that multiple selection processes cooperate in a flexible manner to guarantee the adaptability of attention to a wide range of circumstances. Here we outline some of the principles underlying the flexible coordination of space-, feature-, and object-based selection processes that have emerged from recent studies, with particular emphasis on the contributions of ERP and ERMF recordings in human observers.

Spatial attention

Event-related potential (ERP) recordings have shown how spatial attention influences sensory processing in the visual cortex when attention is directed to briefly flashed stimuli in one visual field while equivalent stimuli in the opposite field are ignored (for reviews see Hillyard & Anllo-Vento, 1998; Hopfinger, Luck, & Hillyard, 2004; Luck, Woodman, & Vogel, 2000; Mangun, 1995). The general finding has been that attended stimuli elicit enlarged early ERP components in the visual cortex during the interval 80–200 ms after stimulus onset relative to unattended stimuli. These amplitude enhancements typically occur without a significant

change in component latencies or scalp topographies, suggesting that spatial attention operates by simply controlling the gain of visual input during early processing stages (Hillyard, Vogel, & Luck, 1998); such a sensory gain control mechanism is consistent with observations from single-unit recordings in monkeys (Lee, Williford, & Maunsell, 2007; Luck, Chelazzi, Hillyard, & Desimone, 1997; Maunsell & Cook, 2002). The earliest consistent ERP modulations produced by spatial attention were found to be amplitude enhancements of the initial positive (P1) and subsequent negative (N1) components of the ERP elicited at latencies of around 80–100 ms and 130–200 ms, respectively (see figure 15.1). While these two components were generally modulated in tandem, there is increasing evidence that they reflect different aspects of attentional selection (reviewed in Hopfinger et al.), with the initial P1 modulation reflecting location selection per se and the subsequent N1-modulation reflecting discriminative processing of the stimulus within the focus of attention (Hopf, Vogel, Woodman, Heinze, & Luck, 2002; Vogel & Luck, 2000). The amplitudes of both the P1 and N1 components have been found to covary with the amount of processing resources that are voluntarily allocated to a spatial location (Handy & Mangun, 1997, 2000; Mangun & Hillyard, 1990). Moreover, reflexive orienting to the location of a nonpredictive cue was found to enhance the P1 amplitude to a subsequent co-localized target, suggesting that at least initially the same modulatory processes of location selection are engaged during voluntary and reflexive orienting (Hopfinger & Mangun, 1998, 2001; Hopfinger & Ries, 2005).

THE PROFILE OF THE SPATIAL FOCUS OF ATTENTION The focus of spatial attention has been likened to a spotlight (Posner, 1980), a zoom lens (Eriksen & Yeh, 1985), or a Gaussian gradient (Downing & Pinker, 1985; Shulman, Wilson, & Sheehy, 1985), which enhances processing of visual stimuli within a circumscribed region of space. While there is general agreement that the size of this attended region may be adjusted voluntarily, it has long been debated whether the spotlight of spatial attention has a unitary “beam” or whether it can be divided flexibly to disparate

JENS-MAX HOPF, HANS-JOCHEN HEINZE, and MIRCEA A. SCHOENFELD Department of Neurology, Otto von Guericke University; Leibniz Institute for Neurobiology, Magdeburg, Germany

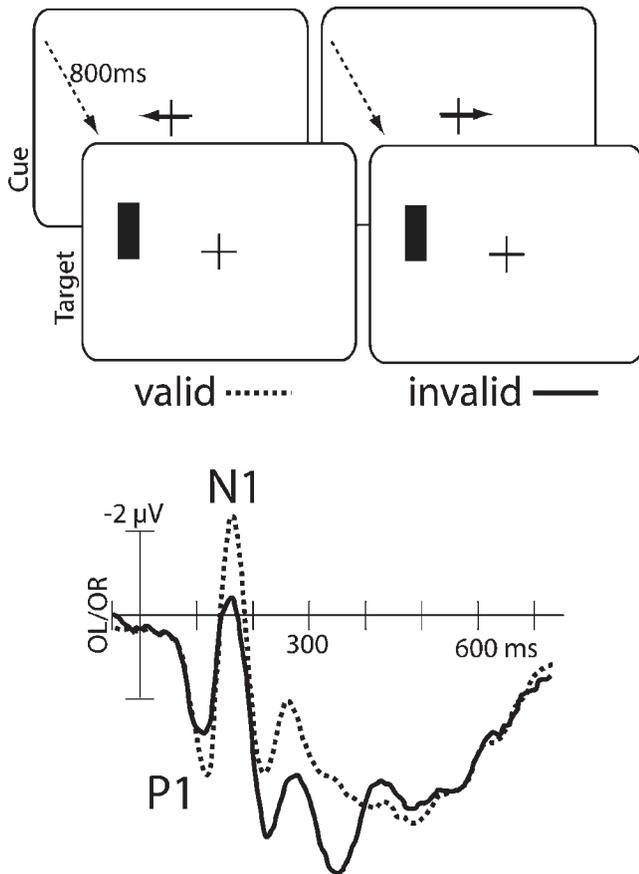

FIGURE 15.1 ERPs recorded in a typical version of Posner's location-cuing paradigm. A small central cue informed subjects of the most probable visual field where the target bar would appear. The subject's task was to perform a demanding length discrimination of the bar. On 75% of the trials the target appeared in the cued VF (valid condition), whereas on 25% of the trials the target appeared in the uncued VF (invalid condition). Below are ERP waveforms elicited by valid (dotted) and invalid targets presented to the same visual field (waveforms collapsed over left and right VF targets). The ERP response to the attended targets shows a prominent amplitude enhancement of the P1 as well as the N1 component without any significant change in latency. (Adapted from Mangun & Hillyard, 1991.)

locations (Awh & Pashler, 2000; Castiello & Umiltà, 1992; Hahn & Kramer, 1998; Juola, Bouwhuis, Cooper, & Warner, 1991; Kramer & Hahn, 1995; Posner, 1980). Evidence consistent with the unitary spotlight hypothesis has come from ERP studies in which target arrays were briefly flashed and hence not continuously visible (Eimer, 1999, 2000; Heinze, Luck, et al., 1994). Under conditions where both attended and unattended stimuli were continuously present, however, studies using both electrophysiological (Müller, Malinowski, Gruber, & Hillyard, 2003) and hemodynamic (McMains & Somers, 2004, 2005) measures of attention have found evidence that the spotlight of spatial attention may be divided. Müller, Malinowski, and colleagues (2003) required subjects to attend to two continuously flickering RSVP

streams of symbols that were spatially interleaved with two irrelevant streams, each flickering at a different rate. By recording the amplitude of the frequency-tagged steady-state visual evoked potential (SSVEP) to each of the streams, the allocation of attention among the four stimulus positions could be determined. It was found that attending to two spatially separated streams produced enhancement of the SSVEP elicited at those locations but not at an interposed location, indicating that attention had been effectively divided into two separate beams. Similar results were obtained by McMains and colleagues (McMains & Somers, 2004, 2005) in an fMRI study where subjects attended to two out of five rapid serial visual presentation (RSVP) streams of characters, two in each visual quadrant and one at fixation. They observed BOLD enhancements in cortical regions that corresponded retinotopically with the location of the attended streams together with a lack of enhancement in regions corresponding to a spatially interposed distracter stream. Taken together, these physiological studies provide strong evidence that spatial attention may be divided flexibly to noncontiguous zones of the visual field when stimuli are continuously present, as is generally the case in the natural environment.

The concept of a unitary spotlight or zoom lens may be inadequate to describe the spatial distribution of attention even when only one location is attended. The spatial profile of attention is typically envisioned as a simple gradient of enhanced sensory processing that falls off gradually from the center (Downing & Pinker, 1985; Handy, Kingstone, & Mangun, 1996; Henderson & Macquistan, 1993). Some evidence from both ERP and single-unit recordings is consistent with such a profile (Connor, Gallant, Preddie, & Van Essen, 1996; Connor, Preddie, Gallant, & Van Essen, 1997; Eimer, 1997a). However, it has been repeatedly observed that measures of sensory processing may actually be reduced instead of enhanced in the near vicinity of a target item (Bahcall & Kowler, 1999; Cave & Zimmerman, 1997; Cutzu & Tsotsos, 2003; Mounts, 2000; Müller, Mollenhauer, Rosler, & Kleinschmidt, 2005), suggesting that a simple gradient may not represent an accurate picture. Computational models of visual spatial attention such as the Selective Tuning Model (Tsotsos, 2005) have made the explicit prediction of a suppressive zone surrounding the focus of attention. In line with this idea, recent physiological studies have reported observing a more complex center-surround structure. For example, Hopf and colleagues (2006) used MEG recordings to investigate the spatial profile of the focus of attention during visual search for a pop-out target. The ERMF response to a probe stimulus presented at varying distances from the target served as a measure of attentional allocation (figure 15.2A). This probe-evoked cortical response was enhanced at the target location but was significantly reduced for probes adjacent to the target (figure 15.2B),

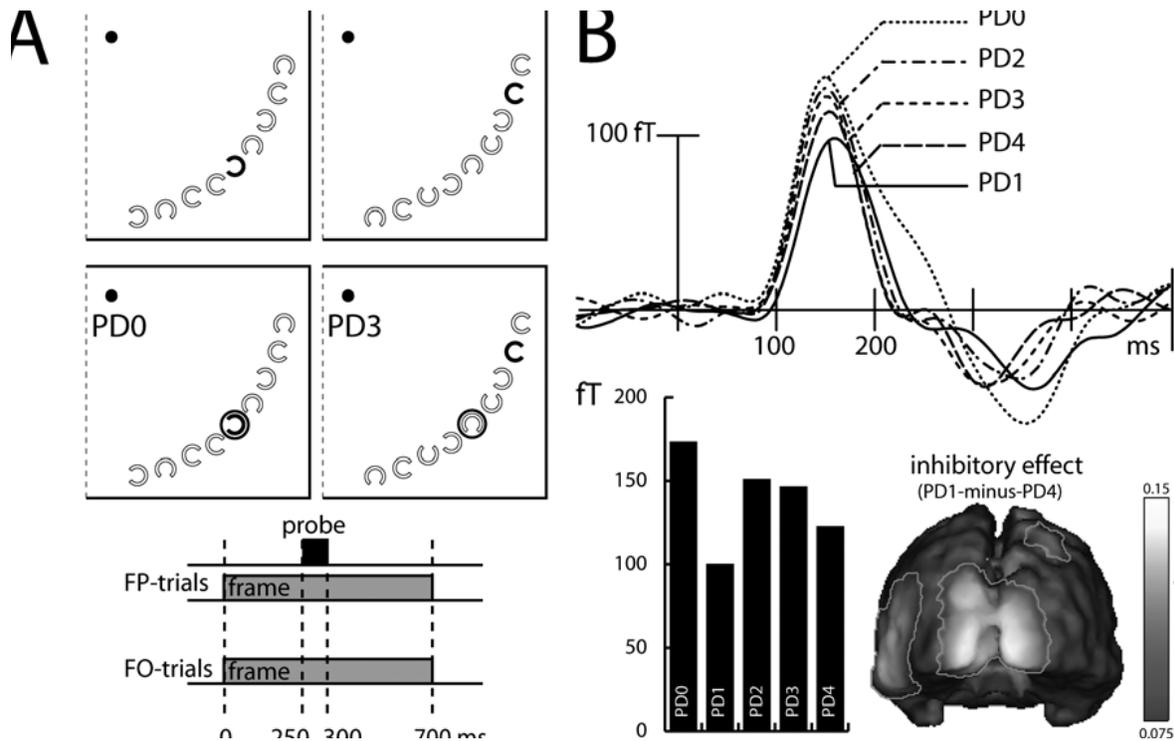

FIGURE 15.2 (A) Stimuli used in the study of Hopf and colleagues (2006). Subjects searched for a unique red *C* (shown in black) that randomly appeared at one of nine item locations in the right lower visual quadrant. On 50% of the trials a small white ring (the probe) was presented at the center position 250 ms after search frame onset (frame-probe, or FP, trials). On the remaining trials no probe appeared (frame-only, or FO, trials). On trials with a probe, the target could appear either at the probe's location (probe-distance 0, or PD0, shown on the middle left) or at a location one through four items away from the probe (PD1–PD4) (the situation for PD3 is illustrated on the middle right). The relative timing of search-frame and probe presentation is shown below. (B) ERMF response to the probe (FP-minus-FO difference waves) for the five different

probe distances (ERMf responses were collapsed across equivalent probe distances toward the horizontal and vertical meridian). A substantial reduction of the probe response was observed when attention was focused next to the probe (PD1) relative to when attention was focused at the probe's location (PD0) or two to four items away (PD2–PD4). This narrow zone of sensory attenuation surrounding the target is further illustrated in the bar graph showing the average size of the probe-related ERMf response between 130 and 150 ms. A source localization analysis of the surround attenuation effect (PD1-minus-PD4) is shown in the lower right, which revealed strongest modulations in early visual cortex areas and smaller effects in lateral and dorsal extrastriate areas. (Adapted from Hopf et al., 2006.)

suggesting that the attended location was surrounded by a narrow zone of relative inhibition. The spatial distribution of attention around a search target thus appears to resemble a Mexican hat profile rather than a simple monotonic gradient. Such a profile may be advantageous in attenuating the most deleterious noise directly adjacent to the target. Studies using ERPs (Slotnick, Hopfinger, Klein, & Sutter, 2002; Slotnick, Schwarzbach, & Yantis, 2003) and fMRI (Müller & Kleinschmidt, 2004) have provided converging evidence and have shown further that surround inhibition may also arise under conditions of sustained focusing.

LOCUS OF SPATIAL SELECTION IN THE VISUAL SYSTEM
To specify the anatomical locus of spatial selection in the visual pathways, recordings of the early sensory ERP/ERMf components have been combined with functional brain-imaging methods that provide high spatial resolution. These

combined analyses have revealed that the amplitude modulations of the P1 and N1 components produced by spatial attention in the interval 80–200 ms take place in extrastriate cortical areas of both the dorsal and ventral streams (Di Russo, Martinez, & Hillyard, 2003; Heinze, Mangun et al., 1994; Hopf et al., 2002; Mangun, Buonocore, Girelli, & Jha, 1998; Martinez et al., 1999; Noesselt et al., 2002; Woldorff et al., 1997). Notably, in none of these studies were modulatory effects due to attention observed in the initial feedforward sweep of processing in the primary visual cortex, which is reflected in the early ERP/ERMf component known as C1 (50–80 ms) (Aine, Supek, & George, 1995; Clark, Fan, & Hillyard, 1995; Clark & Hillyard, 1996; Di Russo, Martinez, Sereno, Pitzalis, & Hillyard, 2002; Foxe & Simpson, 2002; Olson, Chun, & Allison, 2001). Instead, modulations of V1 activity caused by attention were found to appear after a considerable delay, at latencies of around 150–250 ms, well after the onset of modulatory effects in

extrastriate areas that were reflected in the P1 component (Di Russo et al., 2003; Martinez, Di Russo, Anillo-Vento, Sereno, et al., 2001; Mehta, Ulbert, & Schroeder, 2000a, 2000b; Noesselt et al.). These observations are compatible with the hypothesis that the delayed attention effects in V1 reflect feedback activity originating in higher-level extrastriate areas. This hypothesis is in line with findings from single-unit recordings in monkey primary visual cortex (Motter, 1993; Roelfsema, Lamme, & Spekreijse, 1998; Roelfsema, Tolboom, & Khayat, 2007) and with recent proposals that link the operation of attention with recurrent processing and the sustained integration of information across hierarchical levels in visual cortex (Gilbert & Sigman, 2007; Lamme & Roelfsema, 2000; Shipp, 2007). Along these lines Bullier and colleagues (Bullier, 2001a, 2001b) have suggested that area V1 (and V2) function as an active “blackboard” that serves to integrate and refine visual processing in higher-level areas by means of feedback modulations. Such a refinement may require the persistence of an unbiased and detailed representation of the visual input for at least a short while, until feedback modulatory influences reenter V1/V2.

However, fMRI studies have shown that cue-related anticipatory modulation of neural activity does take place in striate cortex (Kastner, Pinsk, De Weerd, Desimone, & Ungerleider, 1999; Serences, Yantis, Culbertson, & Awh, 2004; Silver, Ress, & Heeger, 2007) as well as in multiple extrastriate areas (Chawla, Rees, & Friston, 1999; Hopfinger, Buonocore, & Mangun, 2000; Müller, Bartelt, Donner, Villringer, & Brandt, 2003) prior to the arrival of the attended stimuli. This anticipatory “biasing” of V1 activity could in principle serve as a mechanism that allows attention to influence the initial feedforward sweep of processing. Consistent with this idea, a recent study by Kelly, Gomez-Ramirez, & Foxe (2008) reported that the visual ERP to a target stimulus presented at a cued location showed an early amplitude increase in the latency range of the C1 component (57–80 ms), which was localized to the vicinity of primary visual cortex. The task design of this experiment differed from those of previous studies in that detection of a low-contrast pattern was required, and this target occurred at a predictable time after an initial cue. If this early ERP modulation does represent an influence of attention over the initial evoked activity in area V1, it would appear that both feedforward and feedback mechanisms in primary visual cortex may be subject to attentional control.

THE ROLE OF SPATIAL SELECTION IN VISUAL SEARCH In visual search the allocation of spatial attention is strategically different from that seen in cuing tasks, as it is usually contingent on the prior decoding of the target-defining feature(s), which then serve to guide spatial focusing (Wolfe & Horowitz, 2004). Whereas targets having a single unique

feature tend to pop out and may be detected and attended rapidly, targets that are defined by a conjunction of two or more features are typically detected with longer latencies that increase as a function of the number of distracters in the display. Some theoretical accounts have proposed that search for a feature conjunction involves the serial focusing of attention on each of the display items (Treisman, 1988), while others have argued for a parallel processing of the multiple object features (Bundesen, 1990; Wolfe, Cave, & Franzel, 1989). This question has been investigated in ERP studies by Woodman and Luck (1999, 2003), which provided strong support for serial search models. Woodman and Luck utilized an ERP component called the N2pc, which is a negative deflection elicited between 180 and 350 ms after search display onset over the posterior cortex contralateral to the target position. The N2pc is well documented to reflect shifts of attention toward the location of the target (Hopf et al., 2000; Hopf, Boelmans, Schoenfeld, Luck, & Heinze, 2004; Luck, Girelli, McDermott, & Ford, 1997; Luck & Hillyard, 1994a, 1994b) and therefore can serve as an “online” measure for tracking rapid spatial shifts of attention. The experimental approach of Woodman and Luck (1999) was to present search displays with two potential target items in opposing visual fields, and then bias search order by introducing bottom-up preferences to focus first on the nontarget item. It was found that the N2pc first appeared over the hemisphere contralateral to the nontarget item and then switched hemispheres as attention was focused upon the target item, suggesting a serial deployment of attention. A further experiment ruled out the possibility that the two potential targets were attended in parallel but with different time courses (Woodman & Luck, 2003), thereby providing unequivocal evidence for the serial allocation of spatial attention during visual search.

Feature-based selection

Beginning with the groundbreaking studies of Corbetta, Miezin, Dobmeyer, Shulman, & Petersen (1990, 1991), it has been well established that paying attention to nonspatial stimulus features results in enhanced neural activity in the cortical areas specialized to process those features (Liu, Slotnick, Serences, & Yantis, 2003; O’Craven, Rosen, Kwong, Treisman, & Savoy, 1997; Saenz, Baracas, & Boynton, 2002; Schoenfeld et al., 2007). For example, a recent study that combined fMRI and neuromagnetic recordings (Schoenfeld et al., 2007) found that a moving stimulus elicited an enhanced neural response in the motion-sensitive area MT when movement was relevant, whereas a color-change stimulus produced greater activity in the color-selective area V4/V8 when color was attended. Paying attention to nonspatial visual features such as color, motion, orientation, or spatial frequency is associated with a class of

ERPs known as the *selection negativities* or *selection positivities*, which are typically enlarged in response to stimuli having the attended feature value (Anllo-Vento, Luck, & Hillyard, 1998; Baas, Kenemans, & Mangun, 2002; Eimer, 1997b; Harter & Aine, 1984; Kenemans, Lijffijt, Camfferman, & Verbaten, 2002; Martinez, Di Russo, Anllo-Vento, & Hillyard, 2001; Wijers, Mulder, Okita, Mulder, & Scheffers, 1989). These feature-selective modulations generally occur at longer latencies (120–300 ms) than the initial effects of spatial attention, but their timing can vary in a flexible manner depending upon feature discriminability and task demands. For example, Schoenfeld and colleagues (2007) found that ERMF and ERP modulations associated with selection *between* feature dimensions (color versus motion) occurred with earlier onset than the modulations typically reported for selection *within* a feature dimension (e.g., one color versus another color).

In an early ERP investigation, Hillyard and Münte (1984) obtained evidence that selection of a relevant stimulus color did not take place outside the spatial focus of attention. In their design, red and blue bars were flashed in random order to both the right and left visual fields, and one color in one field was designated as relevant. It was found that all stimuli in the attended field elicited the enhanced P1/N1 components characteristic of spatial attention, whereas stimuli of the attended color only elicited an enlarged selection negativity in the attended field. This result (confirmed by Anllo-Vento & Hillyard, 1996) suggested that nonspatial feature selection was hierarchically dependent upon the prior selection of location, a notion in line with psychophysical experiments showing that location selection has priority in visual attention (e.g., Cave & Pashler, 1995; Treisman & Gelade, 1980; Tsal & Lamy, 2000).

In contrast to the conclusions of Hillyard and Münte (1984), however, subsequent studies using a variety of methodologies have found that paying attention to a nonspatial stimulus feature does enhance neural responses to that feature even outside the spatial focus of attention. In single-unit recordings from the motion-selective area MT in the monkey, for example, Treue and Martinez-Trujillo (Martinez-Trujillo & Treue, 2004; Treue & Martinez-Trujillo, 1999) found that cells tuned to an attended direction of motion showed enhanced firing even when attention was directed to that direction of motion outside the cell's receptive field. The degree of enhancement increased as a function of the similarity between the attended motion direction and the cell's directional preference in a multiplicative way, leading to the proposal that attention operates by increasing the "feature-similarity gain" within the visual cortex (see also Maunsell & Treue, 2006; McAdams & Maunsell, 1999; Motter, 1994). Analogous observations were made using fMRI in human observers (Saenz et al., 2002, 2003). These observers attended to one feature value

in a mixed display that was presented to one visual field. In some studies the display was a field of intermingled horizontally and vertically moving dots, and in other studies it was intermingled red and green dots. The general finding was that a larger BOLD signal was elicited in the visual cortex by the attended than the unattended feature value even for stimuli presented to the visual field opposite to where attention was being directed, thereby supporting the concept of "global feature-based attention." A further demonstration that feature-selective attention is not location bound has recently been provided in a study of SSVEPs in humans (Müller et al., 2006). Müller and colleagues presented subjects with superimposed random dot arrays of two colors that flickered at different rates (7.0 and 11.7 Hz) while changing position randomly. The frequency-tagged SSVEP to each color could therefore be measured independently under conditions where location could not be used as a basis for selection. It was found that the color-specific SSVEP was enhanced when that color was attended versus when the other color was attended (figure 15.3), indicating again that attention can select specific color values independently of their particular location.

These demonstrations of global feature-based attention appear to conflict with the original finding of Hillyard and Münte (1984) that color selection was suppressed outside the focus of spatial attention. A critical difference in experimental design that may explain these disparate results, however, is that Hillyard and Münte presented stimuli briefly and intermittently, while all the studies that observed global feature selection presented the stimuli continuously. This difference suggests that the attended feature must actually be present in the display in order for global feature selection to override spatial selection.

Evidence that the relative priority of location- and feature-based selection may be flexibly adjusted according to task demands comes from ERP/MEG recordings in a visual search task (Hopf et al., 2004). Subjects searched for a simple color-orientation conjunction among distracters, half of which shared an orientation feature with the target and half of which did not (figure 15.4A). It was found that a lateralized brain response indicating the presence of the relevant orientation feature preceded the N2pc response indicating the spatial localization of the conjunction target by about 30 ms (figure 15.4B). These observations were taken to indicate that visual search involves a short phase of parallel, location-independent feature selection that occurs prior to the localization and selection of the target—a sequence of operations proposed by many influential theories of visual search (Cave, 1999; Treisman & Sato, 1990; Wolfe & Bennet, 1997).

Single-unit recording studies in monkeys (Bichot, Rossi, & Desimone, 2005) have provided additional evidence for parallel feature selection in visual search. Monkeys were

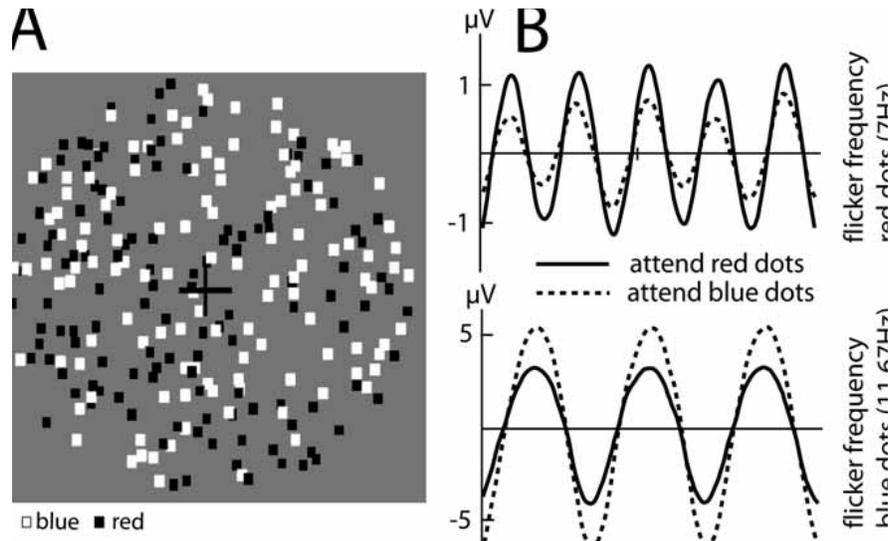

FIGURE 15.3 (A) Stimulus display in study by Müller et al. (2006), which consisted of 75 red dots (flickering at 7.0 Hz) intermingled with 75 blue dots (flickering at 11.67 Hz) within a 5 degree circle. Each dot changed its position in a random direction by 0.08 degrees every 1–3 frames of screen refresh (i.e., every 14.3–42.9 ms). On each trial (lasting 4.1 s) subjects were cued to attend to the red or blue dots and to discriminate occasional 586-ms periods of 75%

coherent motion (targets) of the attended-color dots, which occurred on 32% of the trials. (B) SSVEPs from an occipital electrode elicited by the red and blue dot populations when attended and unattended, on trials without targets. Color-selective attention increased SSVEP amplitudes by an average of 30–40%. (Adapted from Müller et al., 2006.)

trained to search for a target defined by its color or form (or a combination of both) among many colored items of various forms. Search was performed under free gaze conditions, and the cell-firing responses in area V4 were analyzed during intermediate fixations along the search path toward the target, but before the target was fixated. It was observed that cell firing increased whenever a change in fixation brought a distracter that possessed one of the target’s defining features into the cell’s receptive field. These results showed that any item with a relevant feature was highlighted in area V4 even before ultimate target identification; this adds to the ERP/MEG evidence that attention to features acts in a “global” way prior to target selection in visual search.

A recent SSVEP study in humans (Andersen, Hillyard, & Müller, 2008) obtained evidence that the multiple features of an attended stimulus are selected and facilitated in a parallel, additive fashion. Subjects viewed a display containing 150 red and 150 blue bars, with half of each color oriented horizontally and half vertically, all of which were randomly intermixed and moving unpredictably. On each trial subjects were cued to attend to one of these four types of bars, each of which flickered at a different rate and thus elicited its own frequency-tagged SSVEP. It was found that SSVEP amplitudes were largest to the bars of the attended color orientation, intermediate to the bars having one of the two attended features, and smallest to the bars that lacked either attended feature. Most importantly, the SSVEP amplitude to the attended conjunction stimulus was equal to the sum of the amplitudes for the individual feature enhancements.

This evidence for parallel, additive feature enhancement is consistent with the mechanism proposed by “guided search” theories (Wolfe et al., 1989) to account for the rapid identification of feature conjunction targets.

These physiological studies in monkeys and humans show that the time course and priority order of feature- and location-based attention effects can be flexibly adjusted depending on task demands and the particular selection operations that are required. The selection of nonspatial features is frequently delayed relative to the selection of locations but can be considerably accelerated for simple selections between feature dimensions. Moreover, feature selection may precede the selection of location in visual search tasks where the decoding of features is given priority to guide the subsequent spatial focusing of attention. In the next section we describe how such task-dependent flexibility also applies to the relation between feature- and object-based selection operations.

Object-based selection

A large body of psychophysical research indicates that attention can select entire objects for preferential processing (Driver, Davis, Russell, Turatto, & Freeman, 2001; Duncan & Nimmo-Smith, 1996; Egly, Driver, & Rafal, 1994; Scholl, 2001), which is not surprising given the ecological relevance of the multitudinous objects in the environment. It is important to realize, however, that object-based attention is a heterogeneous concept, and it is debated whether elemen-

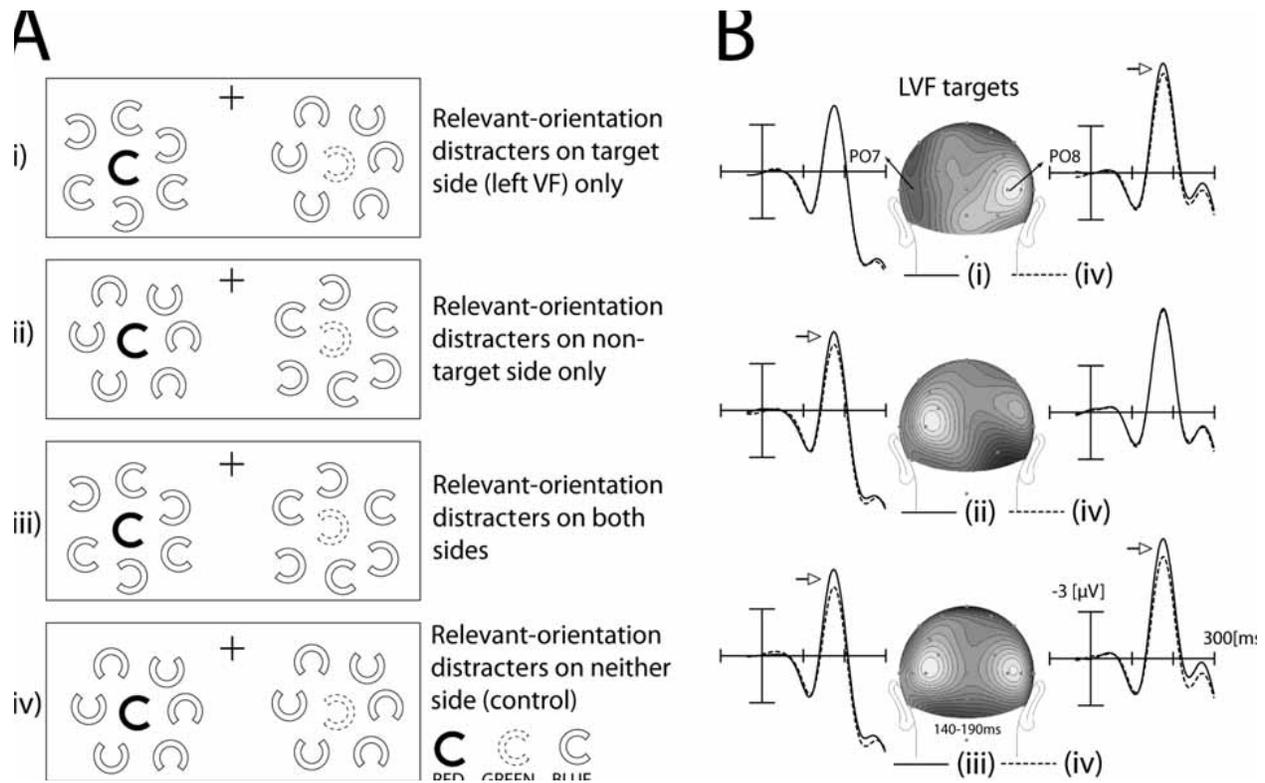

FIGURE 15.4 (A) Stimuli from the study of Hopf, Boelmans, Schoenfeld, Luck, and Heinze (2004). Search frames consisted of distinctively colored *C*'s (red and green, shown as black and dashed, respectively), one presented in the left and one in the right visual field, surrounded by blue distracter *C*'s on each side. The red *C* served as target for half of the trial blocks and the green *C* for the other half. Subjects had to discriminate the orientation of the target *C* (here the red *C*, shown in black, in the left VF), whose gap always varied left-right. In contrast, distracters of one visual field were either oriented left-right, as was the target (relevant orientation distracters, RODs), or up-down (irrelevant orientation distracters).

The location of RODs was varied relative to the location of the target item, such that RODs appeared (i) on the target side only, (ii) on the nontarget side only, (iii) on both sides, or (iv) on neither side (control condition). (B) ERP responses elicited by LVF targets. Waveforms of the different ROD-distributions (i–iii, solid tracings) are separately overlaid with the control condition (iv, dashed tracings). The topographical maps show the distribution of the corresponding voltage difference. The arrows highlight an enhanced negativity between ~140 and 300 ms that appears contralateral to the location of the RODs independent of the target's location in the left VF.

tary perceptual groupings (grouped array representations) or more abstract (spatially invariant) forms of representation serve as the objects of attention (Kramer, Weber, & Watson, 1997; Luck & Vecera, 2002; Mozer & Vecera, 2005; Vecera, 1997; Vecera & Farah, 1994; Weber, Kramer, & Miller, 1997). Another problem for isolating the neural mechanisms of object-based attention is that it appears far from trivial to rule out contributions from location- and feature-based mechanisms.

Valdes-Sosa and colleagues (Pinilla, Cobo, Torres, & Valdes-Sosa, 2001; Valdes-Sosa, Bobes, Rodriguez, & Pinilla, 1998) developed an elegant paradigm for studying object-based attention, which involves the competitive selection of perceived surfaces formed by moving dot arrays. The stimuli were two counterrotating random dot arrays that gave the impression of two superimposed surfaces rotating in opposite directions. This paradigm offers the opportunity to investigate the neural basis of object (surface) selection

unconfounded by spatial attention, since the two rotating dot displays are superimposed. When attention was directed endogenously to one of the surfaces, observers could judge the direction of a brief translation of that surface and a second translation of the same surface much more accurately than translations of the uncued surface. Paralleling this perceptual selection, ERP recordings showed that occipital P1 and N1 (N200) components elicited by translations of the unattended surface were suppressed relative to those of the attended surface. This finding was taken to indicate that attention favors processing of the attended surface by attenuating the object representation of the unattended surface. A subsequent study (Rodriguez & Valdes-Sosa, 2006) carried out current source localization of the ERP modulation reflecting this motion-based surface selection and found that the associated N200 component was generated in part in human MT+, which corresponds to recent findings from a neurophysiological study of surface

segmentation in monkey MT (Wannig, Rodriguez, & Freiwald, 2007).

Reynolds, Alborzian, and Stoner (2003) replicated the findings of Valdes-Sosa's group and showed in addition that a brief translation of one of the surfaces was an effective exogenous cue that automatically engaged attention to that surface, resulting in superior detection of a second translation of the same surface. In an ERP study of this paradigm, Khoe, Mitchell, Reynolds, and Hillyard (2005) found that when the first and second translations were of the same surface (relative to different surfaces), the second translation was discriminated more accurately and elicited an N1 component of greater amplitude. It was concluded that object-based surface selection can be initiated by purely exogenous cuing, resulting in a stronger representation of the cued surface in the visual pathways. A further study (Mitchell, Stoner, & Reynolds, 2004) showed that cuing (translating) one of the rotating surfaces resulted in a sustained dominance for the eye viewing that cued surface when the surfaces were switched to dichoptic viewing (one surface to each eye) immediately after the cue. This binocular rivalry/ocular dominance effect was presumably mediated by the object-based selection of the surface, which was conveyed to a neural representation with eye-of-origin information in visual cortex. This interpretation was confirmed in an ERP study of this paradigm (Khoe, Mitchell, Reynolds, & Hillyard, 2008). As in the original study, subjects were impaired at comparing the first and second translations when they belonged to different surfaces, and this impairment was greater when the surfaces were viewed dichoptically (in rivalry). The P1 component (110–160 ms) in the ERP elicited by the second translation of the same surface was larger than in the ERP elicited by the different surface during dichoptic but not monocular viewing conditions. A larger cuing effect was also found for the subsequent N1 (160–220 ms) during rivalry than during monocular viewing. It was concluded that surface selection can occur at an earlier level of processing when the cued and uncued surfaces are presented to the separate eyes (for similar results see Mishra & Hillyard, 2008).

An important line of evidence that attention operates in an object-based framework comes from the seminal paradigm developed by Egly and colleagues (1994). This design is an extension of Posner's classical cuing paradigm, in which a comparison is made between validly and invalidly cued locations that belong either to the same or to separate objects. A typical observation indicating the operation of object-based attention has been that performance costs at an invalidly cued location were significantly reduced when this location belonged to the cued object versus to the uncued object. Importantly, the Egly type of paradigm provides a framework for investigating the relationship between space-based and object-based attention.

Recent ERP studies using variations of the Egly paradigm (He, Fan, Zhou, & Chen, 2004; Martinez, Ramanathan, Foxe, Javitt, & Hillyard, 2007; Martinez, Teder-Salejarvi, & Hillyard, 2007; Martinez et al., 2006) have revealed that modulations due to object-based selection have important similarities to those seen during space-based selection. For example, in a combined ERP/fMRI study Martinez and colleagues (2006) presented subjects with a display consisting of two bar-shaped objects oriented either horizontally or vertically (figure 15.5) while continuous sequences of stimuli (brief corner offsets) were presented one at a time in random order at both ends of both bars. On each run the corner offsets at one end of one bar were cued to be attended while stimuli at the other three locations were ignored. It was found (figure 15.6) that unattended corner offsets produced a larger amplitude N1 component (but not the P1 component) when they belonged to the attended bar versus when they belonged to the unattended bar (see He et al., 2004, for a similar observation). Although this object-mediated N1 effect (at 160–200 ms) was smaller than the N1 enhancement to attended-location stimuli in the same latency range, both effects showed very similar posterior-contralateral scalp distributions. Furthermore, electric source analysis (confirmed by fMRI in parallel experiments) revealed that both the object-based and location-based N1 enhancements were generated in the same area of the lateral occipital cortex (LOC)—a cortical region that has been strongly implicated as being critically involved in the initial segmentation and encoding of objects (e.g., Grill-Spector, 2003). Similar effects were obtained even when using objects defined by illusory contours (Martinez, Teder-Salejarvi, et al., 2007) and objects of different shapes (Martinez, Ramanathan, et al., 2007). These ERP experiments and a recent fMRI study (Müller & Kleinschmidt, 2003) provide evidence that object-selective attention shares a common neural mechanism with spatial attention that facilitates the sensory processing of stimuli within the boundaries of an attended object. These findings support the view that spatial attention directed to one part of an object spreads throughout its boundaries and strengthens the sensory representation of the entire object (Vecera & Farah, 1994; Weber et al., 1997). This selective enhancement of attended object representations, particularly in area LOC, may reinforce their perceptual integrality and underlie the performance benefits manifested in the same-object advantage.

A major question regarding the neural mechanisms of object-based attention is how the different features of an object, which may be represented in widely dispersed cortical areas, are bound together to form a unified percept. One approach to this "binding problem" comes from Duncan's "integrated competition model" (Duncan, Humphreys, & Ward, 1997). According to this model, directing attention to one of an object's features produces a competitive advantage for the object in the neural module encoding that feature,

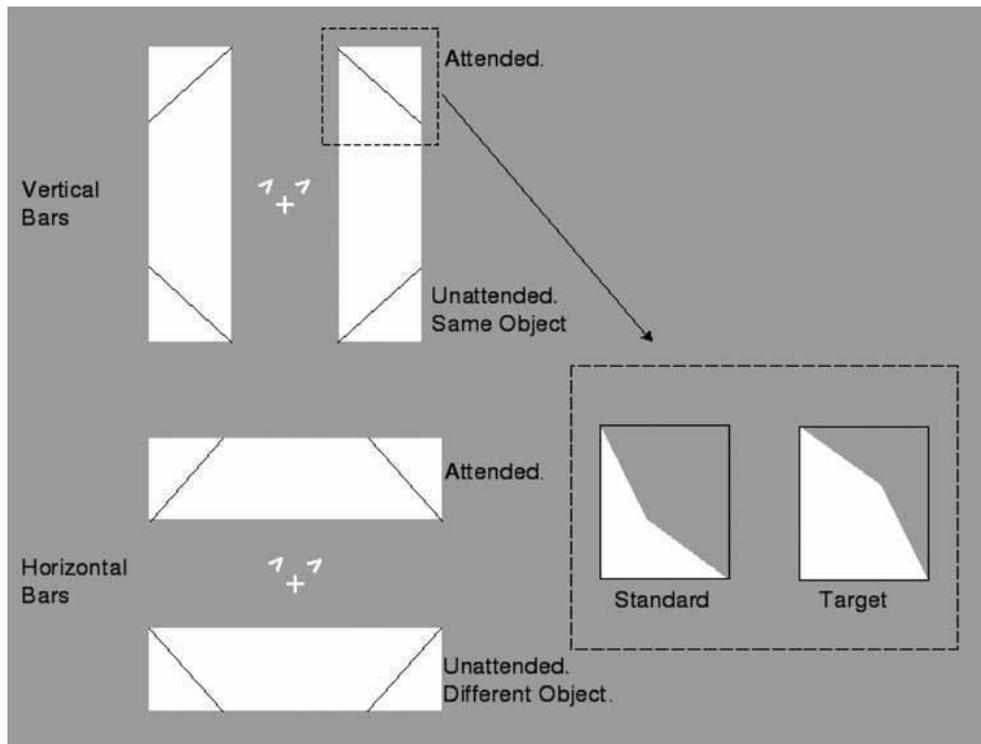

FIGURE 15.5 Experimental design in study by Martinez and colleagues (2006). During each run, either two horizontal or two vertical bars were presented continuously on the screen. Subjects were cued by a pair of arrows near fixation to attend covertly to one of the four visual quadrants. Stimuli were brief (100 ms) offsets of the corners of the bars, leaving either a concave (standard) or convex (target) edge. Corner offsets occurred in random order in all four

quadrants with ISIs of 400–600 ms. Subjects responded to detections of targets in the attended quadrant, which occurred with a probability of 0.2. In the example shown, the upper left quadrant was attended; thus the unattended lower left quadrant belonged to the attended object when the bars were vertical but not when the bars were horizontal.

which is then transmitted to the modules encoding the other features of the object. The resulting activation of the entire network of specialized modules underlies the binding of features into an integrated perceptual object. A key prediction of the integrated competition model is that directing attention to one feature of an object will result in the activation of its other features, including those that are irrelevant to the task at hand. Such an effect was demonstrated in an fMRI study by O’Craven, Downing, & Kanwisher (1999), who presented subjects with superimposed transparent pictures of houses and faces, with one moving and the other being stationary. On different runs subjects selectively attended to houses, to faces, or to stimulus motion itself. It was found that neural activity was increased not only in the critical area specific to the attended stimulus feature (the fusiform face area for faces; the parahippocampal place area for houses; area MT+ for motion), but also in the area encoding the task-irrelevant feature of the attended object. These data provided strong support for object-based selection in the context of the integrated competition model.

While the study of O’Craven and colleagues was elegantly designed, it remains possible that location cues played some role, as the objects were not perfectly overlapping and target-

defining details might have been spatially selected. To verify a mechanism of object-based selection, it is important to eliminate potential contributions from other possible reference frames. In this respect, a convincing behavioral demonstration of object-based attention that eliminated all possible alternative explanations was carried out by Blaser, Pylyshyn, & Holcombe (2000). Subjects had to track the identity of one of two spatially superimposed Gabor patches, which continuously changed along feature dimensions of orientation, color, and spatial frequency. This approach not only eliminated the possibility of location-based selection, but also ruled out featural identity as a basis for tracking the target. The observation that subjects were still able to track the identity of the Gabor patch over time confirmed that visual attention had been directed to an object-based representation.

The key finding of O’Craven and colleagues (1999) was that directing attention to one feature of an object activated the neural representations of its other features, including those not relevant to the current task. Given the low time resolution of fMRI, however, it was not possible to determine whether the activation of irrelevant features occurs rapidly enough to participate in the feature-binding process that underlies the perception of the integrated object. This

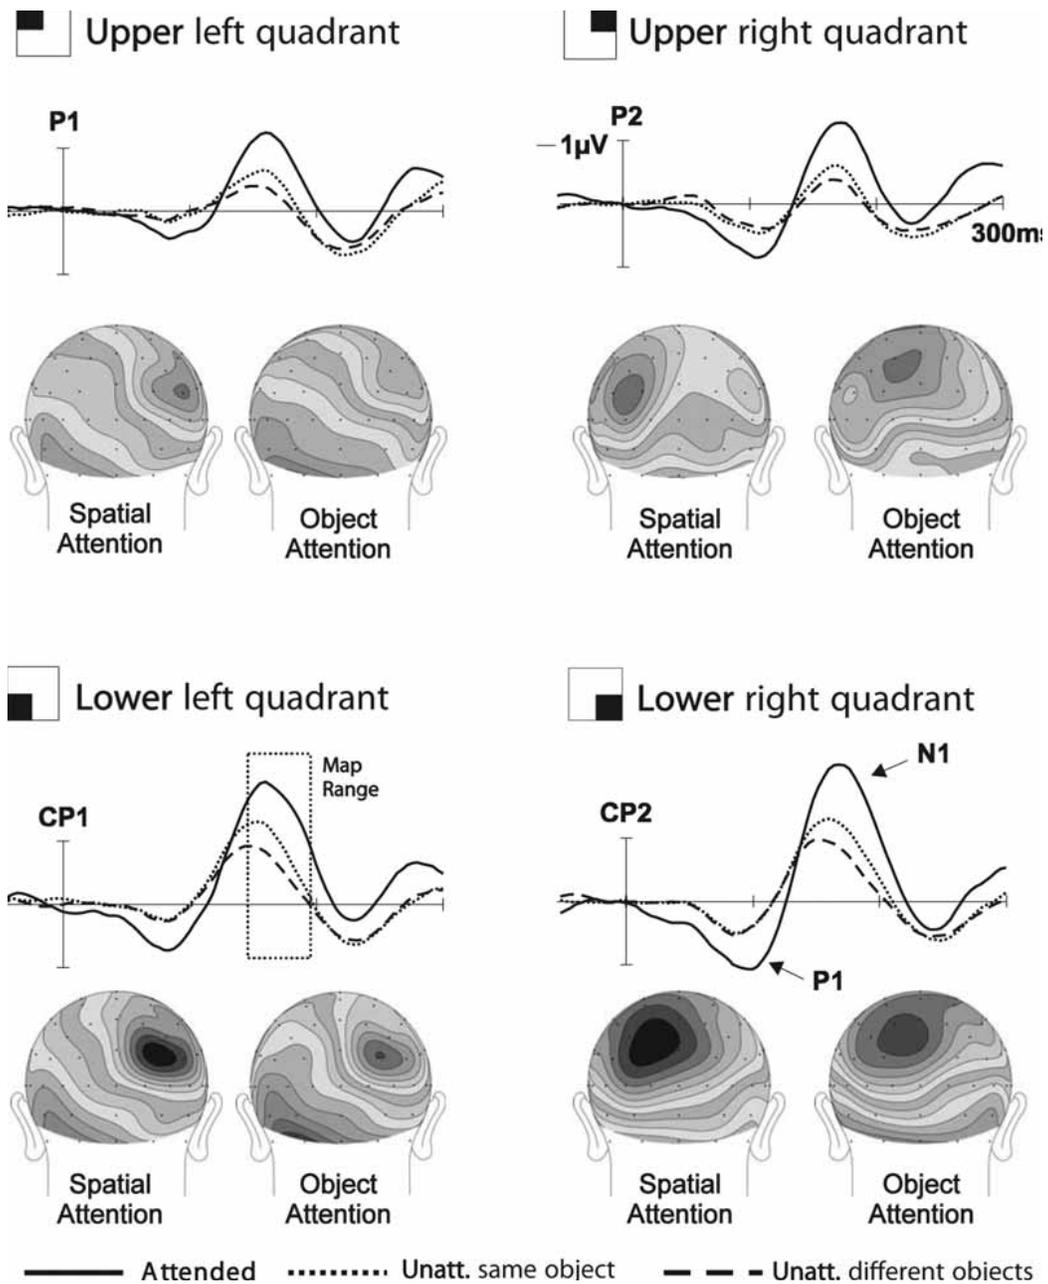

FIGURE 15.6 Grand average ERPs to nontarget stimuli in the four quadrants in the study of Martinez and colleagues (2006). Overlapped waveforms are ERPs to stimuli when attended (solid lines), when unattended but belonging to the attended object (dotted lines), and when unattended and belonging to the unattended object (dashed lines). For each quadrant, voltage maps of attention related difference waves in the latency range of the N1 (160–196 ms) are shown: the spatial attention difference was

obtained by subtracting the unattended from unattended amplitudes; the object attention difference was obtained by subtracting the unattended-location/unattended-object amplitude from the unattended-location/attended-object amplitude. Note the similarity between the object and spatial attention topographies. Increasing darkness on maps indicates increased negativity. Contour intervals are $0.05 \mu\text{V}$ for the object attention maps and $0.15 \mu\text{V}$ for the spatial attention maps.

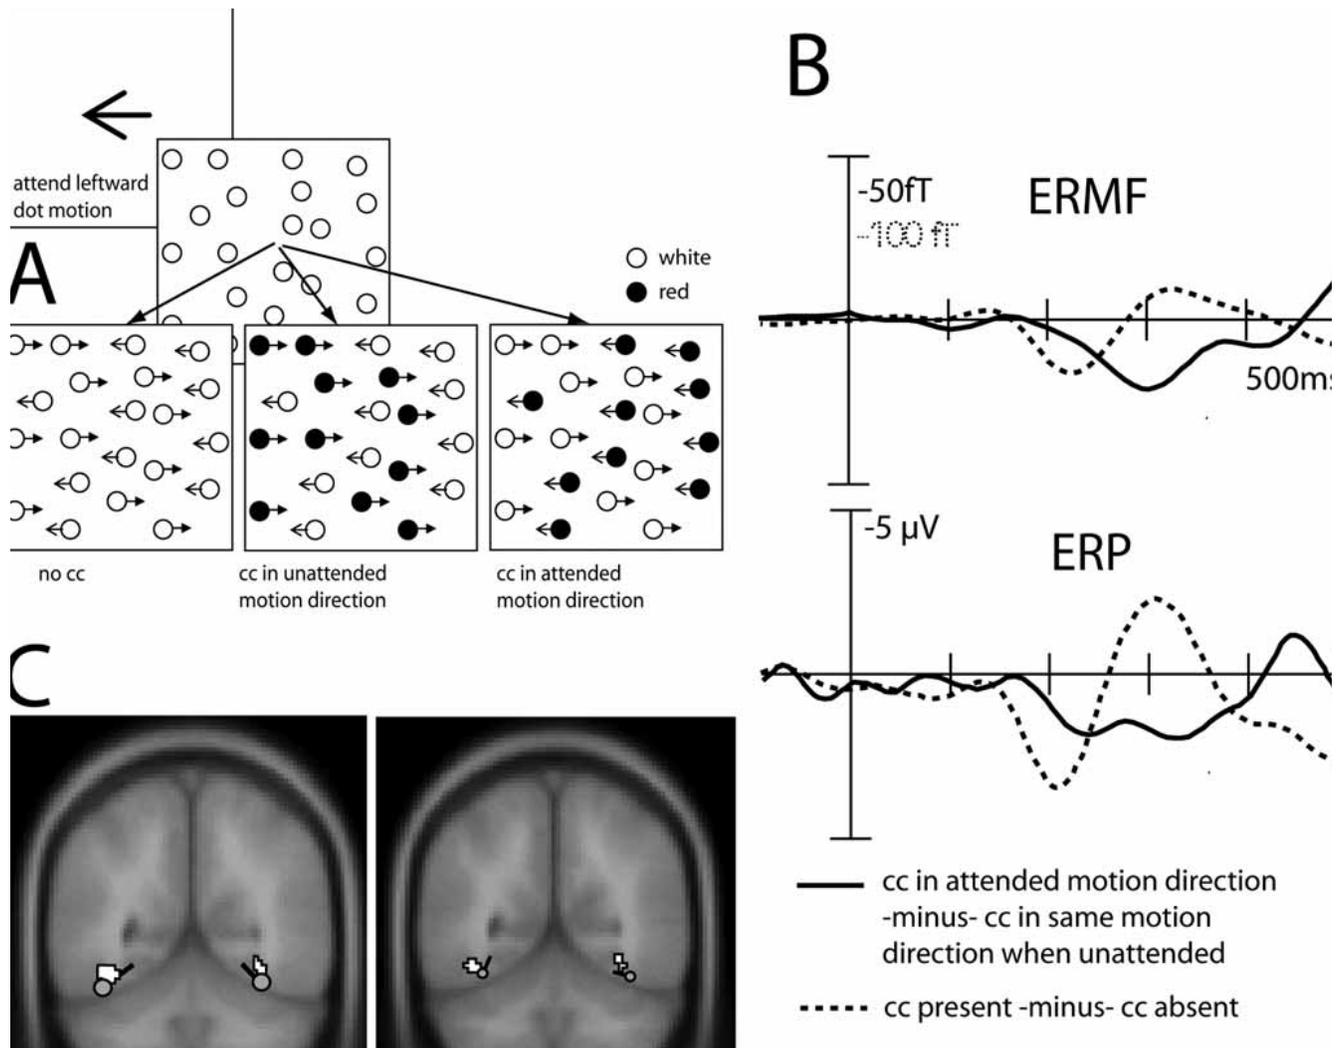

FIGURE 15.7 (A) Experimental design of study by Schoenfeld and colleagues (2003). On each trial a random half of the dots on the screen moved left and half right for 300 ms. Subjects were cued to attend to either the left- or right-moving dots and reported occasional targets of higher velocity. On a random basis, either the left- or right-moving dots could change color (CC) to red or remain white. (B) The sensory effect of color is shown in the dotted ERMF and ERP waveforms: these are difference waves formed by subtracting responses to the no CC condition from the condition where the CC belonged to the unattended dots. The attention-related activation of the irrelevant color feature is represented by the solid

waveforms, formed by subtracting responses when the CC belonged to the unattended dots minus when the CC belonged to the attended dots. Note that the attention-produced enhancement of the irrelevant color feature lags the initial sensory response to color by 30–50 ms. (C) The neural generators of this increased color signal at 220–300 ms were localized to the ventral occipital cortex (area V4v), known to be a specialized module for color processing (McKeefry & Zeki, 1997). This localization was confirmed by BOLD signal activations (irregular areas on brain slices) in a parallel experiment using the same design with fMRI.

question was investigated in a study that combined recordings of ERPs and MEG with fMRI in a task where subjects attended to multifeature objects formed by arrays of dots on a video screen (Schoenfeld et al., 2003). On each trial half of the dots on the screen moved to the left and half to the right, producing the perception of two transparent surfaces moving in opposite directions (figure 15.7A). On each trial subjects were cued to attend to either the left-moving or the right-moving surface, and on a random basis one of the surfaces underwent an irrelevant color change (white to red). When physically identical trials with the attended versus unattended surface changing color were compared, increased fMRI activation was found in the color-specific region of the fusiform gyrus area V4v. More importantly, the ERP and MEG recordings showed enhanced amplitudes at 220–240 ms after stimulus onset on trials when the attended surface was colored (figure 15.7B), and the neural generators of this activity were localized to the same V4v site (figure 15.7C). This attention-related amplification of the color signal occurred about 40–50 ms after the initial arrival of color-specific input to area V4. It was concluded that this amplification of an irrelevant feature of an attended object occurs rapidly enough to participate in the feature-binding process that underlies the perceptual unity of the attended object. These results fit nicely with Duncan’s (Duncan et al., 1997) integrated competition model and provide specific information about the time scale of its operation.

An observation complementary to that of Schoenfeld and colleagues (2003) was recently made with single-unit recordings in macaque V4 (Fallah, Stoner, & Reynolds, 2007). In this study, superimposed rotating dot surfaces of different color were used. To bias the monkey to attend one of the surfaces, the motion onset of one surface was delayed relative to the other surface, thereby producing a predictable bias for the delayed surface. Firing activity was then recorded from V4 cells whose RF overlapped with the dot surfaces. Enhanced firing was seen when the delayed-onset surface was of the neuron’s preferred color, while a relative suppression appeared when the delayed-onset color was of the non-preferred color. Both effects appeared rapidly, with a delay of 10–17 ms relative to the activity elicited by motion onset of a single surface with the preferred color. This finding, together with the results of Schoenfeld and colleagues (2003), points to a fast but clearly delayed facilitation of task-irrelevant features bound into the attended object, which emphasizes the rapid evolution of object-based surface segmentation under those experimental conditions.

Conclusion

The studies reviewed in this chapter summarize the spatio-temporal signatures of space-, feature- and object-based attention as revealed by electromagnetic and electrophysio-

logical recordings, as well as by functional brain imaging. All three aspects of attention turn out to involve multiple selection operations, which are coordinated on a tight temporal scale of a few tens of milliseconds in early visual processing. We have seen that the temporal priority of those selection operations may change flexibly depending on the particular requirements of visual decoding, task demands, and experimental instructions. The selection of features may precede the selection of locations or objects in visual search, but object-based selection may take priority under other conditions. Moreover, the neural mechanisms that underlie each of the different forms of attention may be deployed in a flexible manner. For example, spatial attention involves biasing mechanisms that can be adjusted to select stimuli at single or multiple locations, or at even more complex spatial arrays. Finally, by highlighting the ways in which space-, feature- and object-based attention interact, it has become evident that there may not be a strict demarcation line. Space-based attention was found to facilitate object-based attention, which in turn promoted the selection of the object’s features. Given the enormity of the task of controlling the order of information flow in human vision, this multiplicity, flexibility, and interdependence of attentional operations does not come as a surprise.

16 Integration of Conflict Detection and Attentional Control Mechanisms: Combined ERP and fMRI Studies

GEORGE R. MANGUN, CLIFFORD D. SARON, AND BONG J. WALSH

ABSTRACT Attention involves powerful top-down mechanisms for the control of information processing in the brain, including specialized systems in the frontal and parietal cortex. These networks for attentional control are sensitive to momentary goals, enabling flexibility in behavior under changing conditions. One such influence is that which arises when competing inputs or responses are in conflict. A prominent system for conflict detection, cognitive control, and behavioral adjustment involves the anterior cingulate cortex and dorsal lateral prefrontal cortex. Here we describe how these attentional and conflict-resolution systems interact, and provide a synthesis and model of how these interactions support information processing. We show that conflict detected in the anterior cingulate system influences the activity of the frontal-parietal attention network to modulate attentional selection. As a result, when conditions lead to uncertainty that could be detrimental to successful performance, the brain combines information to strategically alter performance on a moment-to-moment basis.

Visual selective attention is a powerful cognitive ability that aids in the perception of the world around us (see Treisman, chapter 12 in this volume). Directing spatial attention to a location in the visual field facilitates processing of stimuli appearing at the attended location: reaction times (RT) are faster and discrimination accuracy is enhanced for events at attended versus unattended locations (e.g., Luck et al., 1994). In line with this observed RT pattern, neural responses to attended and ignored stimuli are modulated (see Maunsell, chapter 19) to provide a competitive advantage for attention events (see Kastner, McMains, and Beck, chapter 13).

Attentional control

Models of attention have distinguished between top-down and bottom-up influences on the focus of attention. In one prominent framework, the “sources” of attentional control

and the resultant influence at a “site” of action, such as within the perceptual system, outline the push-pull between top-down and bottom-up information (e.g., Posner & Petersen, 1990; Serences et al., 2005). The concept that attention involves the interactions of neural systems that generate *attentional control signals* with other systems that are influenced by those signals remains at the core of most current models of voluntary (goal-directed) attention (e.g., Bundesen, Habekost, & Kyllingsbaek, 2005).

Research in animals, patients with neurological dysfunction, and healthy human subjects using electromagnetic recording, neuronal stimulation, deactivation, neuroimaging, and transcranial magnetic stimulation suggests that voluntary control of visual attention involves a complex network of widely distributed areas, including superior frontal cortex, posterior parietal cortex, posterior-superior temporal cortex, and thalamic and midbrain structures (e.g., Bisley & Goldberg, 2006; Bushnell, Goldberg, & Robinson, 1981; Corbetta, Kincade, Ollinger, McAvoy, & Shulman, 2000; Thiebaut de Schotten et al., 2005; Goldberg & Bruce, 1985; Hopf & Mangun, 2000; Hopfinger, Buonocore, & Mangun, 2000; Hung, Driver, & Walsh, 2005; Knight, Grabowecy, & Scabini, 1995; McAlonan, Cavanaugh, & Wurtz, 2006; Mesulam, 1981; Miller, 2000; Rorden, Fruhmann Berger, & Karnath, 2006). In humans, the functional anatomy of this attentional control network has been identified by combining event-related fMRI methods with tasks that temporally separate preparatory attentional control from target-related activity. For example, using spatial cuing paradigms, it has been possible to demonstrate activity in a frontal-parietal attention system related to top-down attentional control (e.g., Corbetta et al., 2000; Hopfinger et al., 2000; Kastner, Pinsk, De Weerd, Desimone, & Ungerleider, 1999) and to distinguish this activity from activity in visual cortex and the motor system (see Corbetta, Sylvester, & Shulman, chapter 14).

GEORGE R. MANGUN, CLIFFORD D. SARON, and BONG J. WALSH Center for Mind and Brain, University of California, Davis, California

The frontal-parietal attention network has been observed to be active in attentional control for *covert* spatial attention (Corbetta et al., 2000, 2005; Corbetta & Shulman, 2002; Giesbrecht, Woldorff, Song, & Mangun, 2003; Hopfinger et al., 2000; Kastner et al., 1999; Lepsien, Griffin, Devlin, & Nobre, 2005; Sapir, d'Avossa, McAvoy, Shulman, & Corbetta, 2005; Slagter et al., 2007), *overt* spatial attention (Astafiev et al., 2003), visual search (Shulman et al., 2003), nonspatial feature-based attention (e.g., Giesbrecht et al., 2003; Shulman, d'Avossa, Tansy, & Corbetta, 2002), global and local levels of hierarchical stimuli (Weissman, Mangun, & Woldorff, 2002; Weissman, Woldorff, Hazlett, & Mangun, 2002; Weissman, Giesbrecht, Song, Mangun, & Woldorff, 2003), and orienting attention to internal mental representations (Lepsien & Nobre, 2006). Highly similar regions of superior frontal and parietal cortex appear to be activated across studies. However, it has been proposed that attentional control networks might also involve specialization, with a subset of the attention network being highly specialized for the control of spatial attention in comparison to nonspatial attention (Giesbrecht et al., 2003; Slagter et al., 2007).

Conflict and cognitive control

Voluntary attentional control is part of the larger domain of *executive control* that includes a variety of high-level functions (e.g., Baddeley, 1996). A key component of executive control involves monitoring task performance and adjusting strategies appropriately (Gratton, Coles, & Donchin, 1992). A prominent model in this regard is the *conflict-control* model by Carter and Cohen and their colleagues (e.g., Botvinick, Braver, Barch, Carter, & Cohen, 2001; Carter et al., 1998). The conflict-control model focuses heavily on the role of executive control systems in overcoming prepotent responses that generate response conflict during task performance. Such is the case in the Stroop task, for example, where color names (e.g., RED) written in different ink colors (e.g., green ink) are presented and the subject is required to name the ink color (Stroop, 1935). The incompatible information in the color name leads to interference and response conflict. As a result, when an incompatible trial is presented (trial N), on the subsequent trial (trial $N+1$) an increase in executive control leads to a decrease in the errors produced by incompatible information and an overall slowing in responding. This pattern of results is a cornerstone of contemporary research on executive control when response conflict is present in a task.

The conflict-control model proposes that the anterior cingulate cortex (ACC) monitors the amount of response conflict on a given trial, temporarily increasing the strength of executive control when conflict is detected (Carter et al., 1998). The conflict-control model further posits an interaction between the ACC and the dorsolateral prefrontal cortex

(DLPFC), an area widely implicated in executive control processes (D'Esposito et al., 1995; Miller & Cohen, 2001). Both a dissociation and a possible functional interaction between these interconnected brain regions have been demonstrated. MacDonald, Cohen, Stenger, and Carter (2000) showed that the activity in DLPFC but not ACC increased when a "color-naming" cue (as compared with a "word-reading" cue) was presented during a delayed Stroop task, whereas ACC but not DLPFC activity increased in response to the presentation of the incongruent stimulus (compared to a congruent stimulus). The idea supported by such findings is that the conflict-generated activity in ACC could signal the need for increased cognitive control that would be exerted by DLPFC.

A study from Carter and colleagues provided more direct evidence for this neural model by demonstrating "next-trial effects" in DLPFC: High-conflict trials resulted in increased ACC activity on the current trial (trial N), leading to increased DLPFC activity for the subsequent trial (trial $N+1$), and this corresponded with improved behavioral performance (fewer errors) on those subsequent trials (Kerns et al., 2004). Evidence for a causal relationship between DLPFC activity and attentional selection in perceptual processing comes from the report by Egnor and Hirsch (2005), who used a modified Strooplike task containing the names and faces of famous persons (actors and politicians). They reported that when subjects were categorizing faces, the activity in the fusiform face area (FFA) was enhanced for trials following a high-conflict trial, and that there was also increased functional connectivity between the DLPFC and the FFA under such conditions. These results fit nicely with the conflict-control model, which proposes that ACC activity is related to the detection of conflict, which then signals the need for increased cognitive control that is implemented by the DLPFC. Further, the pattern of Egnor and Hirsch suggests that DLPFC activity is correlated with the results of selective attention in perceptual systems.

Conflict and attentional control systems

Interrelationships between the ACC-DLPFC conflict-control system and the frontal-parietal attentional control system might explain how conflict detection ultimately leads to selective stimulus processing. For example, Casey and colleagues (2000) provided evidence that incompatible trials may lead to increased attentional control in tasks where selective attention to targets relative to distracters might minimize interference from irrelevant or incompatible information. They were able to demonstrate that superior frontal and superior parietal cortex (attentional control network) was activated when successive incompatible trials were presented. The idea suggested by this research is that selective attention was engaged to focus attention on the relevant input and suppress

distracter information, much in the way suggested by Egner and Hirsch (2005). Using event-related fMRI, Weissman, Mangun, and Woldorff (2002) demonstrated similar activations in the frontal-parietal attention network to attention-directing cues and subsequent targets containing incompatible local and global information. This type of information can be interpreted as evidence that during the incompatible trials, the voluntary attention system was engaged to focus attention on the information at the relevant level (global or local) and suppress the irrelevant, distracting information. Together these studies suggest a close association between the conflict-control system (ACC-DLPFC) and attentional control networks (frontal-parietal network). However, there is less direct evidence that increased conflict leads to modulations of activity in the frontal-parietal attentional control network. To demonstrate such a relationship, it would be necessary to show that increased conflict leading to activity in the ACC on a trial (trial N) would lead to increased activity in the frontal-parietal attention network on the subsequent trial (trial $N + 1$). Further, such effects should be strongly correlated with attentional selectivity demonstrated behaviorally and in selective stimulus processing in visual cortex.

Integrating brain networks for conflict processing and attention

Using functional magnetic resonance imaging (fMRI), it was investigated whether the ACC conflict-detection system interacts with the frontal-parietal attentional control system when spatial cuing leads to conflicts in attentional orienting (Walsh, 2008). The working hypothesis was that conflict in one trial should result in adjustments in frontal-parietal top-down attentional control to reduce conflict in a subsequent trial.

The paradigm was a hybrid of those used in conflict-controls studies and those typical of spatial attention studies (figure 16.1). Cues consisting of two vertical lines directed the subjects' covert spatial attention (100% instructive) to either the right or the left visual in order to discriminate the features of an upcoming target. The longer of the two lines in the cue indicated that spatial attention should be directed to the hemifield on the side of the longer line. The amount of conflict generated by the cues was systematically manipulated by varying the difference in length of two lines (see figure 16.1*B*), in line with evidence that requiring near-threshold-level perceptual judgments can result in the generation of conflict (Szmalec et al., 2008). As a result, low, medium, and high conflict-generating cues were created. Bilateral targets (200 ms duration) followed the cues after a delay period (1500 ms), and these targets were then masked at offset by pattern masks (300 ms duration). Subjects were required to respond by pressing one of two buttons with their right hand

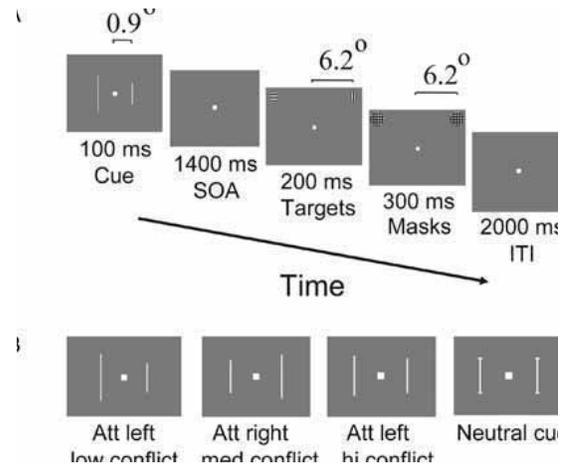

FIGURE 16.1 (A) Stimulus sequence. Subjects received a cue that directed attention to left or right, or to neither side (neutral cues). Following a cue-to-target stimulus onset asynchrony (SOA), targets were presented. Targets were circular Gabor gratings (1.5° diameter, located bilaterally 5.4° from fixation in the upper left and right visual fields), each of which could be horizontal or vertical in orientation. Subjects had to discriminate the grating orientation at the attended location. (B) Sample cue types. The length of each line ranged from 1.1° to 1.7°, depending on the type of cue. Neutral cues (to which subjects did not shift attention) were similar to attend cues, except the vertical lines were of equal length (1.1°) and had short (0.2°) horizontal lines on the top and bottom of each vertical line to distinguish them from attend cues. Subjects were instructed to shift attention to the hemifield indicated by the cue (shift left if left line is longer, shift right if right line is longer). They were told to respond with a button press indicating if the gratings of the subsequent target were vertical or horizontal.

whether the target in the attended field was horizontal or vertical (attended and unattended targets could both be the same orientation or each be different orientations).

As has been observed in numerous prior studies that have used signal-processing methods to decompose cue from target activity (e.g., Ollinger, Shulman, & Corbetta, 2001; Woldorff et al., 2004) in studies of spatial attention (e.g., Corbetta et al., 2000; Hopfinger et al., 2000; see Corbetta et al., chapter 14, this volume, for a review), the frontal-parietal attentional control system was activated in response to the attention-directing cues (collapsed across level of conflict) (figure 16.2*A*), but not to targets. In addition, in visual cortical regions, in response to cues, there was a significant activation of the visual cortex contralateral to the direction attention was cued (left versus right) (figure 16.2*B*). Targets also activated visual cortex, and these sensory-evoked activations were modulated by the direction of covert spatial attention such that responses to the bilateral targets were larger on the hemisphere contralateral to the attended hemifield (not shown in figures). Therefore, independent of cue conflict, the frontal-parietal attentional control network was activated when subjects acted on the cue instructions, and this activation led to changes in visual cortex.

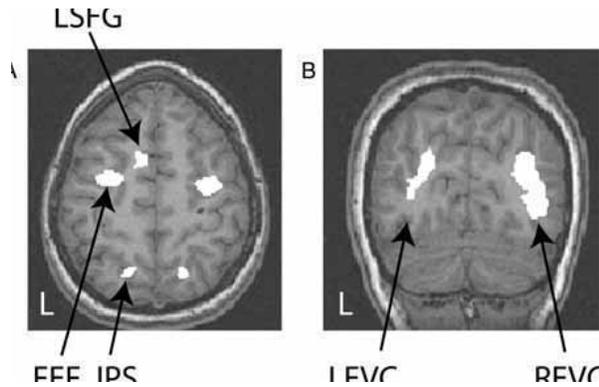

FIGURE 16.2 (A) Frontal-parietal attentional control network defined by the attend-cue versus neutral-cue contrast, collapsed over cue-left and cue-right and levels of conflict. Attentional control activity was observed in bilateral frontal eye fields (FEF), bilateral posterior parietal cortex in and around the intraparietal sulcus (IPS), and the superior frontal gyrus in the left hemisphere (LSFG). (B) Increased baseline activity in visual cortex time-locked to the attention cues. The contrast is for cue-left versus cue-right, where activity is greatest in the visual extrastriate visual cortex contralateral to the cued hemifield. That is, cues directing attention to the right hemifield resulted in increased activity in left extrastriate visual cortex (LEVC), whereas cues to the left resulted in increased activity in the right extrastriate visual cortex (REVC).

The goal in this work was to investigate whether difference in conflict in attentional orienting (a function of cue discriminability) led to systematic changes in the frontal-parietal control regions. This line of argument, however, is dependent on the paradigm and cue discriminability manipulation resulting in conflict that activates the ACC and triggers cognitive control. To establish this relationship, it is important to demonstrate that the cue manipulation resulted in standard effects on behavior and brain activity (e.g., Kerns et al., 2004). Analysis of the reaction times (RT) and accuracy to detect targets at the cued locations were broken down as a function of whether the trial was preceded by a high versus low conflict trial (defined by whether the cue was high versus low conflict in the preceding trial). Reaction times were faster ($p < .001$) and accuracy was higher ($p < .005$) for detecting targets when preceded by high-conflict trials versus low-conflict trials. Thus the expected pattern of improved speed and accuracy of behavioral responses in trials following high versus low conflict trials was observed in this spatial cuing paradigm. This behavioral signature suggests that conflict resulted in increased attentional control that was manifest as improvements in behavior (e.g., Kerns et al., 2004).

Next, whole-brain voxel-wise analyses of the fMRI BOLD responses were conducted to determine whether the observed behavioral adjustments were mediated by the well-known mechanisms involving the ACC. Activity associated with high-conflict cues compared to activity associated with low-conflict attend cues was found to include the dorsal anterior cingulate cortex (dACC), as well as small regions of DLPFC,

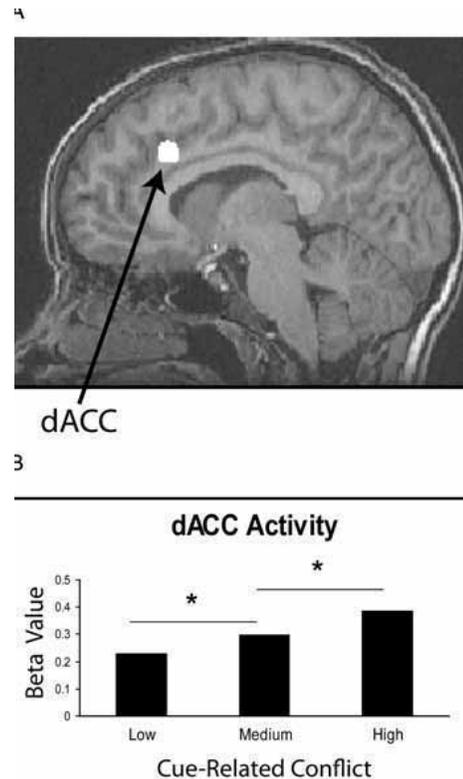

FIGURE 16.3 (A) Activity in dorsal anterior cingulate cortex (dACC) related to cue-induced conflict (contrast between high- and low-conflict cue trials—see figure 16.1B). (B) Within the dACC region of interest (ROI) shown in A, there was a parametric increase in fMRI BOLD signal (plotted as beta values) as function of increasing cue-related conflict.

right lateral parietal cortex, and left anterior insula (figure 16.3). Within the dACC region identified by the contrast, the amplitudes of BOLD signals were observed to be parametrically related to degree of conflict engendered by the cues (i.e., as a function of cue discriminability). These findings were in line with numerous prior studies of the role of the ACC in conflict detection and indicate that the cue manipulation was effective in activating the ACC (Botvinick, Nystrom, Fissell, Carter, & Cohen, 1999; MacDonald et al., 2000; Liston, Matalon, Hare, Davidson, & Casey, 2006).

Finally, electrophysiology measures have previously been related to conflict detection and should therefore be elicited in the present hybrid design. Studies using ERP have identified an anterior midline negativity (referred to as the N2 component) that is generated in the ACC and increases in amplitude to stimuli that are more likely to induce conflict (van Veen & Carter, 2002a, 2002b; Donkers & van Boxtel, 2004; Szmalec et al., 2008). In a subset of the same subjects tested in the fMRI study, ERPs were recorded from 128 channels as they performed the task shown in figure 16.1 (Walsh, 2008). As expected, the amplitude of the N2 component of the evoked potential at frontocentral electrode

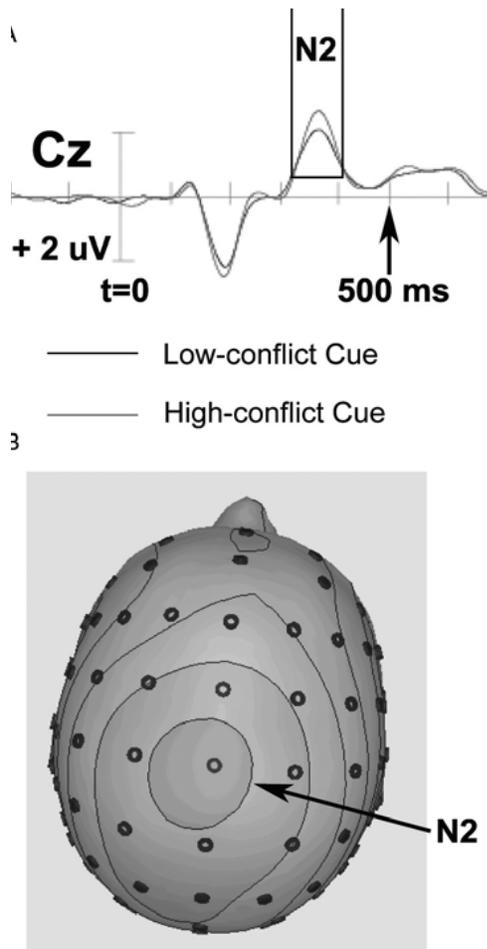

FIGURE 16.4 (A) Grand average ERPs to cues as a function of conflict, recorded from midline central scalp electrode site Cz. Negative voltage is plotted upward, and cue onset is the upright bar at time zero. High-conflict cue ERPs are plotted in red. The box indicates the N2 component, peaking at approximately 360 ms from cue onset. The N2 is significantly greater in amplitude for high-conflict cues. (B) Scalp topography at the peak of the N2 response showing the midline central scalp maximum of the response (blue colors). The nose is at the top of the figure of the scalp, and left is on the left of the image. The small red circles are the locations of the electrodes. (See color plate 18.)

sites reflected the degree of conflict engendered by the cues. The N2 was larger in response to high-conflict cues (high > low conflict cue: FCz/Cz, $p < .02$) (figure 16.4).

CONFLICT INDUCES MODULATIONS OF THE FRONTAL-PARIETAL CONTROL NETWORK The behavioral, fMRI, and ERP data provided evidence that changes in cue discriminability resulted in conflict that activated the dACC, affecting performance on the next trial. If activity in the dACC triggers increased attentional control, we might expect to observe those changes on the next trial in the frontal-parietal attention network. To investigate this question, the activations identified by contrasts of attention

cues to neutral cues were used as regions of interest (ROIs). The hemodynamic responses in these regions of interest could then be investigated as a function of attention or conflict in the current trial (trial N) and the next trial (trial $N+1$). These results are shown in figure 16.5 for the dACC, the FEF, and the intraparietal cortex. Two main findings can be highlighted.

First, as described earlier, contrasts related to attention revealed activity in the frontal-parietal network but not the dACC, whereas contrasts related to conflict affected the dACC but not the frontal-parietal network (figure 16.5). This pattern draws the distinction between the dACC that is sensitive to cue conflict (e.g., Kerns et al., 2004) and the frontal-parietal network that is sensitive to attentional control (e.g., Corbetta et al., 2000; Hopfinger et al., 2000).

The second finding is the pattern of attention and conflict in the dACC and the frontal-parietal network for trial N versus trial $N+1$. This can be observed in figure 16.5 by observing the time courses of the hemodynamic responses. The key finding is that although cue conflict does not result in fMRI BOLD signal changes in the frontal-parietal network for trial N , in response to trial $N+1$ (following a high-conflict cue) this network shows a robust response. This pattern shows that high (versus low) cue conflict on one trial leads to increased activity in the frontal-parietal network on the next trial. This pattern is consistent with that observed in behavior where target performance was improved on trials that followed a high-cue-conflict trial (described earlier).

Conclusions

The results of these fMRI and ERP studies support the idea that conflict-monitoring networks and attentional-control networks interact to modulate spatial attention to improve performance. High attentional cue conflict in one trial (trial N) generated high ACC activity in that trial, and then led to increased frontal-parietal activity in the next trial (trial $N+1$). Such a pattern of results establishes a long-hypothesized relationship between conflict and control mechanisms and selective attention (e.g., Casey et al., 2000). Stated more generally, a performance-monitoring system that detects conflict related to orienting attention appears to signal attentional control systems to exert greater control over the focus of attention (Botvinick et al., 2001; Kerns et al., 2004; Egner & Hirsch, 2005; Liston et al., 2006). The interactions of these systems are diagrammed in figure 16.6, which shows how conflict signals the need for attentional control that leads to changes in behavior.

The neural substrates for such interactions between conflict and attention systems have been reported. The ACC has been shown to project directly to both frontal eye fields (FEF) (Huerta, Krubitzer, & Kass, 1987; Stanton, Bruce, & Goldberg, 1993) and posterior parietal cortex

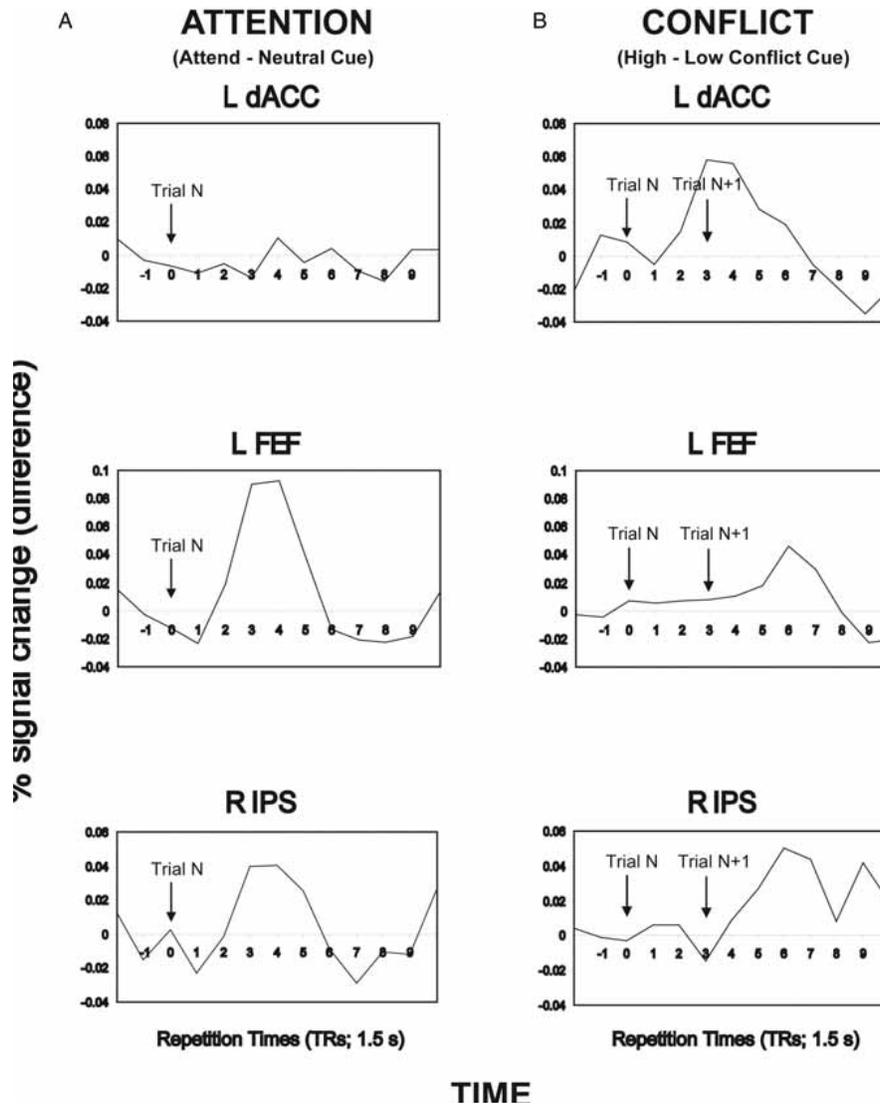

FIGURE 16.5 Hemodynamic responses from dorsal anterior cingulate cortex (dACC), frontal eye fields (FEF), and the intraparietal sulcus (IPS) in parietal cortex. The plots represent differences in percent signal change computed by subtracting two conditions. (A) Time courses for attend cues minus neutral cues (the effects of attentional control) show activity in the FEF and IPS but not in the

dACC. (B) Time courses for high-conflict cues minus low-conflict cues (the effects of conflict) show that for the current trial (trial N) the dACC was active while the FEF and IPS were not. In contrast, however, the reverse pattern was true for trial $N + 1$ where a hemodynamic response is observed that is delayed, being time-locked to trial $N + 1$ in the FEF and IPS (but not dACC).

(Pandya, Van Hoesen, & Mesulam, 1981; Selemon & Goldman-Rakic, 1988), critical elements of the frontal-parietal attentional control network. Given this connectivity, and the results obtained in the experiments described in this chapter, one might speculate that the ACC projects directly to structures in the frontal-parietal attention network critical to modulating attentional control.

Prior research in cognitive control has established a relationship between the ACC and the dorsolateral prefrontal cortex (DLPFC) where conflict resulting in ACC activation triggered DLPFC activity that was related to changes in performance (e.g., Kerns et al., 2004). In the studies reported in this chapter, no such DLPFC involvement was measur-

able, raising the possibility that for attentional conflict, interactions between ACC and the frontal-parietal attention network were not mediated by the DLPFC; this must remain a hypothesis for future investigation.

The present formulation can be considered in relation to other models of cortical control systems. One such model is the recent proposal regarding the interaction of cortical networks in default-mode processing and cognitive control. Dosenbach, Fair, Cohen, Schlagger, and Petersen (2008) proposed a model in which a frontal-parietal system is involved in top-down control processes that meet moment-to-moment demands, while a cingulate-opercular system (involving ACC, anterior prefrontal cortex, and inferior

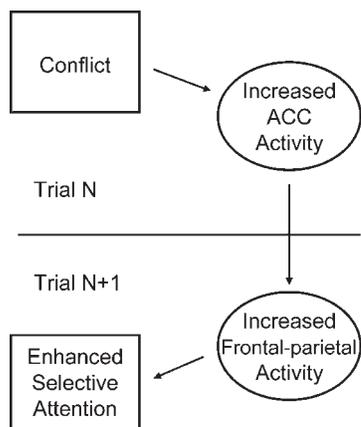

FIGURE 16.6 Diagram of the interactions of the conflict and attention systems.

lateral prefrontal cortex, as well as subcortical structures) is involved in maintaining a stable set over time during task performance. They noted that “it seems likely that additional controllers might exist, operating at other temporal and/or spatial scales” (p. 103). The findings reviewed in the present chapter emphasize this general notion of interacting cortical networks that act to achieve different specific computational needs during performance. By showing that systems involved in conflict monitoring and error processing interact in dynamic ways with voluntary attentional control networks to modulate selective attention, the present work establishes the interactions of two major cognitive control systems for evaluating, controlling, and improving perception and performance.

ACKNOWLEDGMENTS We are deeply grateful to Cameron S. Carter, Michael H. Buonocore, Barry Giesbrecht, Sean P. Fannon, and Dorothee Heipertz for their collaboration, advice, and assistance. Supported by NIMH R01 MH55714 to GRM and NEI Traineeship T32 EY015387 to BJW.

17 A Right Perisylvian Neural Network for Human Spatial Orienting

HANS-OTTO KARNATH

ABSTRACT Homologous neural networks seem to exist in the human left and right hemispheres tightly linking cortical regions straddling the sylvian fissure. White matter fiber bundles connect the inferior parietal lobule with the ventrolateral frontal cortex, ventrolateral frontal cortex with superior/middle temporal cortex, and superior/middle temporal cortex with the inferior parietal lobule. It is argued that these perisylvian networks serve different cognitive functions, a representation for language and praxis in the left hemisphere and a representation for processes involved in spatial orienting in the right. The tight perisylvian anatomical connectivity between superior/middle temporal, inferior parietal, and ventrolateral frontal cortices might explain why lesions at these distant cortical sites around the sylvian fissure in the human right hemisphere can lead to the same disturbance of orienting behavior, namely, to spatial neglect.

In recent years it has been shown that functional and structural lateralization of the brain is more widespread among vertebrates than previously believed. Nevertheless, it is still appropriate that many motor, sensory, and visual, but also cognitive, functions show bihemispheric representations in the human and nonhuman primate. Only a few (so-called higher) cognitive functions have obvious asymmetrical representations. Among them are language, praxis, and spatial orienting. While an elaborate representation for language and praxis has evolved in the human left hemisphere, a neural system involved in spatial orienting is dominantly represented in the right hemisphere. Consequently, locally corresponding damage to one of the two hemispheres leads to different symptoms. While the dominant disorders in neurological patients with left hemisphere involvement are aphasia and apraxia, patients with right hemisphere damage typically show spatial neglect. This term describes a spontaneous deviation of the eyes and the head toward the ipsilesional, right side (Fruhmann-Berger & Karnath, 2005; Fruhmann-Berger, Pross, Ilg, & Karnath, 2006). Patients with such a disorder disregard objects located

on the contralesional, left side. When searching for targets, copying, or reading, for example, they concentrate their exploratory movements predominantly on the right side of space (Heilman, Watson, Valenstein, & Damasio, 1983; Behrmann, Watt, Black, & Barton, 1997; Karnath, Niemeier, & Dichgans, 1998). The question thus arises whether the development of these different functions in the human left and right hemispheres corresponds with different anatomical representations. Or is it possible that homologous neural structures serve as correlates for language and praxis in the left and for spatial orientation in the right hemisphere?

Three major cortical areas have been described as neural correlates of spatial neglect in the human right hemisphere. A first study by Heilman and coworkers (1983) revealed the right inferior parietal lobule (IPL) and the temporoparietal junction (TPJ). Subsequent studies reported comparable observations (e.g., Vallar & Perani, 1986; Mort et al., 2003). Lesions located in the right ventrolateral frontal cortex were also observed to correlate with spatial neglect (Vallar & Perani, 1986; Husain & Kennard, 1996; Committeri et al., 2007). Finally, several studies have revealed the right superior temporal cortex and adjacent insula as being critically related to the disorder (Karnath, Ferber, & Himmelbach, 2001; Karnath, Fruhmann-Berger, Küker, & Rorden, 2004; Buxbaum et al., 2004; Corbetta, Kincade, Lewis, Snyder, & Sapir, 2005; Committeri et al., 2007; Sarri, Greenwood, Kalra, & Driver, 2009).

Interestingly, a similar pattern of perisylvian correlates has been observed in the human left hemisphere when stroke patients suffer from aphasia. Early analyses (e.g., Kertesz, Harlock, & Coates, 1979; Poeck, de Bleser, Graf von Keyserlingk, 1984), as well as more recent studies of cortical lesion localization in neurological patients with disorders in language comprehension and/or speech production (e.g., Kreisler et al., 2000; Dronkers, Wilkins, Van Valin, Redfern, & Jaeger, 2004; Borovsky, Saygin, Bates, & Dronkers, 2007), revealed involvement of the ventrolateral frontal cortex, superior and middle temporal gyri, insula, and IPL. These

HANS-OTTO KARNATH Center for Neurology, University of Tübingen, Tübingen, Germany

findings are supported by electrical mapping of the human cortex during surgery in awake patients as well as functional magnetic resonance imaging (fMRI) in healthy subjects. A recent meta-analysis of 129 fMRI studies on phonological, semantic, and syntactic processing revealed activation in distributed areas predominantly involving left middle and inferior dorsolateral frontal, superior and middle temporal, and inferior parietal cortices (Vigneau et al., 2006). These sites correspond very well with those in which intraoperative cortical stimulation evoked disturbances of language processes, such as anomia, alexia, or speech arrest (e.g., Boatman, 2004; Duffau et al., 2005; Sanai, Mirzadeh, & Berger, 2008).

These perisylvian brain areas in the human left hemisphere do not appear to represent language processes solely. Recent analyses of lesion localization in patients suffering from apraxia suggested that they are also involved in the organization of motor actions (Goldenberg & Karnath 2006; Goldenberg, Hermsdörfer, Glindeman, Rorden, & Karnath, 2007). Stroke patients with either disturbed pantomime of tool use or with disturbed imitation of finger postures typically showed damage of the left inferior frontal gyrus (IFG) and adjacent portions of the insula, while disturbed imitation of hand postures was associated with posterior lesions affecting the IPL and TPJ. This close anatomical relationship between the representation of praxis on the one hand and language on the other led to the assumption that these left perisylvian areas might represent an observation/execution matching system providing the bridge from “doing” to “communicating” (Rizzolatti & Arbib, 1998; Iacoboni & Wilson, 2006). Its development was seen as a consequence of the fact that before speech appearance the precursors of these areas in the monkey were endowed with a mechanism for recognizing actions made by others. This mechanism was seen as the neural prerequisite for the development of inter-individual communication and finally of speech (Rizzolatti & Arbib, 1998).

Thus it seems as if very similar anatomical cortical areas straddling the sylvian fissure are involved in representing language and praxis in the human left hemisphere and spatial orienting in the right hemisphere. Recent anatomical studies have revealed that a dense white matter connectivity exists specifically between these perisylvian cortical areas. In the following sections, it will be argued that intimately interconnected homologous perisylvian networks have evolved in the human left and right hemispheres serving for different cognitive functions, a representation for language and praxis in the left hemisphere and a representation for spatial orienting in the right hemisphere. Further, it will be argued that for these cognitive processes the functioning of the perisylvian cortical areas is critical, not the mere disconnection of their white matter interconnections.

Dense perisylvian white matter connectivity

Beyond traditional axonal-tract-tracing and myelin-staining techniques, the development of diffusion-based imaging—for example, diffusion tensor and diffusion spectrum imaging (DTI/DSI)—has opened new opportunities for identifying long-range white matter pathways. By combining the findings from DSI and from histological tract tracing, Schmahmann and colleagues separated ten long, bidirectional association fiber bundles in the monkey brain (Schmahmann & Pandya, 2006; Schmahmann et al., 2007). Anatomical homologies have been described in the human with the aid of diffusion-based imaging in vivo (e.g., Catani, Howard, Pajevic, & Jones, 2002; Catani, Jones, & ffytche, 2005; Catani et al., 2007; Makris et al., 2005, 2007; Mori, Wakana, van Zijl, & Nagae-Poetscher, 2005; Upadhyay, Hallock, Ducros, Kim, & Ronen, 2008) and myelin staining postmortem (Bürgel et al., 2006). In the following, the focus will be on those pathways that connect the perisylvian cortical areas—that is, the superior/middle temporal, inferior parietal, and dorsolateral frontal cortices—where damage has been shown to provoke spatial neglect in the case of right brain lesions and aphasia and/or apraxia after left hemisphere involvement.

In the monkey and human, the superior longitudinal fasciculus (SLF) is the major cortical association fiber pathway linking parietal and frontal cortices. It is subdivided into different, separable components (Petrides & Pandya 1984; Makris et al., 2005; Schmahmann et al., 2007). One part—the SLF I—is situated dorsally of the perisylvian network area, connecting the superior parietal lobule with dorsal premotor areas. Two further subcomponents connect the IPL with premotor and prefrontal cortices. The SLF II links the IPL and intraparietal sulcus with the posterior and caudal prefrontal cortex, while the SLF III connects the rostral IPL with the ventral part of premotor and prefrontal cortex. A further fiber tract that is separable from these connections stems from the caudal part of the superior/middle temporal gyrus (STG/MTG), arches around the caudal end of the sylvian fissure, and extends to the lateral prefrontal cortex along with the SLF II fibers. This latter fiber tract is termed the arcuate fasciculus (AF) and has been described in humans (Burdach, 1819–26; Dejerine & Dejerine-Klumpke, 1895; Catani et al., 2002, 2005; Makris et al., 2005; Vernooij et al., 2007; Upadhyay et al., 2008) as well as in the monkey (Petrides & Pandya, 1988; Schmahmann et al., 2007). Some disagreement exists related to whether or not this fiber bundle is regarded as a fourth subdivision of the SLF (SLF IV; Makris et al., 2005; Vernooij et al., 2007), a stand-alone connection adjacent to the SLF (Schmahmann et al., 2007), or only part, namely, the long segment (discussed later), of a three-way AF structure (Catani et al., 2005).

A fiber bundle situated in close proximity to the SLF II and the AF is the superior occipitofrontal fasciculus (SOF), also termed the (superior) fronto-occipital fasciculus ([S]FOF) by some authors. The SOF forms the medial border of the corticospinal tract and separates it from the lateral ventricles. The fibers run parallel to the dorsolateral margin of the lateral ventricles below the corpus callosum. Some of its fibers intermingle with SLF II and AF fibers. Different from expectations based on its labeling, the SOF connects not only occipital but also inferior parietal with frontal lobe areas. In the monkey as well as in humans, this long association bundle bidirectionally extends from the IPL and dorso-medial parastriate occipital cortex to caudal, dorsal, and medial frontal lobe areas (Catani et al., 2002; Bürgel et al., 2006; Makris et al., 2007; Schmahmann et al., 2007).

Two further, ventrally located fiber bundles contribute to the perisylvian network focused on in this chapter, namely, the strong pathway running through the extreme capsule (EmC) and the middle longitudinal fasciculus (MdLF). Both bundles have been described in monkeys (Seltzer & Pandya, 1984; Schmahmann & Pandya, 2006; Schmahmann et al., 2007; Petrides & Pandya, 2007) as well as in humans (Makris & Pandya, 2009; Makris et al., 2009). The EmC is situated between the claustrum and the insular cortex interconnecting the inferior frontal and orbitofrontal gyri with the midportion of the superior temporal region. It further continues caudally toward the occipital cortex and toward the IPL, flanking here another fiber pathway, namely the MdLF (Makris & Pandya, 2009; Makris et al., 2009).

The MdLF is a fiber bundle that runs within the white matter of the superior temporal gyrus extending from the IPL to the temporal pole. Although there is no common agreement yet, it appears as if the EmC corresponds with the bundle termed “inferior occipitofrontal fasciculus (IOF)” [also “inferior frontooccipital fasciculus (IFOF)”] by other authors (Nieuwenhuys, Voogd, & van Huijzen, 1988; Catani et al., 2002; Kier, Staib, Davis, & Bronen, 2004; Wakana, Jiang, Nagae-Poetscher, van Zijl, & Mori, 2004; Bürgel et al., 2006).

For clarification it should be pointed out that Catani and colleagues used a different terminology when they investigated the long perisylvian association fibers of the human left hemisphere (Catani et al., 2002, 2005, 2007). The SLF and AF historically have been regarded as a single fiber bundle in the human (Burdach, 1819–26; Dejerine & Dejerine-Klumpke, 1895). The terms “superior longitudinal fasciculus” and “arcuate fasciculus” thus often were and still are used interchangeably by some authors, including Catani and coworkers. However, despite the different terminology, Catani and colleagues (2005) also found a long and two shorter segments between the superior/middle temporal, inferior parietal, and lateral frontal cortices (figure 17.1A). Tractography reconstruction for a group of 11 healthy subjects revealed a direct connection between the left rentrolateral frontal and the superior/middle temporal cortex—that is, between Broca’s and Wernicke’s language areas. In addition, two shorter pathways were found connecting superior/middle temporal with the inferior parietal

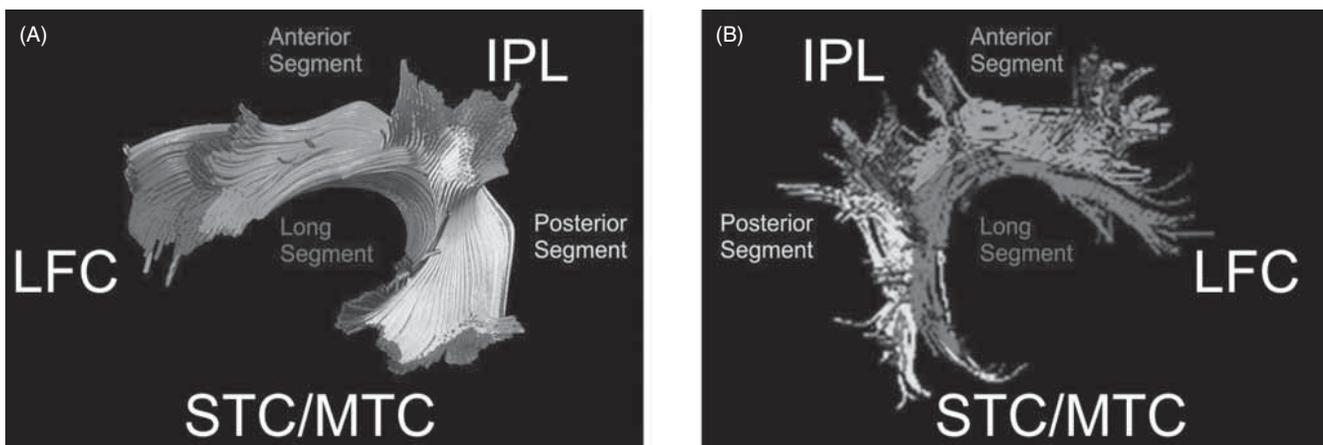

FIGURE 17.1 Averaged tractography reconstruction for fiber connections between the superior/middle temporal, inferior parietal, and lateral frontal cortices by using a two-region-of-interest approach in (A) the human left hemisphere (Catani, Jones, & ffytche, 2005) and (B) the human right hemisphere (Gharabaghi et al., 2009). A long connection was observed linking superior/middle temporal and lateral frontal cortices (shown in red). Two shorter pathways also were found. The posterior segment running

from the superior/middle temporal to the inferior parietal cortex is shown in yellow. The anterior segment running from the inferior parietal to the lateral frontal cortex is shown in green. IPL, inferior parietal lobule; LFC, lateral frontal cortex; STC, superior temporal cortex; MTC, middle temporal cortex. (With modifications from Catani et al., 2005, and from Gharabaghi et al., 2009.) (See color plate 19.)

cortex (“posterior segment”) and the inferior parietal with the dorsolateral frontal cortex (“anterior segment”). There is no doubt that the long connection between the superior/middle temporal and inferior frontal cortex represents the fiber bundle that has been termed AF in the work of other groups (Petrides & Pandya, 1988; Makris et al., 2005; Schmahmann et al., 2007; Upadhyay et al., 2008). The “anterior segment” between the inferior parietal and inferior frontal cortex most probably represents the fiber bundle(s) that have been termed SLF II—maybe in combination with the SLF III and/or SOF. The “posterior segment” between the superior temporal and inferior parietal cortex had been assumed to represent the MdLF (Schmahmann et al., 2007). However, the recent work by Makris et al. (2009) in the human rather argues that the MdLF is distinct from and located medial to the SLF-AF fibers.

To analyze the perisylvian connectivity between the superior/middle temporal, inferior parietal, and lateral frontal cortices in the human right hemisphere, Gharabaghi and coworkers (2009) investigated 12 right-handed male subjects without neurological deficits by using the same procedure that Catani and colleagues (2005) applied for the left hemisphere analysis. Figure 17.1*B* shows the averaged tractography reconstruction obtained from this DTI analysis. It revealed a pattern of fiber connections that largely corresponded to the one demonstrated by Catani and colleagues (2005) in the human left hemisphere (figure 17.1*A*). While Gharabaghi and coworkers were conducting this analysis, Catani and colleagues published a study (Catani et al., 2007) in which they also had analyzed the perisylvian connectivity in the human right hemisphere. In line with the findings illustrated in figure 17.1*B*, they found an indirect connection with a posterior segment connecting the supe-

rior/middle temporal with the inferior parietal cortex and an anterior segment running from the inferior parietal to the dorsolateral frontal cortex. In contrast, they found the long, direct segment between the superior/middle temporal and the lateral frontal cortices in only about 40% of their individuals, while this segment was present in all subjects (100%) studied by Gharabaghi and colleagues (2009). Likewise, some studies observed largely symmetrical conditions between the human hemispheres for volume, bundle density, and location of the left- and right-sided AF and SLF (Makris et al., 2005; Bürgel et al., 2006; Upadhyay et al., 2008), while discrepant observations have also been reported (Powell et al., 2006; Vernooij et al., 2007; Glasser & Rilling, 2008). Possible reasons for the discrepancy between these studies can be attributed to differences in fiber tracking methods, in the choice of the seeding ROIs, and/or the composition of subject samples. Future studies will have to clarify this issue. However, beyond the discrepant observations regarding the long, dorsally located direct connection via the AF, it is undisputed that the superior/middle temporal, lateral frontal, and inferior parietal cortices show dense direct (via the EmC/IOF) as well as indirect interconnectivity.

To summarize the hitherto existing findings from tract-tracing, myelin-staining, and diffusion-based imaging techniques, a dense perisylvian network seems to exist in both hemispheres connecting the inferior parietal lobule with the ventrolateral frontal cortex (via SLF II, SLF III, SOF), ventrolateral frontal cortex with superior/middle temporal cortex (via AF, EmC/IOF), and superior temporal cortex with the inferior parietal lobule (via MdLF, EmC/IOF). Figure 17.2 illustrates these tightly connected perisylvian neural networks.

FIGURE 17.2 Sketch of the perisylvian neural network linking the inferior parietal lobule with the ventrolateral frontal cortex (via SLF II, SLF III, SOF), ventrolateral frontal cortex with superior/middle temporal cortex and insula (via AF, EmC/IOF), and superior temporal cortex with the inferior parietal lobule (via MdLF,

EmC/IOF). SLF II/III, subcomponents II/III of the superior longitudinal fasciculus; SOF, superior occipitofrontal fasciculus; AF, arcuate fasciculus; IOF, inferior occipitofrontal fasciculus; EmC, extreme capsule; MdLF, middle longitudinal fasciculus.

Functional role of the perisylvian network in the human right hemisphere

There is no disagreement that the perisylvian network in the human left hemisphere is involved in language processes (e.g., Frey, Campbell, Pike, & Petrides, 2008; Saur et al., 2008; Catani & Mesulam, 2008; Makris & Pandya, 2009). In contrast, the functional involvement of the right hemisphere perisylvian network is less clear. Catani and colleagues suggested that the perisylvian network in the human right hemisphere might represent—as in the human left hemisphere—a network involved in language functions (Catani et al., 2007, p. 17166). In this chapter, a different view is suggested. The perisylvian pathways between the right IPL, ventrolateral frontal, and superior/middle temporal cortices and insula connect those areas which have repeatedly been associated with spatial neglect in the case of brain damage (Heilman et al., 1983; Vallar & Perani, 1986; Mort et al., 2003; Karnath et al., 2001, 2004; Committeri et al., 2007; Sarri et al., 2009). In contrast, aphasia is only extremely rarely associated with lesion of these right hemisphere perisylvian areas (as rarely as spatial neglect is observed after left hemisphere damage). Thus it is proposed that the perisylvian network in the human right hemisphere represents the anatomical basis for processes involved in spatial orienting and exploration.

Supporting evidence for this hypothesis has been reported from transcranial magnetic stimulation (TMS), electrical mapping of the human cortex during neurosurgery, and fMRI in healthy subjects. Using TMS, Ellison, Schindler, Pattison, and Milner (2004) induced “virtual lesions” at the right STG and right posterior parietal cortex (PPC) in healthy subjects. They observed a specific impairment induced by TMS over the right STG for serial feature search (termed “hard feature search task”). In contrast, TMS over the right PPC resulted in increased reaction times during “hard conjunction search.” Gharabaghi, Fruhmann-Berger, Tatagiba, and Karnath (2006) observed that intraoperative inactivation of the middle portion of the STG in human leads to disturbed serial visual search. Using the same technique Thiebaut de Schotten and colleagues (2005) found that inactivating regions in the right IPL or at the caudal and the middle parts of the STG leads to deficits in the perception of line length.

Evidence for the involvement of superior temporal, inferior parietal, and lateral frontal areas in processes of spatial orienting has also been obtained from fMRI experiments in healthy subjects. In a cued spatial-attention task, Hopfinger, Buonocore, and Mangun (2000) found bilateral activation in these cortical areas correlated with covert attentional shifts in the horizontal dimension of space. Himmelbach, Erb, and Karnath (2006) investigated active visual exploration in healthy subjects, using a task (visual search in a letter

array) that closely resembled the clinical procedure employed to detect spatial neglect in stroke patients. The authors observed significant activation associated with visual exploration located at the TPJ, the midportion of the STG, and the IFG.

Thus observations deriving from different techniques converge to suggest that the densely interconnected perisylvian neural system in the human right hemisphere (figure 17.2) represents the anatomical basis of processes that are involved in spatial orientation, provoking spatial neglect in the case of damage. The tight anatomical connectivity between superior/middle temporal, inferior parietal, and ventrolateral frontal cortices might explain why lesions at these distant cortical sites around the sylvian fissure in the human right hemisphere can lead to the same disturbance of orienting behavior, namely, to spatial neglect.

Spatial neglect—A disconnection syndrome?

Beginning with the seminal work of Dejerine and his wife (Dejerine & Dejerine-Klumpke, 1895) on the human cortical pathways, several authors developed the idea that some neurological conditions might result from the disconnection of one area of the brain from another. Among them, Geschwind (1965) put forward the view that several neuropsychological disorders could best be interpreted as resulting from interruption of specific cortical association pathways. With respect to spatial neglect, Mesulam and Geschwind (1978) suggested that this disorder—among other disorders of attention and emotion—results from disruption of neural connections between limbic structures and neocortex. Mesulam (1981, 1985) further evolved this concept, suggesting that an interconnected network between posterior parietal, frontal, and cingulate cortices as well as the reticular formation is involved in spatial neglect. A disconnection hypothesis has also been put forward by Watson, Heilman, Miller, and King (1974) and Watson, Miller, and Heilman (1978) when observing that spatial neglect can be evoked in the monkey by a lesion in the mesencephalic reticular formation.

More recently, some authors have revived the concept to view spatial neglect as a “disconnection syndrome” (Catani, 2006; Bartolomeo, Thiebaut de Schotten, & Doricchi, 2007; He et al., 2007). Bartolomeo and colleagues proposed that long-lasting signs of spatial neglect result from frontoparietal intrahemispheric and from interhemispheric disconnection. They suggested that “a particular form of disconnection might have greater predictive value than the localization of gray matter lesions concerning the patients’ deficits and disabilities” (Bartolomeo et al., 2007, p. 2484). Intrahemispherically, they related disconnection of the SLF (Thiebaut de Schotten et al., 2005, 2008; Bartolomeo et al., 2007) but also of the IOF (Urbanski et al., 2008) to spatial neglect. Using DTI tractography, He and colleagues found damage to the

SLF and AF in five patients with severe spatial neglect but not in five patients with mild cases. Furthermore, the analysis of interregional functional connectivity, based on coherent fluctuations of fMRI signals, suggested that not only anatomically but also functionally disrupted connectivity in dorsal and ventral attention networks might constitute a critical mechanism underlying the pathophysiology of spatial neglect (He et al., 2007).

To investigate the possible impact of damage to white matter association fibers for the genesis of spatial neglect, Karnath, Rorden, and Ticini (2009) analyzed lesion location in a large seven-year sample of 140 right-hemispheric stroke patients. This large number of stroke patients allowed the authors not only to study a representative sample of subjects with spatial neglect, but also to perform a statistical voxel-wise lesion-behavior mapping (VLBM) analysis (e.g., Bates et al., 2003; Rorden, Karnath, & Bonilha, 2007) to estimate which brain regions are more frequently compromised in neglect patients relative to patients without neglect. Karnath and coworkers (2009) studied the patients' white matter connectivity by using a new method that combines a statistical VLBM approach with the histological maps of the human white matter fiber tracts provided by the stereotaxic probabilistic atlas developed by the Jülich group (Amunts & Zilles, 2001; Zilles, Schleicher, Palomero-Gallagher, & Amunts, 2002). In contrast to the reference brain of the Talairach and Tournoux atlas (Talairach & Tournoux, 1988) or the MNI single-subject or group templates (Evans et al., 1992; Collins, Neelin, Peters, & Evans, 1994), the Jülich probabilistic atlas is based on the analysis of the cytoarchitecture in a sample of 10 different human postmortem brains. It thus provides information on the location and intersubject variability of brain structures, illustrating for each voxel of the MNI reference space the relative frequency with which a certain structure was present in 10 normal human brains. Using a modified myelin-staining technique, Bürgel and colleagues (2006) were able to distinguish 10 individual white matter fiber tracts for this atlas at microscopic resolution.

The analysis of the 140 right-hemisphere stroke patients revealed that 7.0% of the right SLF, 8.2% of the IOF, 12.7% of the SOF, and only 0.6% of the uncinate fasciculus were significantly more affected in patients with spatial neglect than in those not showing the disorder (figure 17.3). The authors concluded that damage of right perisylvian white matter connections is a typical finding in patients with spatial neglect. However, the proportion of involvement of each of the fiber bundles was very low. When the authors analyzed how much of the lesion area in neglect patients overlapped with all of the perisylvian white matter connections, they found an overlap between 3.4% and 10.9% (Karnath et al., 2009).

Although the study by Karnath and coworkers (2009) cannot finally decide whether or not spatial neglect should

best be interpreted as a “disconnection syndrome” (Mesulam & Geschwind, 1978; Watson et al., 1974; Watson, Miller, & Heilman, 1978; Catani, 2006; Bartolomeo et al., 2007; He et al., 2007), one may conclude that their data argue more against than in favor of such a hypothesis. In fact, their analysis revealed that between 89.1% and 96.6% of the lesion area in spatial neglect affected brain structures other than the perisylvian white matter fiber tracts, namely, cortical and subcortical gray matter structures such as the superior temporal, inferior parietal, inferior frontal, and insular cortices, as well as the putamen and caudate nucleus (Karnath et al., 2009). Damage to these gray matter structures in the right hemisphere thus appears to be a strong predictor of spatial neglect.

Another aspect arguing against the view of spatial neglect as a white matter disconnection syndrome in the traditional sense is the perfusion-weighted imaging (PWI) results obtained in patients with subcortical infarcts. Perfusion-weighted imaging is an MR technique that allows the identification of brain regions that are receiving enough blood supply to remain structurally intact but not enough to function normally. By using this technique, several studies showed that left- or right-sided subcortical lesions—including selective white matter strokes—cause spatial neglect only if the subcortical damage provokes additional malperfusion of cortical gray matter structures in the ipsilesional hemisphere (Demeurisse, Hublet, Paternot, Colson, & Serniclaes, 1997; Hillis et al., 2002, 2005). Without this malfunction of cortical structures, subcortical brain lesions did not provoke disturbances of spatial orienting. Thus it seems that damage to subcortical white matter connectivity alone does not provoke spatial neglect but rather requires additional malfunction of cortical gray matter structures.

Conclusions

Homologous perisylvian neural networks seem to exist in the human left and right hemispheres composed of tightly connected cortical areas straddling the sylvian fissure (cf. figure 17.2). It is suggested that the neural network consisting of superior/middle temporal, inferior parietal, and ventrolateral frontal cortices in the human right hemisphere represents the anatomical basis for processes involved in spatial orienting. Neurons of these regions provide us with redundant information about the position and motion of our body in space. They seem to play an essential role in adjusting body position relative to external space (Karnath & Dieterich, 2006). Damage to this perisylvian system in the right hemisphere may provoke spatial neglect. In the human left hemisphere, a similar perisylvian network seems to exist but is serving different functions, namely, language and praxis. This functional specialization of left and right perisylvian networks is still not observed in the nonhuman

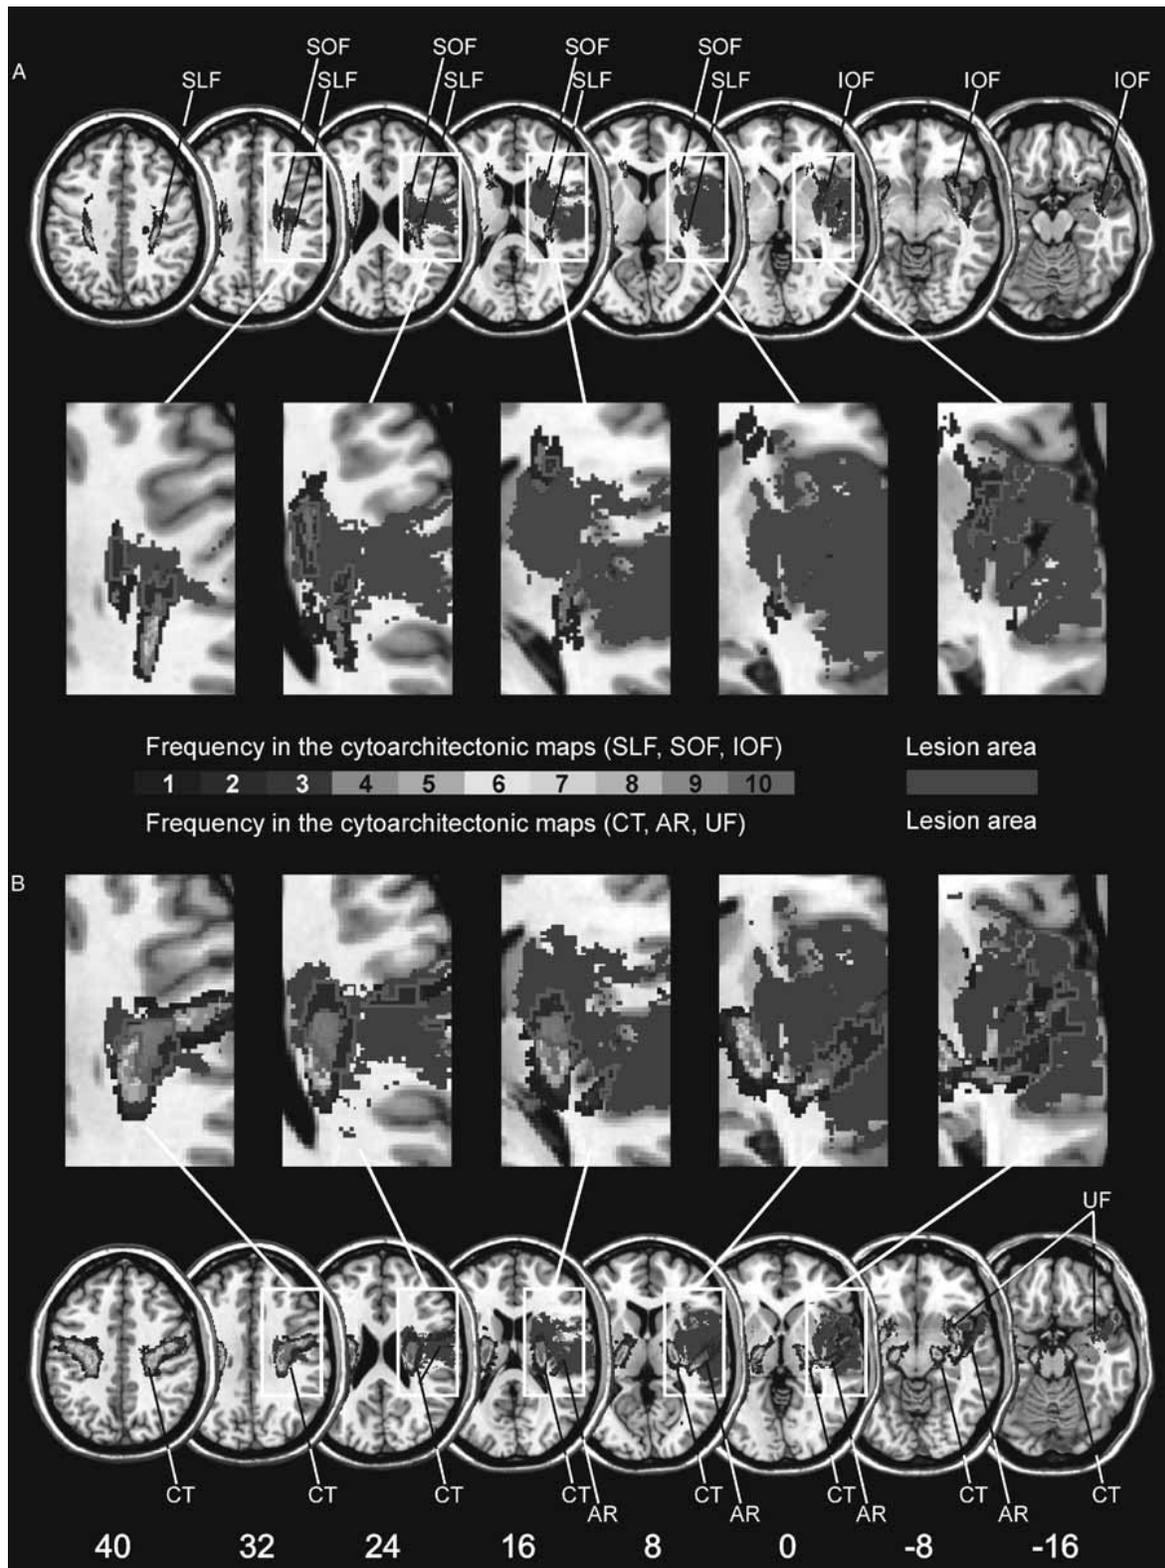

FIGURE 17.3 Overlap of the statistical VLBM lesion map (the brain territory significantly more affected in 78 patients with spatial neglect than in 62 stroke patients without this disorder) with the probabilistic, cytoarchitectonic maps of the white matter association fiber tracts from the Jülich atlas. The statistical lesion map is illustrated in homogeneous brown color. The color coding of the Jülich atlas from 1 (dark blue, observed in 1 postmortem brain) to 10 (red, overlap in all ten postmortem brains) represents the absolute frequency for which in each voxel of the brain a respective

fiber tract was present (e.g., yellow color indicates that the fiber tract was present in that voxel in seven out of ten postmortem brains). The pink contour demarks the area of the fiber tracts affected by the statistical lesion map. (A) Overlap illustrated for perisylvian fiber tracts SFL, superior longitudinal fasciculus; IOF, inferior occipitofrontal fasciculus; and SOF, superior occipitofrontal fasciculus. (B) Overlap illustrated for fiber tracts CT, corticospinal tract; AR, acoustic radiation; and UF, uncinate fascicle. (From Karnath et al., 2009.) (See color plate 20.)

primate. Here, lesions of this perisylvian system in both hemispheres induce disturbed exploration and orientation toward the respective contralateral side (e.g., Luh, Butter, & Buchtel, 1986; Watson, Valenstein, Day, & Heilman, 1994; Wardak, Olivier, & Duhamel, 2002, 2004). Hence the phylogenetic transition from monkey to human brain seems to be a restriction of a formerly bilateral function represented within right- and left-sided perisylvian networks to the right hemisphere (Karnath et al., 2001). It appears as if this lateralization of spatial orientation to the right hemisphere network parallels the emergence of an elaborate representation for language in the left-sided perisylvian network.

ACKNOWLEDGMENTS This work was supported by the Bundesministerium für Bildung und Forschung (BMBF-Verbundprojekt "Räumliche Orientierung" 01GW0641) and the Deutsche Forschungsgemeinschaft (SFB 550-A4). I would like to thank Bianca de Haan and Marc Himmelbach for their discussion and helpful comments on the manuscript.

18 Spatial Deficits and Selective Attention

LYNN C. ROBERTSON

ABSTRACT The focus of this chapter is on spatial deficits that produce a complete or partial loss of spatial awareness of the visual world after damage to the dorsal pathway of the human brain. Not surprisingly, when spatial awareness is deficient, controlling spatial attention is also compromised. Yet even with complete loss of spatial information of the external world, object-based and feature-based processes continue to influence what is seen. Nevertheless, features may be inaccurately bound to form abnormal rates of illusory conjunctions even under free viewing conditions. There also is emerging evidence from priming studies that conjunctions are bound late in processing whereas features are coded early. How the multiple spatial representations in the brain may interact to influence selection is also discussed.

The influential 18th-century philosopher Immanuel Kant claimed that space and time were the two necessary mental concepts supporting all other human experience. A mental representation of space separates sensory experience occurring at the same time into different entities that are spatially segregated yet related to one another, while a mental representation of time separates sequentially presented information into segmented events. Kant himself wrote, “We never can imagine or make a representation to ourselves of the nonexistence of space.”

Although it is very nearly impossible to imagine a world in which space does not exist, there are individuals with damage to certain brain areas who must contend with the loss of spatial perception on a daily basis. These are neurological patients who have suffered unilateral damage to parietal (and/or less often frontal or superior temporal) areas, producing unilateral neglect, and those with bilateral parietal damage, which can produce a complete loss of spatial information beyond a person’s own body (Balint’s syndrome). Studies of such individuals have shown that certain perceptual experiences remain relatively intact, but others are altered or lost altogether. Contrary to Kant’s claims, a mental representation of space is not necessary for all perceptual phenomena, and the exceptions provide insights into the cognitive and neurobiological bases of

spatial representations and their interactions with perception and other attention mechanisms.

The loss of perceptual space

I will begin by classifying spatial deficits in behavioral neurology into three general classes: complete (there is no there there), partial (only a portion is there), and scrambled (here when it should be there). Complete, or nearly complete, loss of a mental spatial map can be observed in Balint’s syndrome (Balint, 1909; Holmes & Horax, 1919; Rafal, 1997), partial loss can be observed in unilateral neglect (Heilman, Watson, & Valenstein, 1994; Bartolomea & Chokron, 2001), and scrambling is seen in integrative agnosia, where stimuli are processed piecemeal, producing a fragmented percept of parts with little overall coherence (Riddoch & Humphreys, 1987a). Although any of these can be observed in more than one modality, the deficits appear most often or at least are more obvious in vision.

All three types of spatial loss have been associated with (although not necessarily limited to) posterior damage of the human brain, with complete and partial loss more prevalent after dorsal damage (although see Karnath, Ferber, & Himmelback, 2001), whereas spatial scrambling is more prevalent after ventral damage. Complete loss occurs after bilateral dorsal damage, and partial loss occurs after unilateral damage. Also, partial loss and scrambling are more likely to occur after right than left hemisphere damage (Heilman et al., 1994; Ivry & Robertson, 1998; Mesulam, 1981). The common denominator for complete and partial loss is damage to the parietal lobe, but the areas involved are different depending on the nature of the spatial deficits. In fact, several researchers have suggested that the critical areas that produce unilateral neglect (a partial loss of space) are centered in the temporal-parietal junction and the inferior parietal lobe (e.g., Heilman et al., 1994; Mort et al., 2003, but see Karnath, chapter 17 in this volume). Conversely, a recent review of this literature has made a compelling argument for unilateral neglect as a disconnection syndrome. When lesions include the white matter tracts that connect posterior regions to the frontal lobe, neglect is more severe and more likely to be

LYNN C. ROBERTSON Veterans Administration Research, Department of Psychology, and Helen Wills Neuroscience Institute, University of California, Berkeley, California

chronic (Bartolomeo, Thiebaut de Schotten, & Doricchi, 2007).

Conversely, the common denominator in Balint's syndrome appears to be the angular gyrus and dorsal occipital association cortex bilaterally (Rizzo & Vecera, 2002; Rafal, 2001; L. Robertson, 2004). Although there are far fewer cases of patients with Balint's than with neglect, all cases of Balint's syndrome reported in the literature have included damage to these areas. The same areas were also implicated in a postmortem study by Hof, Bouras, Constantinidis, and Morrison (1989) examining the brains of a group of Alzheimer's patients who showed signs of Balint's syndrome during life (an occurrence rate of about 6%). He found more plaques and tangles in the dorsal occipital association cortex and angular gyrus (areas 19 and 39) than in any other portion of the visual brain. Accordingly, Balint's syndrome is not simply the bilateral version of unilateral neglect. Although lesions in unilateral neglect may extend into these areas on occasion, they are not the central areas implicated in the neglect syndrome.

Consequences of complete spatial loss and attention

Obviously, spatial attention will be disrupted if the spatial map that guides it is damaged or lost. When the computations needed to construct this spatial map are compromised, spatial attention deficits will be one major consequence. Thus Balint's syndrome presents an opportunity to study how deficits in spatial attention affect other perceptual and cognitive abilities. It also permits the study of how spatial maps support and interact with other perceptual phenomena. Intuitively, it seems that no meaningful percept would be possible without a spatial framework in which to individuate one entity from another or to guide selective attention within a visual display. Yet studies of cases of Balint's syndrome demonstrate that although the patients are functionally blind, they continue to experience a rather complex perceptual world in which features and objects rise to the level of perceptual awareness but their locations and spatial relationships to each other are unknown (Rafal, 2001). The result is a chaotic perceptual world, but not an absent one as Kant might maintain.

BALINT'S SYNDROME AND OBJECT-BASED ATTENTION There is a great deal of evidence that attention can select objects and locations (see Treisman, chapter 12, this volume) but that these may be independent. In one of the first behavioral studies of object-based attention, Duncan (1984) showed that reporting values on two dimensions (orientation and texture) was faster when the two were on the same object rather than when they were on separate objects. Several other studies have shown that objects modulate spatial attention. For example, Egly, Driver, and Rafal (1994) presented two

parallel rectangles on a screen and cued an end of one of the rectangles randomly on each trial (see Treisman, this volume, figure 12.2). The cue was followed by a target, and response time to detect the target was recorded. Importantly, the distance between the cue and the target in the same rectangle was the same as the distance between the cue and the target in the opposite rectangle. Responses were faster when the target appeared within the cued rectangle than when it appeared in the other rectangle (this difference is the object-based effect). Recently, Alice Albrecht, Alexandra List, and I (2008) showed that this object-based effect depends on whether the rectangles are perceived as objects or holes in a surface. We presented the same type of displays stereoscopically (figure 18.1), so that the rectangles were either seen as objects in front of a homogeneous surface or as two holes through that surface. We found object-based effects that were very similar in magnitude to that reported by Egly and colleagues, but only when the rectangles were perceived as objects. When the rectangles were perceived as holes, the object-based effect disappeared. Importantly these findings were not due to differences in perceived depth of the two rectangles. In a second study we split the background into individuated regions, and now the object-based effect reemerged (figures 18.1 and 18.2).

Object-based attention also has been studied in the fMRI literature. For instance, O'Craven, Downing, & Kanwisher (1999) showed two objects (a house and face) in the center

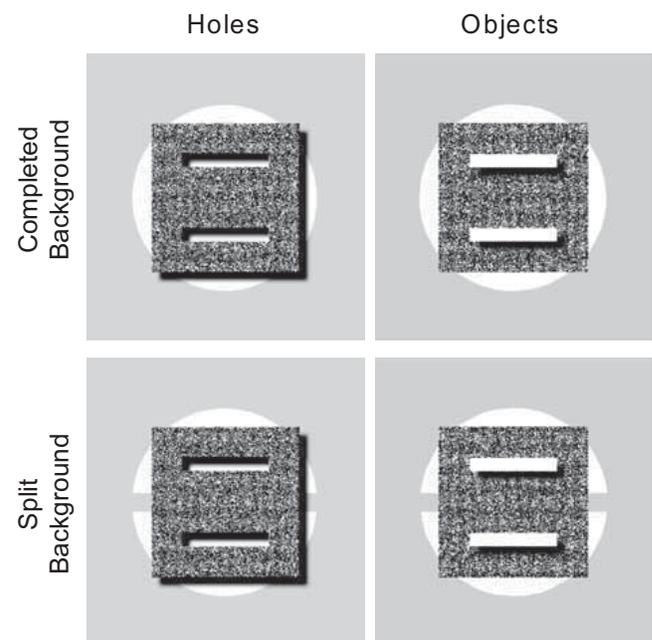

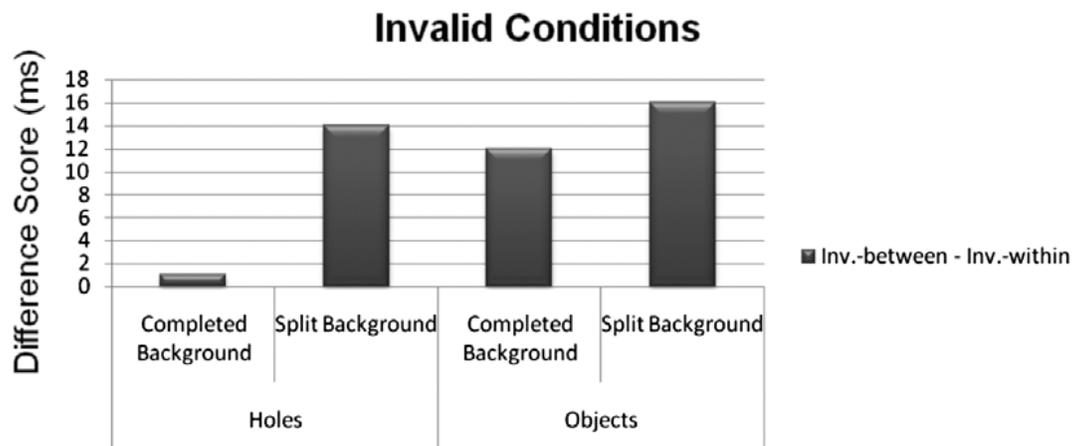

FIGURE 18.1 Example of hole and object stimuli with completed (top) and split (bottom) backgrounds. Shadows are included here only to illustrate the depth that was perceived by the participants when wearing the stereogoggles. They were not present in the actual experiment.

	Holes		Objects	
	Completed Background	Split Background	Completed Background	Split Background
Inv.-Within	422	409	422	403
Inv.-Between	423	423	434	419

FIGURE 18.2 Object-based effects (reaction time difference between the two invalid conditions—between minus within) for rectangles perceived as holes and those perceived as objects when

the background was split and when it was completed (top). Mean reaction time for each invalid condition (bottom). The effects were significant for all but the completed background/holes condition.

of the screen. The two objects were superimposed and appeared transparent. On each trial either the house or the face moved slightly. While making judgments about the motion, there was more activity in ventral areas of the brain that respond to houses (parahippocampal place area) when the houses moved and more activity in the areas of the brain that respond to faces (fusiform face area) when faces moved. Attentional selection for motion (a feature that drives different areas of the brain than houses or faces) incorporated the object that was moving as well.

If object- and space-based attention utilize different neural systems, complete loss of space with Balint's syndrome should attract attention to objects, but there should be little or no knowledge of where they are located, and this result is what occurs. Individuals with this problem see only one object at any given moment (known as simultanagnosia), but they can be at chance in locating it. Neither reaching, pointing, nor verbally reporting where the object is located is accurate. Even spatial judgments such as saying whether the object is toward the top or bottom of the screen when they are several inches apart or toward the patient's own head or feet can be near chance levels. In addition, an object in a visual display will automatically and seemingly randomly attract attention with no control over how long the object remains in view or what object will take its place. The one object that is seen abruptly disappears and is replaced by another object (which need not be in the line of sight and

can be large, small, simple, or complex). This new object is then perceived for a time, until another object takes its place. The computations needed to individuate objects or to define their locations are absent, and the objects that attract attention can come from anywhere in the visual scene. Although patients can move their eyes in any given direction on command, they only rarely do so unless instructed by the observer. They suffer from what Balint (1909) called a "pseudo paralysis of gaze." It is as if the one object they do see fills their entire visual field. Consistently, RM, the Balint's patient whom we studied for several years in my laboratory, reported that the size of objects did not appear as they should be.

The fact that an object as a whole can be perceived at all when spatial deficits are nearly complete is very strong evidence for an object-based system that is separate from a space-based one. However, when the spatial map that individuates objects is absent, voluntary movement of attention between objects is also a problem. It is as if there is a lineup of objects that compete for object selection when spatial information is gone.

BALINT'S SYNDROME AND FEATURE-BASED ATTENTION
Feature-based attention is also well supported in the perceptual literature. It too is thought to be separate from space-based as well as object-based attention. Indeed, attending to a feature in one location makes it difficult to

ignore the same feature simultaneously presented in another location. For example, Saenz, Buracas, and Boynton (2002) measured fMRI activity in motion- and color-sensitive areas of the human brain and found that attending to a particular direction of motion or a particular color in one location modulated activity for the same features presented in distant locations. In the motion study, they presented a set of dots with half the dots moving upward and half moving downward, and directed attention to either the upward or downward movement during a block of trials. The speed of the attended dots varied slightly from trial to trial. The interwoven dots were presented in one visual field throughout a block of trials, and participants were told that they should pay attention to that side and to ignore the other side. The ignored side contained a set of dots that all moved either upward or downward. Thus they were either moving in the same direction as the attended motion or in the opposite direction. When the movement in the ignored field was the same as the selected movement in the attended field, activity in motion-sensitive areas in the hemisphere contralateral to the ignored side was greater than when the motion was different. The same pattern occurred in the color condition in color-sensitive areas. An attended feature produced more activity in areas specialized for that feature whether spatial attention was oriented to the stimulus location or not (also see Hopf, Schoenfeld, & Heinze, 2005). In other words, the feature was attended whether it was on the attended or ignored side. Spatial attention did not interact with feature attention.

If spatial and feature attention are separate, feature-based attention should be present in patients with complete spatial deficits, and this is the case. For instance, a red circle presented among blue and yellow circles of about the same luminance attracted the attention of the Balint's patient RM. Although features were not detected as rapidly or as accurately as for normal observers, the number of distractors in the display did not affect performance (L. Robertson, Treisman, Friedman-Hill, & Grabowecky, 1997). In other words, features did not "pop out" as rapidly as for normal observers, but they did continue to pop out. Importantly, when we asked RM where the feature was located, he was at chance, and he was reluctant to make a judgment, saying things like "You know I don't know where it is." This response occurred even when it remained on the screen until he responded.

We also wondered whether he saw only one feature at a time, similar to his simultanagnosia for objects, but this did not seem to be the case. Marcia Grabowecky and I showed RM a series of displays containing 9 colored circles arranged in a 3×3 matrix. He was shown 180 of these matrices, 60 containing one red or one green circle among 8 blue circles, 60 containing 2 red or 2 green circles among 7 blue ones, and 60 containing one red and one green circle among 7

blue ones. We asked RM to report how many circles were green and/or red. When there was only 1 red or 1 green circle, he correctly reported there was one 90% of the time (7% omissions). When there were 2 colored circles, with 1 green and 1 red, he correctly reported there were two 83% of the time (7% omissions). However, the most interesting finding was when the 2 circles were both green or both red; his accuracy rate dropped to 10%, reporting he saw only one (3% omissions). Afterward we asked him to simply report how many circles he saw in each display and what the colors were. He reported all the colors that were present on each trial but said he saw only 1 circle of all three colors. For example, when shown a display with 1 red among 8 blue, he reported seeing 1 red and 1 blue circle, which was the same response he gave when shown a display with 2 red circles among 7 blue. When shown a display with 1 red, 1 blue, and 7 green, he easily named the 3 colors but said there was only one of each. Subsequently, when asked if there was more blue on the page, he said no.

The undamaged portions of RM's brain encoded basic features in the visual scene but not their location or their relative magnitude. The result was a chaotic perceptual world in which objects appeared and disappeared without warning, and features coded by specialized neural populations were not bound to a location. The result was a high rate of illusory conjunctions (see Treisman, chapter 12). In the absence of space, binding the wrong color, size, or motion with the object of attention is prominent (Bernstein & Robertson, 1998; Friedman-Hill, Robertson, & Treisman, 1995; Humphreys, Cinel, Wolfe, Olson, & Klempen, 2000; L. Robertson et al., 1997).

Consistently, visually searching for a target that was the conjunction of two features was severely compromised (presumably due to RM's binding problem). He was very poor at reporting the presence or absence of a red X among only 3 distractors (e.g., red O and 2 green X 's) and was extremely frustrated by the task. More tellingly, when the red X was absent from the display (e.g., two red O 's and 2 green X 's), he reported that the target was present 38% of the time (L. Robertson et al., 1997). This high false alarm rate was especially revealing when compared to his 4% miss rate when the target was present. When asked if he was reporting what he actually saw, assured us that he was.

RM's description of his visual experiences in everyday life was consistent with a binding problem as well. For example, he reported he saw a house on his street moving sideways. It is quite possible that the motion from a passing car was detected and then bound incorrectly with the object of his attention (the house).

IMPLICIT SPATIAL MAPS Any task that engages spatial attention obviously will be disrupted when the spatial map

that guides it is damaged. Other studies with Balint's patients have corroborated this conclusion. For instance, utilizing a cue to attend to a given location in anticipation of an upcoming target (Posner, 1980) is all but impossible (L. Robertson & Rafal, 2000), and shifting attention from local to global levels of a display is disrupted as well.

Nevertheless, exogenous spatial orienting appears to be intact, and priming measures have shown that shape at a global level of a hierarchically structured pattern is implicitly represented even when it is not perceived (Egley, Robertson, Rafal, & Grabowecky, 1995; Karnath, Ferber, Rorden, & Driver, 2000). In addition, priming studies have shown that implicit spatial information is present in Balint's patients (Kim & Robertson, 2001; L. Robertson et al., 1997). For example RM read the word "up" faster when it was in the upper part of a rectangle than the word "down" in the same location and vice versa, while he was at chance in reporting the word's location. This result leads to the question of why these spatial maps are not accessible after damage to bilateral occipital-parietal areas.

There is ample evidence from neurobiological studies for the existence of multiple spatial maps throughout the visual cortex. Topographical tuning of visual neural responses in animals and fMRI BOLD responses in humans have been mapped from the fine spatial resolution of V1 to the rough spatial resolution of the parietal lobes, as well as in posterior temporal lobes and the frontal eye fields (Anderson, Batista, Snyder, Buneo, & Cohen, 2000; Colby & Goldberg, 1999; Desimone & Duncan, 1995; Graziano & Gross, 1994; Grill-Spector & Malach, 2004; Laeng, Brennen, & Espeseth, 2002; Silver, Ress, & Heeger, 2005; Wandell, Brewer, & Dougherty, 2005). Gross and Graziano (1995) argued that the parietal lobe functions as a selection hub and noted its strong connections to several other areas of the brain that contain topographical maps. Basically, the suggestion is that the parietal lobe is the gatekeeper in a network of spatial maps that decides which spatial map to access for the task at hand. The loss of parietal functioning would deny access to remaining spatial maps through disconnection.

Another possibility is that parietal functions integrate spatial information from other areas that contain topographical information, which then emerges into what Treisman (1988) called a "master map of locations," and it is this map that guides voluntary spatial attention (L. Robertson, 2003). It is also this map that allows for the perception of a unified spatial world. In this scenario, the loss of parietal function directly damages the master map and consequently the necessary spatial information for object individuation, feature colocation, perceptual organization, and of course the voluntary control of spatial attention. The hypothesis is that spatial information that feeds into the computation of the master map stays below the level of spatial awareness even in normal perception to attenuate the possibility of spatial

confusion. Further research is needed to sort out which of these accounts is more plausible.

Consequences of partial spatial loss and attention

Partial spatial loss is much more frequent than Balint's syndrome, and as a result more is known about how syndromes such as unilateral neglect affect perception and attention. In addition to the many scientific papers on the subject, there are several books and chapters that discuss the symptoms, diagnosis, rehabilitation, and/or natural course of recovery over time (see DeRenzi, 1982; Driver, Vuilleumier, & Husain, 2004; Karnath, Milner, & Valler, 2002; Heilman, Watson, & Valenstein, 2003; I. Robertson & Halligan, 1999). Although the neuroanatomical damage that produces unilateral visual neglect is thought to be more anterior than that found in Balint's syndrome (see L. Robertson, 2004), the two spatial problems can produce similar spatial attention deficits that can affect perception in similar ways, but obviously more severely on the contralesional than ipsilesional side for neglect.

Studies of patients with unilateral visual neglect have shown that feature search, although longer on the neglected than unneglected side, remains relatively intact. The difference in search rate for features on the contralesional and ipsilesional sides for patients with neglect is not a result of the fact that a normally parallel search turns into a serial search, since adding distractors on the neglected side does not change response time or accuracy of feature detection (Brooks, Wong, & Robertson, 2005; Esterman, McGlinchey-Berroth, & Milberg, 2000). Conversely, searching for the conjunction of two features (requiring binding and endogenous control of attention) is either not initiated on the neglected side or substantially delayed (often taking a minute or more to begin). Most importantly, the time required to make a decision about the presence or absence of a target on the contralesional side increases as the number of distractors increases (Eglin, Robertson, & Knight, 1989; Esterman, et al.; Laeng et al., 2002; Pavolovskya, Ring, Groswasser, & Hochstein, 2002; Riddoch & Humphreys, 1987b). These findings demonstrate that not all information on the neglected side fails to attract attention. Features that are coded independent of spatial awareness continue to pop out, while conjunctions that require controlled spatial attention do not.

Illusory conjunctions are also more likely on the neglected side of space in cases of unilateral neglect (Cohen & Rafal, 1991), similar to Balint's syndrome, but of course limited to the contralesional side. The most apparent problem in both syndromes is a deficit in spatial attention, and this fact led to the idea that Balint's syndrome was the bilateral version of unilateral neglect. However, this seems not to be the case, as there are important differences between the two

FIGURE 18.3 Example of object-based neglect in drawing of a chair next to a fireplace.

syndromes other than their bilateral/unilateral incarnation. For instance, between 50% and 80% of patients with unilateral neglect also show evidence of object-based neglect (figure 18.3), while patients with Balint's syndrome see nothing but objects, even if only one at a time. Their commonality in disrupting spatial attention does not affect object-based attention in a common way. Also, neglect often disrupts the very concept of space on the neglected side. Patients with neglect act as if that side does not exist, while patients with Balint's syndrome know there is a space out there; they just cannot see it. This observation leads to the possibility that one syndrome represents direct damage to spatial selection, whereas the other represents the loss of a master spatial map on which selection relies.

IMPLICIT PROCESSING AND NEGLECT There has been much interest in what gets processed outside the focus of attention, both in normal observers and in patients with attentional disorders. The case of unilateral neglect presents a situation in which the effects of spatial awareness can be studied in the same individual by comparing performance when stimuli are presented on the ipsilesional and contralesional sides of the visual field. It also provides an opportunity to explore the level at which perceptual processing takes place when the very existence of a sensory event in neglected space is absent.

As with studies of Balint's syndrome, priming methods have shown that a great deal of visual information exists below the level of awareness in the neglected field. For instance, an undetected line drawing of a baseball bat presented on the neglected side speeds the ability to determine whether the letter string "baseball" is a word or not (McGlinchey-Berroth, Milbert, Verfaellie, Alexander, & Kilduff, 1993). The semantics of the undetected object (the baseball bat) primes the word decision response.

Priming from undetected objects in the neglected field can be observed even after almost an hour delay between the prime and probe. Vuilleumier, Schwartz, Clarke, Husain, and Driver (2002) showed primes on the neglected side that

were complete line drawings of objects followed 50 minutes later by probes that were either new or from the prime list. The probes varied in the number of line segments used to draw each object (from sparse to dense) and were presented where the stimuli were clearly visible. Fragmentation threshold was measured and defined as the number of fragments that were necessary for the patients to identify the probe. Thresholds for primes that were not detected at all were lower for old than for new objects and closer to primes that had been seen during the prime phase (although still significantly higher).

Findings such as these show that undetected objects are processed up to and including semantic knowledge and suggest that visual objects are bound as a whole before attention is engaged. They have been used to argue that attention simply acts to modulate information, boosting these preattentively bound items above some threshold for awareness. However, as the next section will show, this is not always the case. Attention does have a role to play in addition to modulation.

IMPLICIT PROCESSING, BINDING, AND ATTENTION The evidence for implicit representations of objects as a whole in the neglected field is consistent with results of studies with normal observers. For instance, using psychophysical measures, Breitmeyer, Ogmen, Ramon, and Chen (2005) varied the time between a shape and mask and examined priming effects for wholes and parts. In one case the shapes were "invisible," and in the other case they were "visible." The prime shapes were a square and diamond with one being shown on each trial followed by a mask that was either congruent or incongruent in shape with the prime (figure 18.4). The primes were either wholes (had connected contours) or parts (e.g., corners). The primes were shown for 13 ms followed by a mask 40 or 200 ms later. At 40 ms participants were unable to identify the primes any better than chance, but at 200 ms, accuracy in discriminating the primes was about 95%. This difference in accuracy was

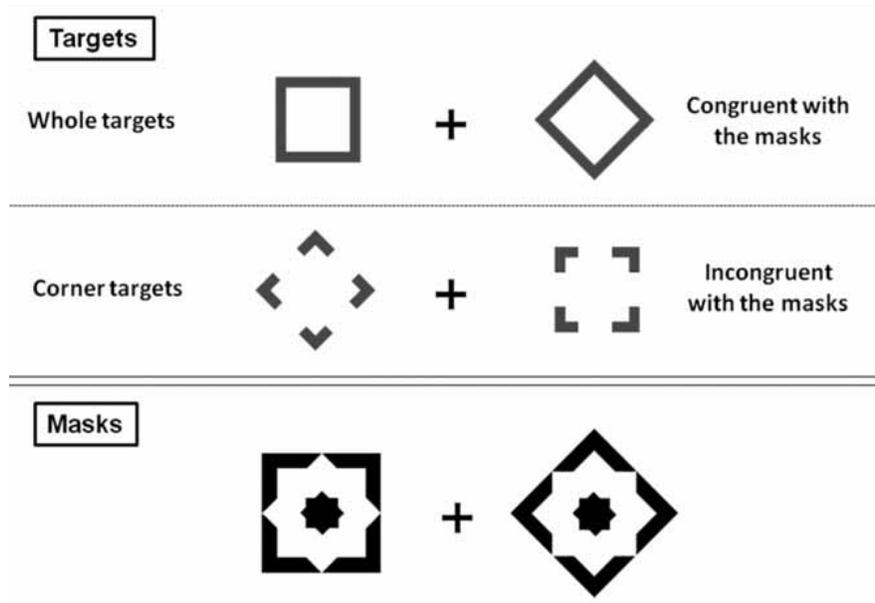

FIGURE 18.4 Example of stimuli used by Breitmeyer, Ogmen, Ramon, and Chen (2005) to study preattentive binding of parts into shapes.

about the same whether the primes were wholes or parts. But the most interesting finding was that congruency between the prime and mask influenced reaction times to report whether the mask was a square or a diamond even in the 40-ms condition where the primes were invisible. Whether the primes were wholes or corners, responses to the mask shape in the congruent conditions were faster than those in the incongruent conditions. The results are consistent with an implicit holistic representation of the prime. However, there was a difference between priming by wholes and parts that depended on visibility, with the congruency effects being larger for wholes than parts when the primes were invisible, but the reverse when they were visible. At the preattentive level, shape representations were stronger when the primes were wholes than when they were parts, while the reverse was true when they were visible. These results suggest that more processing was needed in perceptually binding the corners into a square when the primes were visible, possibly because of their weaker representation at the preattentive level.

A more recent study by Tapia, Breitmeyer, and Schooner (in press) used a similar design to investigate effects of target/mask congruency in binding color and shape and found no evidence for preattentive binding in this case. The primes were again square or diamond shapes, but now all had connecting contours, and the “parts” were shape and color. The shapes were either blue or green on each trial, and the mask was congruent with either the color, the shape, both, or neither. When participants were instructed to respond to the color only or shape only, prime visibility did not affect the degree of priming. However, when they responded to

the combination of feature and shape (i.e., conjunctions), there was no evidence to support conjunction priming in the invisible condition, whereas priming was evident in the visible condition.

These results are also consistent with other behavioral findings reported by Lavie (1997) examining the effects of focused and distributed attention on feature and conjunction processing using a flanker task. Three colored shapes were arranged horizontally across the screen with a target appearing either in the same location on every trial (focused attention) or in one of the three locations (divided attention). When participants were focused on a location throughout the trial, congruency between the target and flanker features (color or shape) influenced response time, with incongruent features causing more interference than congruent features. However, flankers that contained the combination of the two target features were no more influential than the features alone. Conversely, when attention was divided across the display, both incongruent feature and incongruent conjunction flankers interfered with response time. Together these studies suggest that shapes may be bound preattentively, but that features that are properties of a shape (see Treisman, 1996) such as color require spatial attention to be correctly bound.

Tom Van Vleet and I recently pursued this issue by studying three patients with left neglect resulting from right hemisphere stroke in the middle cerebral artery distribution. In a priming study we presented feature or conjunction displays as primes in the periphery followed by probes presented at fixation. Using a staircase procedure, we first determined how long a search display had to be presented (threshold

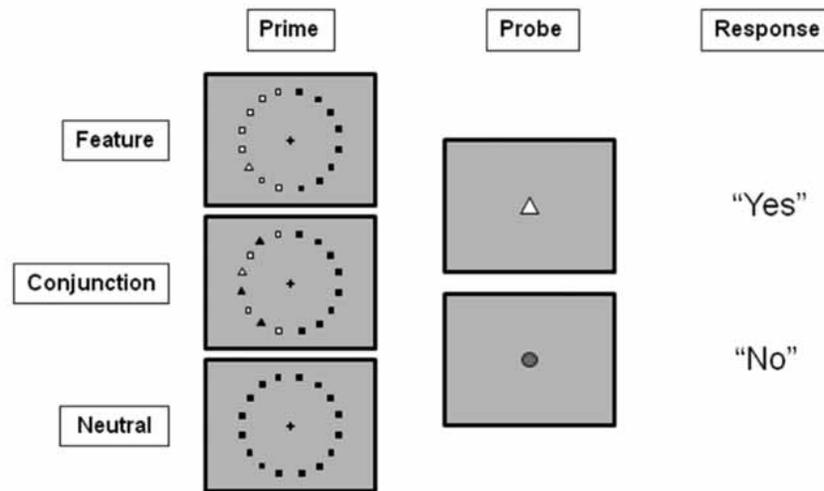

FIGURE 18.5 Example of stimuli used by VanVleet and Robertson in a study of patients with unilateral left neglect/extinction. Dark items in the figures were actually “blue,” white items were actually “red,” and the gray circle probe was actually “yellow.”

presentation time, TPT) to produce a high (75%) or low (25%) probability of target detection for each patient for features on the one hand and conjunctions on the other (figure 18.5). In this way, we equated for detection of features and conjunctions at two levels of difficulty: one in which targets were detected most of the time and another in which they were missed most of the time. We then used the resulting TPTs in a priming stage of the experiment, showing the primes (the same feature and conjunction displays) at the estimated high and low detection TPTs, randomly presented throughout a block of trials. The prime was followed 500 ms later by a single colored shape in the center of the screen, and the patient was asked to respond yes or no as rapidly as possible whether it was a red triangle or not. Priming effects were calculated by subtracting responses to the red triangle when the prime was neutral from when it was either a feature or conjunction target. Priming effects were greater for the conjunction condition when the target was more often visible (high TPT) than when it was more often invisible (low TPT). Conversely, although there was significant priming in the feature condition, it did not differ for high and low TPT (figure 18.6). Follow-up studies demonstrated that neither the differences in the number of red and blue items in the feature and conjunction displays shown in figure 18.5 nor the color differences between the right and left sides of the display could account for these effects.

The evidence from normal observers and patients with unilateral neglect converges to support the conclusion that features coded by specialized neural populations are integrated through spatial attentional control and that parietal functions are critical. Features themselves prime a subsequent response whether or not they are likely to be detected.

The studies in normal observers also suggest that there is a difference between preattentive binding of features such as color and shape and preattentive binding of parts into shape. Top-down control is involved in binding depending on what is to be bound. The visual system appears to work independent of spatial awareness when integrating parts into whole shapes but seems to require spatial attention to bind across separated feature maps. It has been suggested that the neural signal involved in binding produces increased gamma band responses in the EEG (Womelsdorf & Fries, chapter 20, this volume). Consistently, Landau, Esterman, Robertson, Bentin, and Prinzmetal (2007) showed that voluntary spatial attention produced greater induced gamma than did automatic spatial orienting. Likewise, increased BOLD activity in the fusiform face area has been observed when a cue predicts the location of an upcoming target face but not when the same cue is unpredictable (Esterman et al., 2008). Voluntary attention seems to increase the perceptual fidelity of the target, while involuntary does not (Prinzmetal, McCool, & Park, 2005).

FEATURE INTEGRATION THEORY (FIT) REVISITED According to feature integration theory as it was originally proposed by Treisman and Gelade (1980), the reason spatial attention was engaged in conjunction search but not feature search was the binding requirements in detecting a conjunction target among multiple items with similar features. Some investigators have argued that it is not the binding requirements per se but rather differences in difficulty (some call it saliency) between targets embedded in the two types of search displays. When difficulty is high, more top-down mechanisms that control attention must be

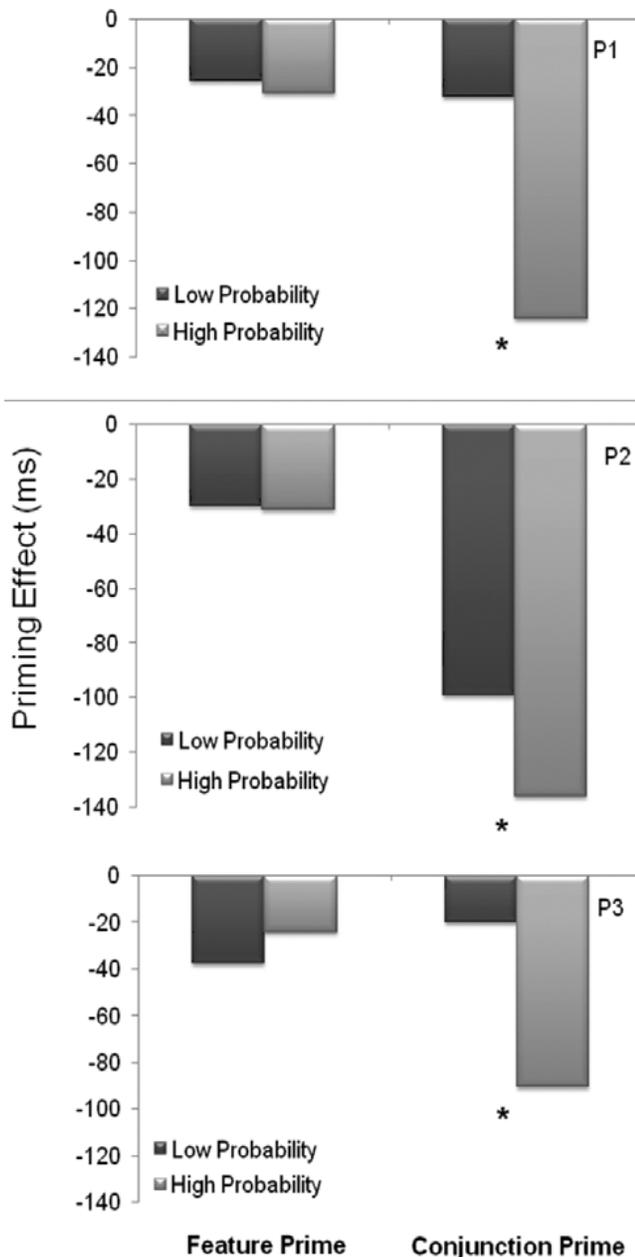

FIGURE 18.6 Differences in reaction time to respond to the central target as a function of prime type (respective search prime minus neutral prime conditions) for three different patients.

engaged than when difficulty is low, and when more top-down attentional control is needed, parietal activity will be higher. There is general agreement that dorsal frontal-parietal attentional systems are activated under most conditions when top-down attentional control is needed to perform a task.

The related question is whether the typical differences in difficulty between feature and conjunction search are a sufficient explanation or whether something else is required, namely, a binding process. The study of neglect described earlier equated search difficulty at a high and low detection threshold, yet found differences in priming between feature and conjunction displays. There is also fMRI evidence that binding can be separated from search difficulty. Donner and colleagues (2002) presented normal participants with conjunction and feature search displays, with the feature search being either the same as or different from the conjunction search in difficulty. Consistent with a difficulty component for search, they found more parietal and frontal activity for both the hard-feature and conjunction-search tasks than for the easy-search task. Nonetheless, they also found an area of activation that could not be explained by difficulty. Activity at the junction of the posterior inferior parietal sulcus and dorsal occipital lobe was more pronounced with conjunction search than with hard-feature search even though behaviorally they were equally difficult. These findings are consistent with a feature-binding mechanism that is engaged in conjunction search but not feature search. They also support FIT in that parietal activity increases whenever a serial search is initiated, but parietal functions are also involved when feature integration is required. The findings are also consistent with previous results using PET to examine the neurobiology of conjunction and feature search. For instance, Corbetta, Shulman, Miezin, and Petersen (1995) showed search displays and varied the task to look for either a feature (motion or color) or the conjunction of motion and color. They found increased activity in both posterior temporal and superior parietal lobes when participants responded to the conjunction of motion and color but only temporal activation when they responded to only motion or only color.

Conclusions

Even when the representation of external space disappears completely with damage to both parietal lobes, anatomically intact areas outside these regions continue to respond to objects and object parts as well as basic features encoded by specialized neural populations (e.g., color, size, motion). However, the locations of these objects and their surface features may not be accurately bound together in perception. Studies of the interaction between spatial maps, attention, and binding with patients who suffer spatial loss (both complete and partial) have contributed to a better understanding of the neural systems involved in the perception of a normally unified spatial world. They also support a role for this spatial map in guiding spatial attention and in perceiving properly bound features. These studies have also clarified what a patient with spatial loss may and may not

see as well as what representations below the level of awareness remain intact.

19 The Effect of Attention on the Responses of Individual Visual Neurons

JOHN H. R. MAUNSELL

ABSTRACT Performance on sensory tasks depends not only on the quality of the sensory signals that are available, but also on the aspects of the sensory signals that the subject attends to. Recordings from individual neurons in trained, behaving monkeys have shown that attention to particular visual stimuli alters the way that those stimuli are represented in cerebral cortex. The primary effect of attention appears to be a gain change, which increases the responses of neurons that represent attended stimuli while decreasing the responses of other neurons. This gain change affects responses to all stimuli proportionately, without affecting the selectivity of neurons or the stimulus that they prefer. This effect alone can explain much of the improvement in behavioral performance that is conferred by attention.

One of the most useful features of a personal computer is its ability to multitask. A computer can simultaneously input text for a document, check the spelling and grammar of recently entered words and phrases, copy the text to disk, check for updates to its software, put up reminders about appointments, and do dozens of other important chores. However, in its low-level hardware, the computer is a serial device. All its tasks are accomplished by a central processing unit (or a few central processing units) stepping rapidly through a sequence of instructions. For the most part, parallel processing in a computer is an illusion created by a central processing unit doing one task at a time, but switching between dozens of different tasks so rapidly that the user does not notice. Much of the effort in computer design during the last few decades has been directed at making the hardware of computers more genuinely parallel by adding more central processing units and by delegating minor tasks to peripheral devices.

In contrast to a computer, the neurons and synapses that make up the hardware of the brain process information in a massively parallel way. Sensory signals are collected and analyzed simultaneously by hundreds of millions of

neurons in the sensory epithelia, and broad fiber tracts convey the results to more central structures that carry out further parallel computations. The brain uses parallel hardware throughout. Even the simplest behavioral response depends on the concerted activity of thousands of motor neurons.

It seems ironic that while computer engineers strive to make the serial hardware at the heart of a computer emulate parallel behaviors, the brain, with a low-level architecture that seems to be the embodiment of parallel processing, completes tasks in a largely serial way. Unlike a multitasking computer, people and animals generally do one thing during any brief interval. While certain vegetative functions can operate autonomously and in parallel, the higher function of the central nervous system seems to be largely limited to one task at a time.

There are physical constraints on what a single organism can do at one time, but no aspect of body design would prevent a person from, say, doing completely independent tasks with each hand. Nevertheless, the brain does most tasks one at a time. This serial nature of the brain is often described in terms of attention. Attention determines which sensory signals control behavior. We attend to one item or group at a time and shift attention from one subject to another to accomplish our goals. Thus attention is a key player in the brain's serial processing of tasks, and it limits the rate at which information can be processed. For example, evidence from split-brain patients suggests that visual search goes faster when each cerebral hemisphere employs an independent focus of attention (Luck, Hillyard, Mangun, & Gazzaniga, 1989).

What is attention, and how does it affect the processing of sensory signals in the brain? Some of the most detailed information about the role of attention in controlling sensory processing has come from studies of the visual system. Here we will focus on findings from studies that examine how attention affects some of the low-level hardware that supports behaviors: the responses of individual units of visual cerebral cortex in monkeys.

JOHN H. R. MAUNSELL Department of Neurobiology, Harvard Medical School, Howard Hughes Medical Institute, Boston, Massachusetts

How severe is the attentional bottleneck?

Before considering how attention affects neuronal signals, it is useful to consider how much attention affects behavioral responses. Attention is often viewed as a bottleneck through which only a small fraction of sensory signals can pass to reach a stage where they are fully processed. Articles describing experiments on attention often note that the brain can only process a tiny fraction of the welter of sensory information that it receives, and they suggest that attention is the mechanism by which the brain selects the most important signals. Such statements evoke the common experience of arriving home with no recollection of the drive from work. However, an inability to produce details of a recent experience may have little to do with attention. Brains do not have the capacity to record every sensory experience. A failure to recollect events is as likely to reflect the limits of memory, recall, or report as it is the limits of attention at the time those events occurred.

When attention is studied with methods designed to isolate it from memory and other factors, the magnitude of its effects varies considerably. In tasks that involve searching for a stimulus that is hidden among similar distractors, attention can impose a severe bottleneck on sensory processing (Verghese & Pelli, 1992). However, most neurophysiological studies of attention do not explore such challenging situations. Instead, many studies of attention to sensory stimuli use designs related to the Posner paradigm (Posner, 1980), where the behavioral consequences of attention are typically moderate changes in thresholds or reaction times. Even within the controlled conditions of the Posner paradigm, attention may have widely varying effects depending on task

demands. Attention might be directed equally to two locations or with different weight to each location depending on reward probabilities (e.g., Mangun & Hillyard, 1990) or the complexity of the task being performed at one location (Lavie & Tsal, 1994; Lavie, 1995). Because the relative amount of attention directed to different stimuli is flexible, behavioral performance may be either severely limited by attention or hardly affected, depending on the stimuli, task, instructions, and reward expectations.

Correspondingly, the effects of attention on neuronal signals can depend on the task a subject performs. Single-unit studies of attention in the monkey visual system have shown that changes in the relative amount of attention allocated to different locations are reflected in the strength of neuronal responses to visual stimuli (Spitzer, Desimone, & Moran, 1988; Spitzer & Richmond, 1991; Basso & Wurtz, 1998; Platt & Glimcher, 1999; Ikeda & Hikosaka, 2003; Boudreau, Williford, & Maunsell, 2006).

A recent study has shown that when task difficulty is increased, the amount that spatial attention changes neuronal responses also increases (Boudreau et al., 2006). In this experiment, a monkey's attention was directed either to a stimulus inside the receptive field of a neuron being recorded in area V4 or to a second stimulus in the opposite hemifield. Responses were typically stronger when attention was directed to the receptive field stimulus than when attention was directed to the other stimulus. However, the difference in response depended on whether the animal was doing an easy or difficult version of the task. When the animal shifted its attention between the two locations in order to detect a 90° change in orientation, responses were modulated relatively little (median 7%, figure 19.1A). In interleaved trials

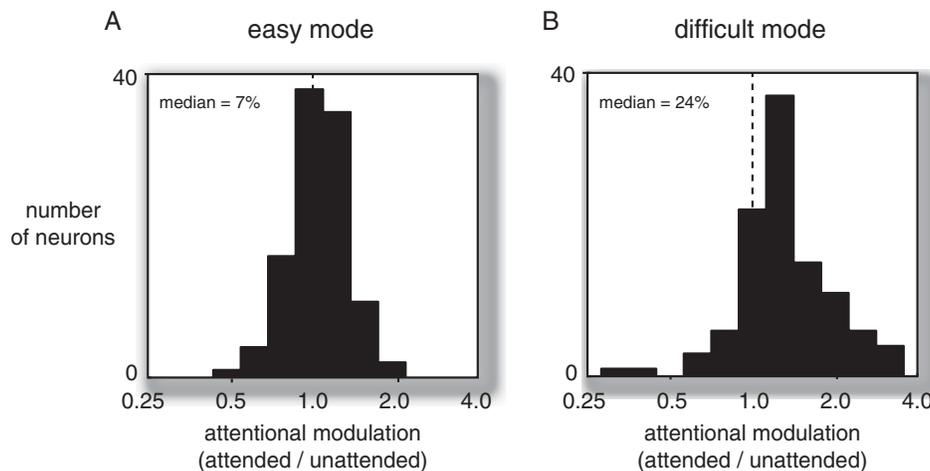

FIGURE 19.1 Attentional modulation of neuronal responses is affected by task difficulty. (A) When animals shifted their attention between a stimulus in the receptive field of a V4 neuron and a distant stimulus, the median modulation across all neurons tested was only 7% when the task was easy (detecting an orientation

change of 90°). (B) When the same neurons were tested during interleaved trials when animals were doing a much more difficult detection (orientation change of ~10°), the median modulation was much greater, 24%. (Data from Boudreau, Williford, & Maunsell, 2006.)

in which the animal was attending to one location or the other to detect a much smaller change in orientation ($\sim 10^\circ$), the locus of attention affected responses much more (median modulation 24%, figure 19.1B).

The amount of attentional modulation of neuronal responses that is observed should be expected to depend on details of the task design. On one hand, because most experiments do not push subjects to the limit of their performance, the magnitude of the attentional modulation of neuronal responses measured in most experiments is almost certainly more modest than it might be. On the other hand, we are rarely pushed to the limits of our abilities in everyday life, so the results reported may be representative of the operating range of attention in typical situations.

How much does attention change the strength of sensory responses?

Because attentional modulation depends on task conditions, there can be no veridical answer to the question of how much attention alters neuronal responses in different parts of visually responsive cerebral cortex. Some general observations are possible, however. First, most studies of attentional modulation of single units describe moderate modulations of rate of firing in all parts of monkey visual cortex, averaging 10–50% (see Maunsell & Cook, 2002). Directing attention toward or away from a stimulus is rarely seen to turn neurons on or off. Functional imaging studies of attentional modulation of neural activity in corresponding regions of human visual cortex have found stronger modulations than those described for single units in monkeys (Kanwisher & Wojciulik, 2000; Pessoa, Kastner, & Ungerleider, 2003). However, EEG and local field potential recordings from human visual cortex typically find moderate effects that are more in keeping with the results from monkey single-unit recording (Hillyard & Anllo-Vento, 1998; Yoshor, Ghose, Bosking, Sun, & Maunsell, 2007), suggesting that the difference may depend more on the indirect measure of neuronal activity used in functional imaging, rather than a species difference. Overall, attention seems to act much more like a moderate filter for sensory representations, rather than a gate, at least in the relatively reduced visual displays that are used in most experiments.

The amount of attentional modulation can depend on stimulus configurations, and some arrangements of visual stimuli consistently produce stronger attentional modulations. Most single-unit studies of attention compare neuronal responses to a given stimulus while attention is directed toward or away from that stimulus. However, shifting attention between two stimuli that are both within a neuron's receptive field can produce stronger modulations. Neurons in later stages of visual cortex generally have receptive fields

that are large enough to hold two stimuli that are sufficiently well separated that a subject can direct attention to one or the other. If one stimulus is a preferred stimulus for the neuron and the other is a nonpreferred stimulus, shifting attention between them can produce two- or threefold changes in neuronal response (Moran & Desimone, 1985; Motter, 1994; Luck, Chelazzi, Hillyard, & Desimone, 1997; Treue & Maunsell, 1999).

Whether this stronger modulation reflects a different mechanism than that engaged when a single stimulus is in the receptive field is an important question that remains to be addressed. To date, no experiment has measured attentional modulations with one and two stimuli in the receptive field under comparable conditions. It remains possible that the greater modulation with two stimuli is only apparent, because measurements made with that configuration compare responses with attention to a preferred stimulus with responses with attention to a nonpreferred stimulus. With a single stimulus in the receptive field, the comparison is instead between responses with attention to a preferred stimulus and with responses to a neutral stimulus (one well outside the receptive field that cannot affect responses directly). Additionally, measurements with two stimuli inside a receptive field require closely spaced stimuli, which make the task more difficult. This extra difficulty may contribute to the stronger attentional modulation in this condition. More information about the role of attention with cluttered visual displays will fill an important lacuna in our understanding of attentional modulation. It is possible that the relatively sparse displays used in most experiments produce modest neuronal modulation compared with that occurring in natural viewing conditions. For example, it has been reported that the responses of neurons in inferotemporal cortex are virtually all-or-none depending on whether monkeys notice a target in a cluttered scene (Sheinberg & Logothetis, 2001), but comparisons were not made using equivalent retinal stimulation in the two conditions.

While attention typically has modest effects on neuronal rate of firing in laboratory experiments, attention has other effects on neuronal response. Attention can also modulate the amount of synchrony or gamma power in neuronal activity, both in monkey microelectrode recordings (Steinmetz et al., 2000; Fries, Reynolds, Rorie, & Desimone, 2001; Taylor, Mandon, Freiwald, & Kreiter, 2005; Fries, Womelsdorf, Oostenveld, & Desimone, 2008) and human macroelectrode recordings (see Gruber, Müller, Keil, & Elbert, 1999; Müller, Gruber, & Keil, 2000; Müller & Gruber, 2001; Jensen, Kaiser, & Lachaux, 2007; Wyart & Tallon-Baudry, 2008). Changes in gamma-band activity have been correlated with the behavioral signatures of attention (Womelsdorf, Fries, Mitra, & Desimone, 2006). While these changes in gamma oscillations or synchrony are

modest, such changes could in principle provide a powerful mechanism for attention to affect sensory processing (see Womelsdorf & Fries, chapter 20 in this volume and Tiesinga, Fellous, Salinas, Jose, & Sejnowski, 2004; Boergers, Epstein, & Kopell, 2005; Tiesinga, Fellous, & Sejnowski, 2008).

Does attention affect the selectivity of visual neurons?

Beyond changing the strength of neuronal responses, attention might also improve behavioral performance by changing the selectivity of neurons. All sensory neurons are selective for certain stimuli. Selectivity for continuous dimensions (e.g., orientation, color, stereoscopic depth) is usually described by tuning curves that plot the strength of a neuron's response to different stimulus values. Narrow tuning curves correspond to high selectivity, while broad tuning curves correspond to low selectivity. How the width of tuning in neuronal populations translates to behavioral performance is a poorly understood and complex subject (see Pouget, Deneve, & Ducom, 1999; Butts & Goldman, 2006), but tuning width is likely to be an important factor in determining behavioral performance. For example, the width of orientation tuning curves might be thought of as the "graininess" of the brain's representation of orientation. By narrowing tuning curves, attention might improve discrimination of different stimulus dimensions.

Given the potential advantages of changing neuronal selectivity, it is notable that single-unit studies have found little evidence for such changes. When orientation tuning curves were measured for neurons in area V4 in monkey visual cortex, attention scaled the entire tuning curve to stronger responses without changing the breadth of tuning (Spitzer et al., 1988; McAdams & Maunsell, 1999a). Figure 19.2 shows average orientation tuning curves from a sample of V4 neurons. The solid points are average responses to different orientations of a receptive field stimulus when attention was directed to the stimulus. The open points are responses to the same stimuli when attention was directed elsewhere. Attention scaled the orientation tuning curve vertically by about 30%, but it did not change the width of orientation tuning.

Similar experiments have shown that attention to a moving stimulus does not affect the breadth of direction tuning for neurons in monkey middle temporal area (MT), even when attention is directed to a specific direction (Treue & Martinez-Trujillo, 1999). Recordings of event-related potentials in humans have likewise seen that spatial attention increases the amplitude of response waveforms with little change in their waveform, latency, or distribution across the scalp (Mangun & Hillyard, 1987, 1990).

A proportional scaling of tuning curves by attention is reminiscent of the effects of changing stimulus contrast or intensity, which similarly increases or decreases responses

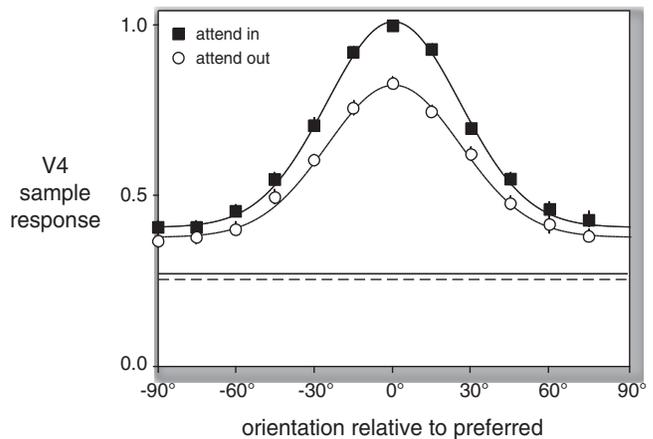

FIGURE 19.2 Average orientation tuning of neurons in area V4 with and without attention directed to the stimulus. The orientation tuning of 262 individual V4 neurons was measured twice: once with the animal attending to the stimulus to report its orientation and once with the animal's attention directed elsewhere. Each neuron's tuning curves were normalized to a maximum response of 1.0 and shifted to align their preferred orientations. Values from both tuning curves were then averaged across cells. Overall, responses were about 30% stronger when the animal was attending to the stimulus in the receptive field (amplitude of the function fitting the response with attention directed to the receptive field, 0.60; with attention directed elsewhere, 0.45). However, width of the tuning curve was unaffected by attention (the width of the fitted functions in both cases was 37°). Horizontal lines mark average spontaneous activity for attended (solid) and unattended conditions (dashed). (Data replotted from McAdams & Maunsell, 1999a.)

without affecting the width of tuning curves (see Troyer, Krukowski, Priebe, & Miller, 1998). This similarity is intriguing because the behavioral advantages conferred by attention, faster responses, and better discrimination are similar to the behavioral consequences of higher stimulus contrast. Thus attention might produce better behavioral performance by effectively increasing the relative intensity of behaviorally relevant stimuli at the level of the cortical representation.

The similarity between the effects of attention and stimulus contrast on cortical responses was reinforced by studies that examined how attention affects neuronal tuning curves for contrast. Most neurons in early stages of visual cortex have sigmoidal tuning curves for contrast. They are insensitive to very low contrasts (lower saturation), produce increasingly strong responses over a middle range of contrasts (rising phase), and then show relatively little change in response as contrast is increased through the highest values (upper saturation). Studies of the effects of attention on contrast response functions in both area V4 (Reynolds, Pasternak, & Desimone, 2000) and MT (Martinez-Trujillo & Treue, 2002) reported that attention had the greatest effect on responses to low contrasts, as if it added a fixed proportion of contrast to stimuli at the attended location

and thereby shifted the contrast tuning curve toward lower values.

However, the effect these reports described was distinct from that described for orientation or direction tuning curves, where attention scaled responses proportionally. If attention scaled contrast tuning curves proportionally, its greatest effect would have been at the highest contrasts, where responses are strongest. A subsequent study of the effect of attention on contrast response functions has called the earlier conclusions into question. Williford and Maunsell (2006) reexamined the effects of attention on contrast tuning curves in V4 and found they could not distinguish whether effects were strongest at low contrast or high contrast. Because most neurons in V4 do not show strong saturation at high contrast, models describing effects primarily at high and low contrast are both able to fit the data well. As noted in that report, while each of the three studies of the effects of attention on contrast tuning curves favored one or the other model, none ruled out the alternative model as an acceptable description.

Thus it remains possible that attention does not have a special effect on stimuli of low contrast, but instead has a single effect on all neuronal tuning curves: a simple proportional scaling of responses to all stimuli, without change in the breadth of tuning or the preferred stimulus. It should be possible to resolve this question by examining neurons with strongly saturating tuning curves and collecting sufficiently precise data to see whether attention has proportionally greater effects at low contrasts.

How does attentional modulation of neuronal responses improve behavior?

What is accomplished by modulating the strength of neuronal responses? One obvious suggestion is that stronger responses can have a better signal-to-noise ratio. Sensory neurons give variable responses. They produce different numbers of spikes in response to different presentations of the same stimulus. For most neurons throughout visual cerebral cortex, the variance in the number of spikes approximates the mean number of spikes for the response, as is true for a Poisson process (Softky & Koch, 1993; Shadlen & Newsome, 1998). If the signal-to-noise ratio of a response is defined as the mean response (signal) divided by the standard deviation of the response (noise), then signal-to-noise is expected to improve systematically as responses are made stronger, because the standard deviation is the square root of the variance, and it therefore remains proportional to the square root of the mean response.

In a study of the effects of attention on the responses to different orientations in V4 (McAdams & Maunsell, 1999b), neurons were found to respond an average of 30% more strongly when attention was directed toward the stimulus in

their receptive field. Calculations showed that this increase in response would improve the median neuron's smallest discriminable orientation (for a peripheral stimulus) from 26.5° to 20.4°, by virtue of improved signal-to-noise.

This study also considered whether attention might have a more dramatic effect on signal-to-noise by reducing the variance directly, but found no evidence for an effect on variance beyond that expected from changing the strength of the response. Recently, however, Mitchell, Sundberg, & Reynolds (2007) reexamined the effects of attention in V4 by classifying neurons as broad-spiking (putative pyramidal cells) and narrow-spiking (putative inhibitory interneurons) based on the duration of their action potentials. Although attention seemed to have proportional effects on the rate of firing of these two cell types, there was a difference in its effects on the variance of their responses. Attention did not affect the relationship between response rate and response variance for the broad-spiking neurons, but for the narrow-spiking neurons there was additional variance when a stimulus was unattended. The effect was small and appeared only at high rates of firing, and the responses of narrow-spiking neurons to attended stimuli had no less variance than broad-spiking neurons showed for attended or unattended stimuli. It is not clear what benefits arise from increasing the variance of responses of one class of cells to unattended stimuli.

This unexpected effect of attention on the variance of the responses of narrow-spiking neurons leads to a more general question about attention and neuronal signal-to-noise. If attention to a stimulus can produce better signal-to-noise through either stronger responses or less variance, why would the brain ever want to decrease the signal-to-noise of neuronal responses? One explanation is the cost of high rates of firing. Metabolic expense is a considerable factor for the brain, which consumes an inordinate amount of the body's energy (Attwell & Laughlin, 2001; Lennie, 2003). It may not be practical to maintain the higher rates of firing to achieve higher signal-to-noise. Alternatively, the answer may instead depend on how neuronal signals translate into target detection and false alarms. Most of the higher signal-to-noise that attention achieves is gained through making neurons more sensitive. When the response of a neuron is enhanced by attention, it will give the same response to some nonpreferred stimuli that it would give to a preferred stimulus when its response is not enhanced. Enhanced responses to nonpreferred stimuli could be interpreted as false alarms about the presence of a preferred stimulus. When you search for red stimuli, it may be acceptable, or even adaptive, to have false alarms from red-preferring neurons, but false alarms from red-preferring neurons are more likely to be maladaptive when searching for other colors.

It has been suggested that attention increases the sensitivity of neurons according to how closely their response

properties match the current target of attention (Treue & Martinez-Trujillo, 1999). For example, if a subject were hunting for red targets in a particular portion of the visual field, the responses of neurons with receptive fields overlapping the attended location would be enhanced regardless of their stimulus preference, and the responses of neurons that preferred red would be enhanced regardless of the location of their receptive fields. Neurons that both preferred red and had a receptive field at the attended location would receive the benefits of both effects and would have responses that were more strongly enhanced than any other neurons.

While this appealing suggestion is consistent with physiological data (see Maunsell & Treue, 2006), it does not address the question of why attention modulates neuronal responses by the amount that it does: what is the right amount of attentional modulation? It is obvious that extreme modulation would be unhelpful. If attention has no effects on neuronal activity, then there could be no behavioral effect of attention. Conversely, if attention acted like a gate that silenced neurons representing unattended attributes while activating neurons that represented attended stimuli, it might produce the equivalent of hallucinations. It is safe to assume that the observed modulations have been optimized, but optimized for what?

An insightful answer to this question was recently provided by Navalpakkam and Itti (2007), who noted that enhancing the responses of neurons with properties that match the target of attention may not be optimal if the visual field contains many distracters that are similar to the target. In a computational study, they showed that in many cases optimal performance is achieved by modulating the sensitivity of neurons not based on how well they respond to the target, but based instead on how well they differentiate the target from distracters. In many situations, the neurons that best differentiate target from distracter will prefer neither. Consistent with this finding, in psychophysical studies with human subjects performing a search for lines of a particular orientation, these investigators found evidence for greatest improvement in sensitivity for an orientation that was neither the target orientation nor the distracter orientation. Neurophysiological recording from single units should be able to provide a direct test of this proposal. Because it provides a specific prediction for the amount of modulation that each neuron should receive, it may help explain the substantial differences in neuronal modulation seen within and between cortical areas (see Maunsell & Cook, 2002).

Concluding comments

There are many important questions about the neuronal underpinnings of attention that remain unanswered. Some of these are straightforward and can be answered using

existing approaches. For example, we still lack information on the specificity of attentional modulation in different areas of visual cortex. Does attention modulate the activity of all neurons with receptive fields overlapping an attended location? Or, if attention is directed to a location to recognize a face, are neurons in areas specialized for motion processing excluded from its effects? Other questions will require approaches that have been used in studies of attention only infrequently. These include exploring whether attention depends on particular neurotransmitters or neuronal circuits. It will be important to know whether attention is a specialized neural system, or if instead it represents just another type of signal that is intermixed with the bottom-up inputs that make up the core of sensory information processing. Finally, there are conceptual challenges to understanding attention and its role in sensory processing. It has been noted that the type of attention we have considered here is formally indistinguishable from what has been called reward expectation in other lines of experiments that are largely separate from studies of attention (see Sparks, 1999; Roesch & Olson, 2003; Maunsell, 2004). Clarifying definitions, terminology, and concepts may play an important role in understanding attention as additional experimental data.

20 Selective Attention Through Selective Neuronal Synchronization

THILO WOMELSDORF AND PASCAL FRIES

ABSTRACT Selective attention relies on the dynamic restructuring of cortical information flow in order to prioritize neuronal communication from those neuronal groups conveying information about behaviorally relevant information, while reducing the influence from groups encoding irrelevant and distracting information. Electrophysiological evidence suggests that such selective neuronal communication is instantiated and sustained through selective neuronal synchronization of rhythmic gamma-band activity within and between neuronal groups: Attentionally modulated synchronization patterns evolve rapidly, are evident even before sensory inputs arrive, follow closely subjective readiness to process information in time, can be sustained for prolonged time periods, and carry specific information about top-down selected sensory features and motor aspects. These functional implications of selective synchronization patterns are complemented by recent insights about the mechanistic consequences of rhythmic synchronization, showing that selective neuronal interactions are subserved by neuronal synchronization that is selective in space, time, and frequency.

Top-down attention is the key mechanism to restructure cortical information flow in order to prioritize processing of behaviorally relevant over irrelevant and distracting information (Gilbert & Sigman, 2007). The behavioral consequences of attentional restructuring of information flow are manifold. Attended sensory inputs are processed more rapidly and accurately and with higher spatial resolution and sensitivity for fine changes, while nonattended information appears lower in contrast and is sometimes not perceived at all (Carrasco, Ling, & Read, 2004; Simons & Rensink, 2005).

These functional consequences of attention require temporally dynamic and selective changes of neuronal interactions spanning multiple levels of neuronal information processing: Attentional selection (1) modulates interactions among single neurons within cortical microcircuits,

(2) modulates the impact of selective local neuronal groups conveying relevant information within functionally specialized brain areas, and (3) controls long-range interactions among neuronal groups from distant brain areas (Maunsell & Treue, 2006; Mitchell, Sundberg, & Reynolds, 2007; Reynolds & Chelazzi, 2004; Womelsdorf & Fries, 2007).

For all these levels of neuronal interactions, converging evidence suggests that the selective modulation of interactions critically relies on selective synchronization. Neuronal synchronization is typically oscillatory in nature; that is, neurons fire and pause together in a common rhythm. When synchronization is rhythmic, it is often addressed as coherence, and we will use these terms interchangeably. This rhythmic synchronization can influence neuronal interactions in several ways: (1) Spikes that are synchronized will have a larger impact on a target neuron than spikes that are not synchronized (Azouz & Gray, 2003; Salinas & Sejnowski, 2001). (2) Local inhibition that is rhythmically synchronized leaves periods without inhibition, while nonsynchronized inhibition will prevent local network activity continuously (Tiesinga, Fellous, Salinas, Jose, & Sejnowski, 2004). (3) Rhythmic synchronization of a local group of neurons will modulate the impact of input to that group, and therefore the impact of rhythmic input will depend on the synchronization between input and target (Womelsdorf et al., 2007). These mechanisms are at work on all levels of attentional selection: At the level of microcircuits, inhibitory interneuron networks have been shown to impose rhythmic synchronization capable of effectively controlling the gain of the neuronal spiking output (Bartos, Vida, & Jonas, 2007; Tiesinga, Fellous, & Sejnowski, 2008). At the level of local neuronal groups, attention is known to selectively synchronize the responses of those neurons conveying information about the attended feature or location (Womelsdorf & Fries, 2007). And the coherent output from these local neuronal groups has been shown to selectively synchronize over long-range connections with task-relevant neuronal groups in distant brain regions (Buschman & Miller, 2007; Saalmann,

THILO WOMELSDORF and PASCAL FRIES Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen, Nijmegen, The Netherlands

Pigarev, & Vidyasagar, 2007; Schoffelen, Oostenveld, & Fries, 2005; Sejnowski & Paulsen, 2006).

These empirical insights suggest that mechanisms underlying neuronal synchronization could be the primary target of selective attention. In particular, top-down attention may act by biasing rhythmic synchronization to establish and sustain a selective neuronal communication structure (Fries, 2005). In the following, we begin by outlining this conceptual framework for selective attention through selective synchronization. We then survey basic insights from empirical and theoretical studies suggesting that rhythmic synchronization is particularly suited to control the selective routing of neuronal information flow, and we review how attention recruits these mechanisms across all levels of cortical processing.

Attentional selection as a dynamic instantiation of a selective neuronal communication structure

During natural sensation, top-down control is dynamically established during ongoing processing. Experimentally, top-down signals are set by task instructions, as well as by instructional cues defining relevant and irrelevant sensory features of the input stream during task performance. In typical paradigms of selective attention, the sensory input is kept identical across trials with variations only in covert attention to different aspects of that input. In such tasks, neuronal responses are modulated with rapid temporal dynamics and high spatial selectivity throughout the cerebral cortex (figure 20.1A).

The temporal dynamics of attentional selection are illustrated by recent evidence of a rapid onset of selective neuronal response modulation in cortical areas as far apart as frontal cortex and primary visual cortices in the macaque brain (Khayat, Spekreijse, & Roelfsema, 2006; Monosov, Trageser, & Thompson, 2008). In these studies, monkeys were instructed to detect a predefined target stimulus in visual displays to guide saccadic eye movement. In frontal and parietal cortex, attentional selection occurred within the first 120 ms following the sensory onset of target and distracter stimuli, allowing prediction of the spatial focus of attention (Gottlieb, 2002; Monosov et al.). Already about 30 ms later, top-down information changes neuronal responses at the earliest visual cortical processing stage in primary visual cortex (Khayat et al.; Roelfsema, Tolboom, & Khayat, 2007), causing a response enhancement for stimuli overlapping with the attentional target stimulus. These findings demonstrate that top-down control restructures cortical activity to sensory inputs across distant cortical sites on a rapid time scale. Attention amplifies almost instantaneously (i.e., with the sensory response latency) the influence of local groups of neurons conveying behaviorally relevant information and attenuates the influence of neuro-

nal groups coding for irrelevant inputs. This finding suggests that distributed groups that process “attended” inputs also interact effectively, establishing selective neuronal communication structures on top of the existing infrastructure of anatomical connections (figure 20.1A): Interactions among neurons conveying information about attended locations or features are rendered effective, while anatomical connections between neuronal groups activated by distracting information are rendered ineffective.

Beyond the temporal dynamics of attentional selection, its spatial selectivity in restructuring cortical information flow is particularly evident across successive processing stages in visual cortex. Neurons at the highest visual processing stage in inferior temporal (IT) cortex have receptive fields that span much of a visual field and respond selectively to complex objects composed of simpler visual features. Part of this selectivity arises from their broad and convergent anatomical input from neurons in earlier processing stages having smaller receptive fields and simpler tuning properties. During natural vision, the large receptive field of an IT neuron will typically contain multiple objects. However, when attention is directed to only one of those objects, the IT neuron response is biased toward the response that would be obtained if only the attended object were presented (Chelazzi, Miller, Duncan, & Desimone, 1993; Moran & Desimone, 1985; Sejnowski & Paulsen, 2006; Sheinberg & Logothetis, 2001).

Such dynamic biasing of responses in IT cortex could be achieved by selective enhancement (suppression) of the impact of those afferent inputs from neurons in earlier visual areas coding for the attended (nonattended) input (Reynolds, Chelazzi, & Desimone, 1999). However, the mechanisms underlying this up- and down-modulation of input gain for subsets of converging connections are only poorly understood, but likely entail a selective increase of temporally precise and coincident inputs from neurons that are activated by attended input in earlier areas. This relevance of spike timing is suggested by fine-grained attentional modulation of precise neuronal synchronization within area V4 (Bichot, Rossi, & Desimone, 2005; Taylor, Mandon, Freiwald, & Kreiter, 2005; Womelsdorf, Fries, Mitra, & Desimone, 2006). Enhanced synchronization of the spiking output among neuronal groups that are activated by attended sensory input (Fries, Womelsdorf, Oostenveld, & Desimone, 2008) results in enhanced coincident arrival of their spikes at their postsynaptic target neurons in area IT. Temporally coincident input is highly effective in driving neuronal activity (Azouz & Gray, 2003; Salinas & Sejnowski, 2001; Tiesinga et al., 2008). It is therefore likely that selective synchronization within area V4 underlies attentional biasing within IT cortex and could thus underlie effective spatial routing of information flow within visual cortex.

Please note that neuronal synchronization is in principle independent of firing rate, in terms of both metrics

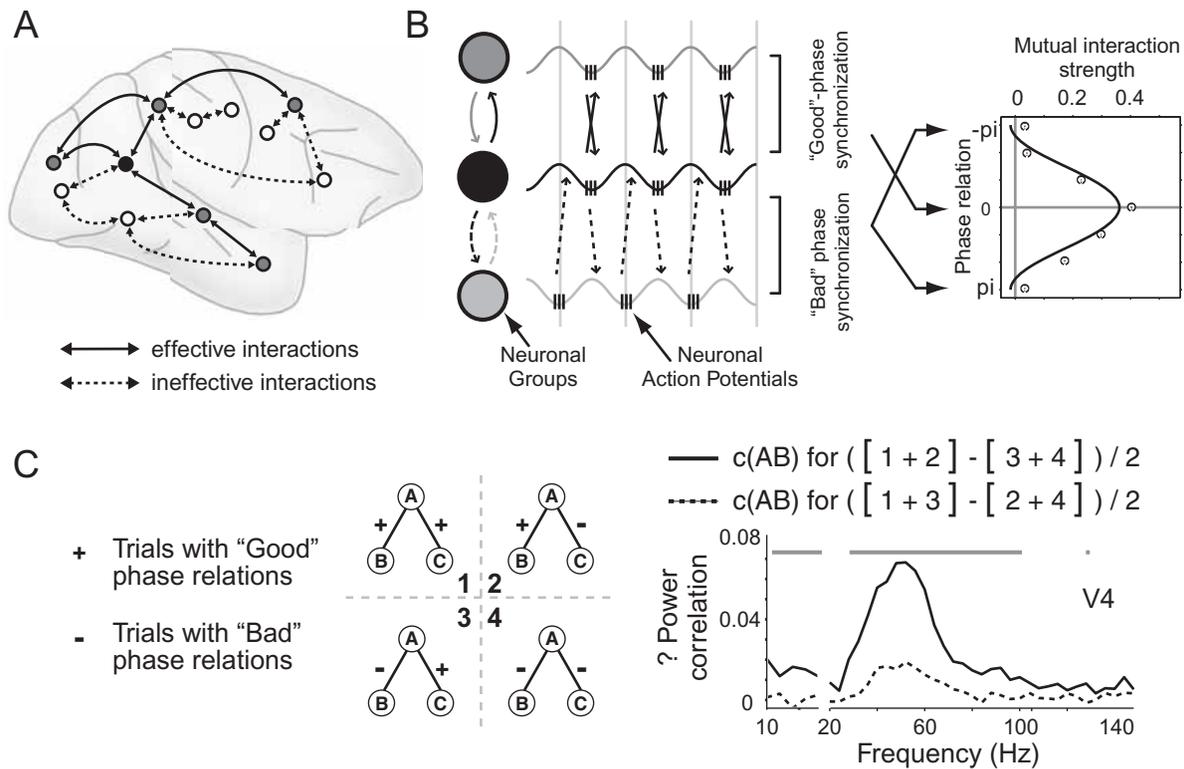

FIGURE 20.1 Selective synchronization renders neuronal interactions among subsets of neuronal groups effective. (A) Anatomical connectivity (sketched as lines) provides a rich infrastructure for neuronal communication among neuronal groups (circles) throughout the cortex. With selective attention, only a small subset of these connections are rendered effective (solid lines). Interactions among groups conveying irrelevant information (light gray circles) for the task at hand are rendered less effective (dashed lines). (B) Illustration of the hypothesized role of selective synchronization for selective communication among three neuronal groups (circles). Rhythmic activity (local field potential, or LFP, oscillations with spikes in troughs) provide briefly recurring time windows of maximum excitability (LFP troughs), which are either in phase

(black and dark gray groups), or in antiphase (black and light gray groups). The plot on the right shows that mutual interactions (upper axis, correlation of the power of the LFP and the neuronal spiking response between neuronal groups) are high during periods of in-phase synchronization and lower otherwise. (C) The trial-by-trial interaction pattern between neuronal groups (A to B and A to C) is predicted by the pattern of synchronization: If AB synchronizes at a good phase, their interaction is strongest, irrespective of whether A synchronizes with C at good or bad phase relations in the same trials. Thus the spatial pattern of mutual interactions can be predicted by the phase of synchronization among rhythmically activated neuronal groups. (Panels in B and C adapted from Womelsdorf et al., 2007.)

and physiology. The different metrics used for quantifying synchronization are typically normalized for firing rate. Physiologically, there are examples where enhanced firing rates are associated with strongly reduced synchronization, for example, the stimulus-induced alpha-band desynchronization in the superficial layers of monkey V4 (Fries et al., 2008). Neuronal gamma-band synchronization typically emerges when neuronal groups are activated, and therefore it is in most cases associated with increased firing rates. However, firing rates and gamma-band synchronization can also be dissociated from each other, and this pattern can be found primarily when firing rate changes are driven not by changes in bottom-up input (e.g., stimulus changes) but rather by changes in top-down input (e.g., attention or stimulus selection) (Fries, Schröder, Roelfsema, Singer, & Engel, 2002; Womelsdorf et al., 2006).

Synchronization is a neuronal population phenomenon, and it is often very difficult to assess it with recordings from isolated single units. Correspondingly, many studies of neuronal synchronization use recordings of multiunit activity and/or of the local field potential (LFP). The LFP reflects the summed transmembrane currents of neurons within a few hundred micrometers of tissue. Since synchronized currents sum up much more efficiently than unsynchronized currents, the LFP primarily reflects synchronized synaptic activity. Changes in LFP power typically correlate very well with changes in direct measures of neuronal synchronization.

Rhythmic synchronization within a neuronal group not only increases its impact on postsynaptic target neurons in a feedforward manner. It also rhythmically modulates the group's ability to communicate, such that rhythmic synchronization between two neuronal groups likely subserves their interaction, because rhythmic inhibition within the two

groups is coordinated and mutual inputs are optimally timed. We capture these implications in the framework of selective attention through selective synchronization (Fries, 2005).

Selective attention through selective synchronization

Local neuronal groups frequently engage in periods of rhythmic synchronization. During activated states, rhythmic synchronization is typically evident in the gamma frequency band (30–90 Hz) (Engel, Konig, Gray, & Singer, 1990; Gray, Konig, Engel, & Singer, 1989; Hoogenboom, Schoffelen, Oostenveld, Parkes, & Fries, 2006). In vitro experiments and computational studies suggest that gamma-band synchronization emerges from the interplay of excitatory drive and rhythmic inhibition imposed by interneuron networks (Bartos et al., 2007; Börgers, Epstein, & Kopell, 2005; Börgers & Kopell, 2003; Buia & Tiesinga, 2006). Interneurons impose synchronized inhibition onto the local network (Bartos et al.; Hasenstaub et al., 2005; Vida, Bartos, & Jonas, 2006). The brief time periods between inhibition provide time windows for effective neuronal interactions with other neuronal groups, because they reflect enhanced postsynaptic sensitivity to input from other neuronal groups, as well as maximal excitability for generating spiking output to other neuronal groups (Azouz, 2005; Azouz & Gray, 2003; Fries, Nikolic, & Singer, 2007; Tiesinga et al., 2008). As a consequence, when two neuronal groups open their temporal windows for interaction at the same time, they will be more likely to mutually influence each other (Womelsdorf et al., 2007). The consequences for selective neuronal communication are illustrated in figure 20.1*B*: If the rhythmic synchronization within neuronal groups is precisely synchronized between the two groups, they are maximally likely to interact. By the same token, if rhythmic activity within neuronal groups is uncorrelated between groups or synchronizes consistently out of phase, their interaction is curtailed (figure 20.1*B*).

This scenario entails that the pattern of synchronization between neuronal groups flexibly structures the pattern of interactions between neuronal groups (figure 20.1*C*). Consistent with this hypothesis, the interaction pattern of one neuronal group (A) with two other groups (B and C) can be predicted by their pattern of precise synchronization (figure 20.1*C*). This result has recently been demonstrated for interactions of triplets of neuronal groups from within and between areas in awake cat and monkey visual cortex (Womelsdorf et al., 2007). This study measured the trial-by-trial changes in correlated amplitude fluctuation and changes in precise synchronization between pair AB and pair AC, using the spontaneous variation of neuronal activity during constant visual stimulation. The strength of amplitude covariation—that is, the covariation of power in the LFP and/or multiunit spiking responses—was considered the measure of mutual interaction strength. The results showed that the interaction

strength of AB could be inferred from the phase of gamma-band synchronization between group A and group B, being rather unaffected by the phase of synchronization of group A with group C (figure 20.1*C*). This finding was evident for triplets of neuronal groups spatially separated by as little as 650 μm , illustrating a high spatial resolution and specificity of the influence of precise phase synchronization between neuronal groups on the efficacy of neuronal interaction. Importantly, additional analysis supported a mechanistic role for the phase of synchronization between rhythmic activities to modulate the effective interaction strength (Womelsdorf et al.). In particular, precise phase synchronization preceded higher amplitude covariations in time by a few milliseconds, arguing for a causal influence of precise phase synchronization to trigger neuronal interactions. Taken together, these results provide the most direct evidence available so far to suggest a critical mechanistic role of selective synchronization for neuronal interactions. They demonstrate that synchronization patterns can shape neuronal interactions with high specificity in time, space, and frequency.

Importantly, these same characteristics of selective neuronal interactions are the key elements underlying selective attention. Attentional selection dynamically evolves at a rapid time scale and with high spatial resolution by enhancing (reducing) the effective connectivity among neuronal groups conveying task relevant (irrelevant) information. Such dynamic restructuring of neuronal interactions could be accomplished through mechanisms evoking selective synchronization patterns within interneuron networks. Selective changes of precise synchronization in local neuronal groups are capable of modulating in a self-emergent manner selective interaction patterns across neuronal groups (Börgers & Kopell, 2008; Mishra, Fellous, & Sejnowski, 2006; Tiesinga et al., 2008).

The outlined scheme of selective attention implemented as selective neuronal synchronization comprises explicit assumptions that selective attention affects interneuron networks and synchronization patterns during task performance. In the following we survey the available insights on interneuron networks and review the emerging signatures of attentional modulation of selective synchronization patterns in macaque cortex.

Synchronization in interneuron networks and their attentional modulation

Interneurons comprise about a fifth of the neuron population, but despite their ubiquitous presence, their functional roles underlying cortical computations or cognitive processes are far from understood (Markram et al., 2004). However, a central role for the control of local cortical network activity has been suggested for a large class of interneurons (primarily of the basket cell type) (Buzsaki, 2006). These neurons

target perisomatic regions of principal cells and are thereby capable of determining the impact of synaptic inputs arriving at sites distal to a cell's soma. Such perisomatic connectivity could therefore critically control the input gain of principal cells across a large population of principal cells (Buzsaki, Kaila, & Raichle, 2007; Cobb, Buhl, Halasy, Paulsen, & Somogyi, 1995; Markram, Wang, & Tsodyks, 1998; Rudolph, Pospischil, Timofeev, & Destexhe, 2007; Tiesinga, Fellous, et al., 2004). As described in the previous paragraph, the inhibitory synaptic influence is inherently rhythmic at high frequencies, carrying stronger gamma-band power than pyramidal cells (Bartos et al., 2007; Hasenstaub et al., 2005).

The prominent role of these high-frequency inputs in shaping the spiking output of principal cells has recently been demonstrated directly in visual cortex of the awake cat. It was shown that the spiking of principal cells is indeed preceded by brief periods of reduced inhibition (Rudolph et al., 2007; see also figure 8 of Hasenstaub et al., 2005). Taken together, these findings suggest that interneurons are the source of rhythmic inhibition onto a local group of neurons synchronizing the discharge of pyramidal cells to the time windows between inhibition.

In the context of selective attention, interneuron networks could be activated by various possible sources. They may be activated by transient and spatially specific neuromodulatory inputs (Lin, Gervasoni, & Nicolelis, 2006; Rodriguez, Kallenbach, Singer, & Munk, 2004). Alternatively, selective attention could target local interneuron networks directly by way of top-down inputs from neurons in upstream areas (Buia & Tiesinga, 2008; Mishra et al., 2006; Tiesinga et al., 2008). In these models, selective synchronization emerges either by depolarizing selective subsets of interneurons (Buia & Tiesinga, 2008; Tiesinga & Sejnowski, 2004) or by biasing the phase of rhythmic activity in a more global inhibitory interneuron pool (Mishra et al., 2006). In either case, rhythmic inhibition controls the spiking responses of groups of excitatory neurons, enhancing the impact of neurons spiking synchronously within the periods of disinhibition, while actively reducing the impact of neurons spiking asynchronously to this rhythm. This suppressive influence on excitatory neurons, which are activated by distracting feedforward input, reflects the critical ingredient for the concept of selective attention through selective synchronization: Attention not only enhances synchronization of already more coherent activity representing attended stimuli, but also actively suppresses the synchronization and impact of groups of neurons receiving strong, albeit distracting, inputs, because they arrive at nonoptimal phase relations to the noninhibited periods in the target group. The computational feasibility of both facilitatory and suppressive aspects and the critical role of the timing of inhibitory circuits have recently received direct support (Börgers & Kopell, 2008).

Despite the prominent computational role of interneuron activity for selective communication, there are only sparse insights into their implications in selective information processing during cognitive task performance. The basic prediction from the preceding models is that interneurons are strongly attentionally modulated. Consistent with this presupposition, a recent study by Mitchell, Sundberg, and Reynolds (2007) reports a clear attentional modulation of putative interneurons in visual area V4 during a selective attention task requiring monkeys to track moving grating stimuli (Mitchell et al.). Putative interneurons showed similar relative increases in firing rate and greater increases in reliability compared to putative pyramidal neurons. However, tests of more refined predictions about the relative modulation of synchronization and the phase relation of spiking responses of inhibitory and excitatory neuron types still need to be conducted (Buia & Tiesinga, 2008).

Selective modulation of synchronization during attentional processing

Direct evidence for the functional significance of selective synchronization within local neuronal groups for attentional selection has been obtained from recordings in macaque visual cortical area V4 (Womelsdorf & Fries, 2007). One consistent result across studies is that spatial attention enhances gamma-band synchronization within neuronal groups that have receptive fields overlapping the attended location (Fries, Reynolds, Rorie, & Desimone, 2001; Taylor et al., 2005; Womelsdorf et al., 2006). The enhanced rhythmic synchronization is strongly evident within the LFP signal, which is a compound signal of activity within a local neuronal group, and is likewise reflected in more precise synchronization of neuronal spiking responses to the LFP. Importantly, the synchronization among the spiking output from neurons coding for the attended location is also enhanced compared to the spiking output of neurons activated by a nonattended distracter stimulus (figure 20.2) (Fries et al., 2008). These attentional effects on spike-to-spike synchronization imply that the postsynaptic targets receive more coherent input from the neuronal groups that convey behaviorally relevant information.

FUNCTIONAL IMPLICATIONS OF SELECTIVE GAMMA-BAND SYNCHRONIZATION In addition to the described attentional effect, recent studies demonstrated that the precision of local synchronization in visual area V4 is closely related to task performance, including behavioral accuracy and the time to detect behaviorally relevant stimulus changes (Taylor et al., 2005; Womelsdorf et al., 2006). This conclusion was derived from an error analysis of the pattern of synchronization in area V4 (Taylor et al.). In this study, the spatial focus of attention could be inferred from the pattern of

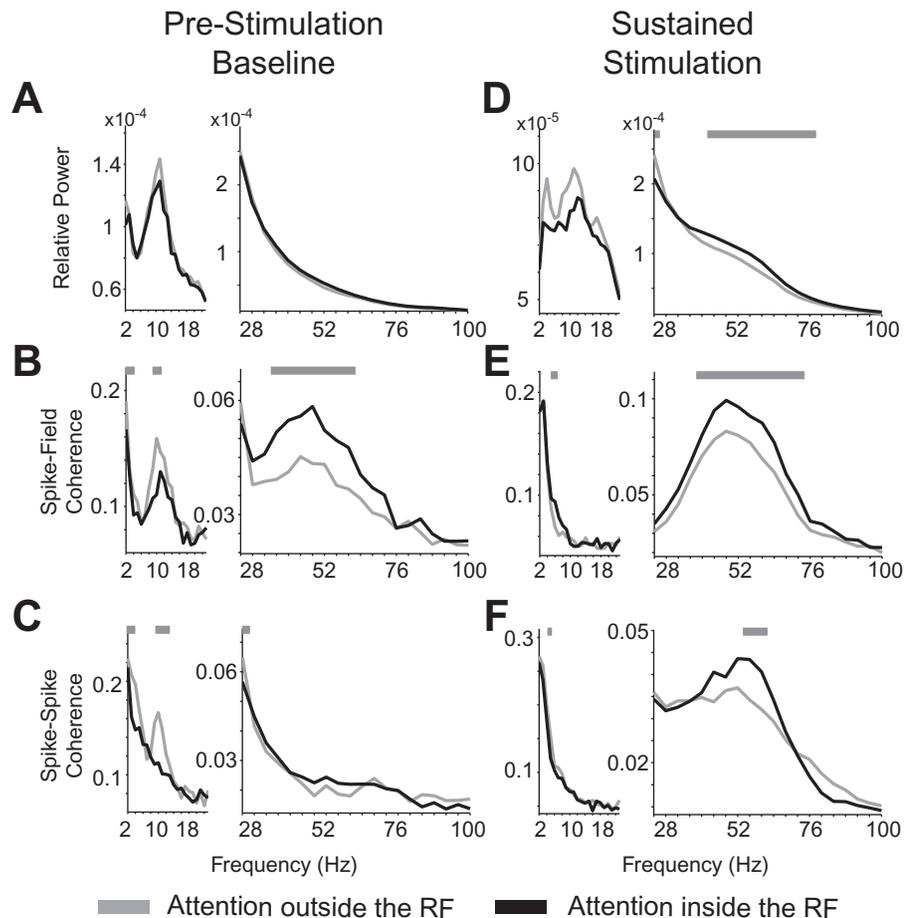

FIGURE 20.2 The pattern of attentional modulation of synchronization in macaque visual area V4 before and during sensory stimulation. (*A–C*) Attentional modulation of relative LFP power (*A*), spike-to-LFP coherence (*B*), and spike-to-spike coherence (*C*) across low and high frequencies during the baseline period of a spatial attention task. Monkeys either attended (dark lines) or ignored

(gray lines) the receptive field location of the recorded neuronal groups in blocks of trials. (*D–F*) Attentional modulation of the neuronal response during stimulation with an attended/ignored moving grating. Same format as in *A–C*. Horizontal gray bars denote frequencies with significant attentional effects. (Adapted from Fries, Womelsdorf, Oostenveld, & Desimone, 2008.)

synchronization measured through epidural electrodes. Gamma-band synchronization was not only stronger for correct trials than for miss trials, but additionally, the degree of synchronization predicted whether the monkey was paying attention to the distracter. Thus this study demonstrated that gamma-band synchronization reflects the actual allocation of attention rather than merely the attentional cuing itself. Furthermore, another recent study demonstrated that the precision of stimulus-induced gamma-band synchronization predicts how rapidly a stimulus change can be reported behaviorally. When monkeys were spatially cued to select one of two stimuli in order to detect a color change of the attended stimulus, the speed of change detection could be partly predicted by the strength of gamma-band synchronization shortly before the stimulus change actually occurred (Womelsdorf et al., 2006). Importantly, the reaction times to the stimulus change could not be predicted at times before the stimulus change by overall firing rates, nor by synchronization outside the

gamma band. Notably, the correlation of gamma-band synchronization with the speed of change detection showed high spatial selectivity: Neurons activated by an unattended stimulus engaged in lower synchronization when the monkeys were particularly fast in responding to the stimulus change at locations outside their receptive field. This finding rules out a possible influence of globally increased synchronization during states of enhanced alertness and arousal (Herculano-Houzel, Munk, Neuenschwander, & Singer, 1999; Munk, Roelfsema, Konig, Engel, & Singer, 1996; Rodriguez et al., 2004). And it argues for a fine-grained influence of synchronization to modulate the effective transmission of information about the stimulus change to postsynaptic target areas concerned with the planning and execution of responses.

These behavioral correlates of gamma-band synchronization during selective attention tasks are complemented by a variety of correlational results linking enhanced gamma-band synchronization to efficient task performance in various

paradigms involving attentional processing. For example, in memory-related structures the strength of gamma-band synchronization has been linked to the successful encoding and retrieval of information (Montgomery & Buzsaki, 2007; Sederberg et al., 2006; Sederberg, Kahana, Howard, Donner, & Madsen, 2003; Sederberg et al., 2007).

SELECTIVE GAMMA-BAND COHERENCE BEYOND VISUAL CORTEX These results of selective gamma-band synchronization with selective spatial attention are supported by a growing number of converging findings from human EEG and MEG studies (Doesburg, Roggeveen, Kitajo, & Ward, 2008; Fan et al., 2007; Gruber, Müller, Keil, & Elbert, 1999; Landau, Esterman, Robertson, Bentin, & Prinzmetal, 2007; Wyart & Tallon-Baudry, 2008). Importantly, attention modulates gamma-band synchronization beyond sensory visual cortex. It has been reported for auditory cortex (Kaiser, Hertrich, Ackermann, & Lutzenberger, 2006; Tiitinen et al., 1993) and more recently in somatosensory cortex. Spatial attention for tactile discrimination at either the right or left index finger in humans enhanced stimulus-induced gamma-band synchronization in primary somatosensory cortex when measured with MEG (Bauer, Oostenveld, Peeters, & Fries, 2006; Hauck, Lorenz, & Engel, 2007). Similar topographies and dynamics of gamma-band synchronization were shown to correlate with the actual perception of somatosensory induced pain (Gross, Schnitzler, Timmermann, & Ploner, 2007). Importantly, enhanced oscillatory dynamics in the gamma band during tactile perception is not restricted to the somatosensory cortex (Ohara, Crone, Weiss, & Lenz, 2006). In recent intracranial recordings in humans, synchronization was modulated across somatosensory cortex, medial prefrontal, and insular regions when subjects had to direct attention to painful tactile stimulation (Ohara et al.).

SPATIALLY SPECIFIC SYNCHRONIZATION PATTERNS DURING PREPARATORY ATTENTIONAL STATES The described gamma-band modulation of rhythmic activity is most prominent during activated states. However, attentional top-down control biases neuronal responses in sensory cortices already before sensory inputs impinge on the neuronal network (Fries, Reynolds, et al., 2001; Fries et al., 2008; Luck, Chelazzi, Hillyard, & Desimone, 1997). In many attention studies, the instructional cue period is followed by a temporal delay void of sensory stimulation. During these preparatory periods, top-down signals set the stage for efficient processing of expected stimulus information, rendering local neuronal groups ready to enhance the representation of attended sensory inputs. Intriguingly, the described preparatory bias is evident in selective synchronization patterns in the gamma band and in rhythmic synchronization at lower frequencies.

In macaque visual cortical area V4, neurons synchronized their spiking responses to the LFP in the gamma band more precisely when monkeys expected a target stimulus at the receptive field location of the respective neuronal group (figure 20.2*B*). This modulation was evident even though rhythmic activity proceeded at far lower levels in the absence of sensory stimulation compared to synchronization strength during high-contrast sensory drive. Lower overall strength, and correspondingly lower signal-to-noise ratio, may account for the lack of significant gamma-band modulation of LFP power or spike-to-spike synchronization during the prestimulus period when compared to attentional modulation during stimulation (figure 20.2).

During preparatory periods, and thus in the absence of strong excitatory drive to the local network, rhythmic activity is dominated by frequencies lower than the gamma band. In the described study from macaque V4, prestimulus periods were characterized by alpha-band peaks of local rhythmic synchronization when monkeys attended away from the receptive location of the neuronal group. Figure 20.2*B,C* demonstrates reduced locking of neuronal spiking in the alpha band to the LFP and to spiking output of nearby neurons (figure 20.2*B,C*). This finding is in general agreement with various studies demonstrating reduced alpha-band activity during attentional processing (Bauer et al., 2006; Pesaran, Pezaris, Sahani, Mitra, & Andersen, 2002; Rihs, Michel, & Thut, 2007; Worden, Foxe, Wang, & Simpson, 2000; Wyart & Tallon-Baudry, 2008). Interestingly, human EEG studies extend this finding by showing that the degree of alpha-frequency desynchronization during prestimulus intervals of visuospatial attention tasks indicates how fast a forthcoming target stimulus is processed (Jin, O'Halloran, Plon, Sandman, & Potkin, 2006; Sauseng et al., 2006; Thut, Nietzel, Brandt, & Pascual-Leone, 2006). For example, reaction times to a peripherally cued target stimulus are partially predicted by the lateralization of alpha activity in the one-second period before target appearance (Thut et al.). While this predictive effect was based predominantly on reduced alpha-band responses over the hemisphere processing the attended position, recent studies suggest that alpha-band oscillations are selectively enhanced within local neuronal groups processing distracting information, that is, at unattended locations (Kelly, Lalor, Reilly, & Foxe, 2006; Rihs et al.; Yamagishi et al., 2003). These findings suggest that rhythmic alpha-band synchronization may play an active role in preventing the signaling of stimulus information. According to this hypothesis, attention is thought to up-regulate alpha-band activity of neuronal groups expected to process distracting stimulus information, rather than to down-regulate local alpha-band synchronization for neuronal groups processing attended stimulus features and locations.

SYNCHRONIZATION PATTERNS REFLECTING TEMPORAL EXPECTANCIES OF TARGET PROCESSING The previous paragraph surveyed evidence for an influence of spatially specific expectancy of target and distracter stimuli on synchronization patterns in visual cortex. In addition to spatially selective expectancy, the expectation of the occurrence of behaviorally relevant target events is known to influence neuronal synchronization patterns and firing rates in parietal and frontal cortex (Ghose & Maunsell, 2002; Janssen & Shadlen, 2005; Riehle, 2005; Schoffelen et al., 2005). Attentional modulation of neuronal firing rates in extrastriate visual area MT is strongest around the time point at which the subjective anticipation for a target change, given that it had not occurred before in the trial (i.e., the hazard rate), is maximal (Ghose & Maunsell, 2002). In premotor and motor cortex, the hazard rate is smoothly reflected in the strength of synchronization (Riehle, 2005; Schoffelen et al.). Importantly, enhanced readiness to respond to attended sensory changes is thereby functionally closely linked to long-range synchronization of motor cortex with spinal motor units suggesting a direct mechanistic influence of synchronization on the speed to respond to behaviorally relevant sensory events (Schoffelen et al.).

An influence of temporal expectancy on synchronization in early sensory cortices has recently been demonstrated in recordings in primary visual cortex of macaques (Lakatos, Karmos, Metha, Ulbert, & Schroeder, 2008). In this study,

monkeys were cued to detect deviant sensory stimuli in either an auditory or visual input stream to receive a reward. Auditory and visual stimuli alternated, and both stimulus streams followed a noisy 1.55-Hz rhythm. This low-frequency rhythm of sensory inputs entrained neuronal responses in early visual cortex, such that responses to individual stimuli in the visual stream added to the entrained response. Attention to the visual stream amplified the entrainment (figure 20.3A), but the most prominent attentional effect was evident in the phase of the 1.55-Hz entrainment in the superficial layers of visual cortex: This entrainment was always determined by the stimulus stream that was attended; that is, it switched by half a cycle when attention switched from the visual to the auditory stream (figure 20.3B), which had a phase opposite to the visual stream. Importantly, low-frequency fluctuations in the LFP likely reflect fluctuations in neuronal excitability. With attention to the visual (auditory) input stream, the phase corresponding to maximal (minimal) neuronal excitability occurred around the average time when the target information was most likely to reach visual cortex. Consistent with a functional role of the entrained delta phase, the authors reported the strongest attentional enhancement of gamma-band synchronization in the LFP and spiking activity around this time (figure 20.3C,D), and showed that the detection of deviant visual stimuli was fastest (slowest) when the delta phase at stimulus onset corresponded to maximal (minimal) neuronal excitability (figure 20.3E).

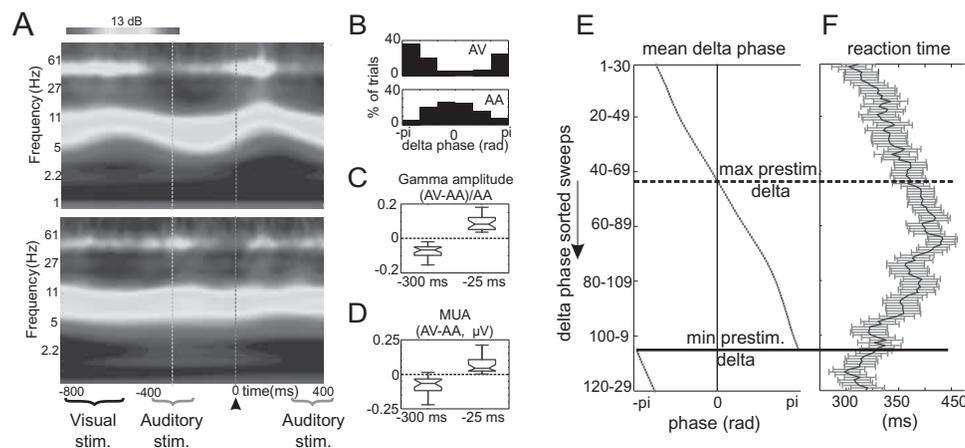

FIGURE 20.3 (A) Entrainment of synchronization from delta- to gamma-band frequencies in supragranular layers of the primary visual cortex during an auditory-visual change detection task. (B) Time-frequency spectrograms during attention to the visual (upper panel) and auditory (bottom panel) input stream, aligned to the onset time of the visual stimulus. The task cued monkeys to detect infrequent deviant stimuli in either the auditory (white noise tones) or visual (red light flashes) input stream. Visual (auditory) stimuli were onset at a regular interval of $650 \text{ ms} \pm 150 \text{ ms}$ indicated below the time axis (mean stimulus rate, 1.55 Hz). (C) Entrainment of delta-frequency phase in visual cortex measured as the delta

(1.55 Hz) phase at the time of visual stimulus onset when attention was directed to the visual (upper panel) and auditory (lower panel) modality across recording sessions. (D, E) Modulation of gamma band amplitude of the LFP (D) and multiunit activity (E) before and at visual stimulus onset. Positive values indicate enhancement with visual versus auditory attention. (F) Reaction times (x -axis) to the visual target stimulus sorted into groups of trials according to the prestimulus delta phase (at 0 ms to stimulus onset) (y -axis). Solid/dashed horizontal lines indicate the group of trials corresponding to maximum/minimum delta amplitudes. (Adapted from Lakatos, Karmos, Metha, Ulbert, & Schroeder, 2008.)

The described results suggest that top-down information selectively modulates excitability in early sensory cortices through changes in the phase of rhythmic entrainment in these areas. The exact frequency band underlying excitability modulations may extend from the low delta band directly imposed by the stimulus structure in the described study to the theta band around 4–8 Hz. This suggestion may be derived from the time-frequency evolution of LFP power in the theta band and its attentional modulation, shown in figure 20.3A. Intriguingly, similar to the effect of delta phase on the gamma-band response demonstrated directly in the discussed study (figure 20.3B), previous studies have linked the phase of rhythmic activity in the theta band to the strength of high-frequency gamma-band synchronization in rodent hippocampus and over large regions in the human cortex (Canolty et al., 2006; Csicsvari, Jamieson, Wise, & Buzsaki, 2003). An additional hint suggesting a functional relevance of low-frequency phase fluctuations can be found in a recent study in rodents demonstrating that neuronal spiking responses in rodent prefrontal cortex phase-lock to theta-band activity in the hippocampus during task epochs requiring spatial decisions in a working memory context (Jones & Wilson, 2005). In macaque visual cortex, the phase of theta-band synchronization has been directly linked to selective maintenance of task-related information (Lee, Simpson, Logothetis, & Rainer, 2005). Taken together, the emerging evidence demonstrates (1) that top-down, task-related information modulates low-frequency rhythmic activity, (2) that the phase of this rhythmic activity can be functionally related to task performance, and (3) that the phase of low-frequency activity shapes the strength of gamma-band synchronization in response to sensory inputs. As such, the pattern of selective synchronization in the gamma band described in the previous paragraphs could be tightly linked to underlying, selective low-frequency activity modulations. Whether both are coupled in an obligatory way, or whether the comodulation may be triggered by specific task demands, will be an interesting subject for future research.

FEATURE-SELECTIVE MODULATION OF RHYTHMIC SYNCHRONIZATION The preceding sections discussed evidence for selective neuronal synchronization patterns evolving with space-based attentional selection of sensory inputs. However, in addition to spatial selection, attention frequently proceeds only on top-down information about the behaviorally relevant sensory feature and independent of the exact spatial location at which input impinges on sensory cortices. Such feature-based attention is known to modulate the responses of neurons that are tuned to the attended feature such as a particular motion direction or the color of a visual stimulus (Maunsell & Treue, 2006).

Importantly, a recent study demonstrated that attention to a particular feature selectively synchronizes the responses

of neurons tuned to the attended stimulus feature (Bichot, Rossi, & Disimone, 2005). In this study, spiking responses and LFPs were recorded from neuronal groups in macaque visual area V4 while monkeys searched in multistimulus displays for a target stimulus defined either by color, shape, or both. When monkeys searched, for example, for a red stimulus by shifting their gaze across stimuli on the display, the nonfoveal receptive fields of the recorded neurons could either encompass nontarget stimuli (e.g., of blue color) or the (red) target stimulus prior to the time when the monkey detected the target. The authors found that neurons synchronized to the LFP more strongly in response to their preferred stimulus feature when it was the attended search target feature rather than a distracter feature.

Thus attention enhanced synchronization of the responses of the neurons that shared a preference for the attended target feature—and irrespective of the spatial location of attention (Bichot et al., 2005). This feature-based modulation was also evident during a conjunction search task involving targets that were defined by two features: When monkeys searched for a target stimulus with a particular orientation and color (e.g., a red horizontal bar), neurons with preference to one of these features enhanced their neuronal synchronization (Bichot et al.). This enhancement was observed not only in response to the color-shape-defined conjunction target, but also in response to distracters sharing one feature with the target (e.g., red color). This latter finding corresponds well with the behavioral consequences of increased difficulty and search time needed for conjunction-defined targets.

This study shows that feature salience is indexed not only by changes in firing rates as has been shown before (Martinez-Trujillo & Treue, 2004; Treue & Martinez-Trujillo, 1999; Wannig, Rodriguez, & Freiwald, 2007), but also by selectively synchronizing neuronal responses depending on the similarity between neuronal feature preferences and the attended stimulus feature. The mechanisms behind this selective influence of featural top-down information could be based on a similar spatial weighting of interneuron network activity as implicated for spatial selection. Neuronal tuning to many basic sensory features is organized in regularly arranged local maps. Correspondingly, the tuning of groups of neurons measured with the LFP is locally highly selective. Importantly, neuronal stimulus preference is systematically related to the strength of neuronal synchronization in the gamma frequency band. This relationship has been demonstrated for stimulus orientation and spatial frequency (Frien, Eckhorn, Bauer, Woelbern, & Gabriel, 2000; Gray, Engel, König, & Singer, 1990; Kayser & König, 2004; Kreiter & Singer, 1996; Siegel & König, 2003), the speed and direction of visual motion (Liu & Newsome, 2006), and the spatial motor intentions and movement directions (Scherberger & Andersen, 2007; Scherberger, Jarvis, &

Andersen, 2005). These findings show that rhythmic synchronization conveys feature-selective information. Feature-based attention appears to recruit this property with high spatial resolution by modulating which neurons synchronize to the local rhythmic activity.

Taken together, the previous subsections surveyed the accumulating evidence demonstrating selective neuronal synchronization patterns that evolve with selective spatial and feature-based attention within sensory cortices. Only a few studies have extended these insights to ultimately reveal how synchronization patterns within sensory areas are related to selective neuronal interaction patterns between different visual areas and between visual and higher-order cortical areas during task performance. Recent evidence shows that such dynamic inter-areal interaction patterns are evident in long-range synchronization patterns between cortical areas.

Selective inter-areal synchronization during attentional processing

In the preceding sections, selective synchronization patterns evolved for local neuronal groups in sensory cortices and were evident primarily within a confined gamma frequency band. These findings critically support a functional role for gamma-band synchronization for the selective restructuring of neuronal communication during attentional processing

(cf. figure 20.1). However, attentional processing relies on effective interactions between local subsets of neuronal groups from distant cortical regions. So far, only a few studies have investigated these inter-areal interaction patterns during task epochs with selective attention (Engel, Fries, & Singer, 2001; Varela, Lachaux, Rodriguez, & Martinerie, 2001; Womelsdorf & Fries, 2007). The emerging evidence from these studies points toward a critical role of rhythmic long-range synchronization in frequencies both within and below the gamma band, including prominently a beta band that spans frequencies from 15 Hz to 30 Hz.

Early studies in awake cats demonstrated transiently enhanced beta-frequency synchronization among visual cortical and premotor regions, and between visual cortex and thalamus during nonselective states of expectancy of a behaviorally relevant stimulus (in, e.g., go-no-go tasks) (Roelfsema, Engel, König, & Singer, 1997; von Stein, Chiang, & König, 2000; Wrobel, Ghazaryan, Bekisz, Bogdan, & Kaminski, 2007). Recent studies in the macaque monkey have extended these findings by showing that frontoparietal and intraparietal interactions between areas are accompanied by synchronization at high beta frequencies (20–35 Hz) during task epochs requiring searching for and selecting behaviorally relevant visual stimuli (Buschman & Miller, 2007; Saalman et al., 2007). Figure 20.4 illustrates findings from a visual search task requiring monkeys to detect a search target that is either salient and pops out among distracting stimuli

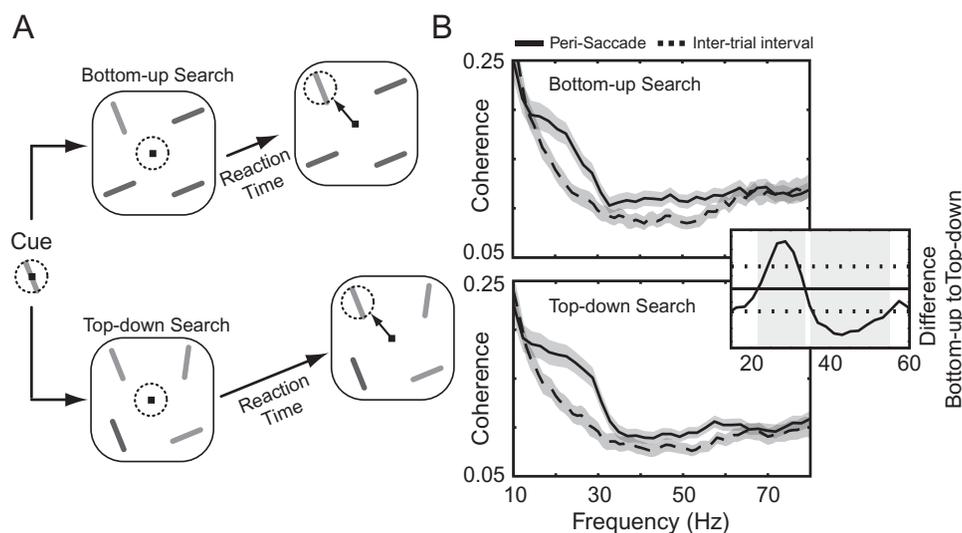

FIGURE 20.4 Selective modulation of long-range synchronization between frontal and parietal cortex during visual search. (A) Sketch of two visual search tasks used by Buschman and Miller (2007). A cue instructed monkeys about the orientation and color of a bar that was the later search target in a multistimulus display during a bottom-up search task (both target color and orientation were unique, upper panels) and during a top-down search task (target shared color or orientation with distracting stimuli, bottom panels). Monkeys covertly attended the multistimulus array and made a

saccade to the target stimulus position as soon as they found it. (B) The authors measured the coherence of the LFP activity of neuronal groups in the frontal eye field and dorsolateral prefrontal cortex and parietal area LIP. The line plots on the right show the coherence (y -axis) for different frequency bands (x -axis) in the bottom-up and top-down tasks, along with the coherence difference across tasks (solid line in inset). The results show that attentional demand modulated long-range frontoparietal coherence at different frequency bands. (Adapted from Buschman & Miller, 2007.)

(“bottom-up search”) or that is nonsalient because it shares features with distracting stimuli (Buschman & Miller, 2007). In contrast to bottom-up salient targets, the nonsalient target stimuli were detected more slowly, indicating that they require attentive search through the stimuli in the display before they are successfully detected (“top-down search”). Paralleling the difference in behavioral demands, the authors found a selective synchronization pattern among the LFPs in frontal and parietal cortex. While attentive “top-down search” enhanced specifically rhythmic synchronization at 20–35 Hz compared to the “bottom-up” search, the stimulus driven “bottom-up” search resulted in stronger inter-areal synchronization in the gamma-frequency band (figure 20.4B). The pattern of results is most likely due to relative differences in task demands in both search modes and was unaffected by differences in reaction times. Therefore these findings suggest that inter-areal communication during attentional top-down control is conveyed particularly through rhythmic synchronization in a high beta band, either in addition to or separate from the frequency of rhythmic interactions underlying bottom-up feedforward signaling.

Consistent with a functional role for top-down-mediated long-range neuronal communication, various experimental paradigms demanding attentive processing have shown long-range synchronization in a broad beta band, although mostly at frequencies below 25 Hz. The following provide a few examples of beta-band modulation in recent studies using very different task paradigms: Variations in reaction times and readiness to respond to a sensory-change event induced corresponding fine-grained variations of motor-spinal coherence in the beta band (Schoffelen et al., 2005). Somatosensory and motor cortex synchronize in the beta band during sensorimotor integration (Brovelli et al., 2004). Selective working memory maintenance in a delayed match-to-sample task results in stronger coherence in the beta band between higher visual areas in humans (Tallon-Baudry, Bertrand, & Fischer, 2001) and locally predicts performance in a similar task in the monkey (Tallon-Baudry, Mandon, Freiwald, & Kreiter, 2004). The failure to detect a target stimulus in a rapid stream of stimuli in the attentional blink paradigm is associated with reduced frontoparietal and frontotemporal beta-band synchronization (Gross et al., 2004). And as a last example for a potential functional role of beta-band activity, the perception of coherent objects from fragmented visual scenes goes along with transiently enhanced beta-band synchronization of the LFP among prefrontal, hippocampal, and lateral occipital sites (Sehatpour et al., 2008).

Taken together, these diverse findings agree to suggest that inter-areal synchronization critically subserves neuronal interactions during attentive processing. In the surveyed studies, synchronization in a broadly defined beta band occurred selectively during task epochs requiring effective

neuronal integration of information across distributed cortical areas. However, further studies need to elucidate the properties of particular frequency bands and their characteristic recruitment during specific tasks (Kopell, Ermentrout, Whittington, & Traub, 2000).

Concluding remarks

Selective attention describes a central top-down process that restructures neuronal activity patterns to establish a selective representation of behavioral relevance. The surveyed evidence suggests that attention achieves this functional role by selectively synchronizing those neuronal groups conveying task-relevant information. Attentionally modulated synchronization patterns evolve rapidly, are evident even before sensory inputs arrive, follow closely subjective readiness to process information in time, can be sustained for prolonged time periods, and carry specific information about top-down selected sensory features and motor aspects.

In addition to these functional characteristics, insights into the physiological origins of synchronization have begun to shed light on the mechanistic underpinning of selective neuronal interaction patterns at all spatial scales of cortical processing: At the level of single neurons and local microcircuits, studies are deciphering the role of inhibitory interneuron networks, how precise timing information is conveyed and sustained even at high oscillation frequencies, and how rhythmic synchronization among interneurons is actively made robust against external influences (Bartos et al., 2007; Vida et al., 2006). These insights are integrated at the network level in models demonstrating how selective synchronization patterns evolve in a self-organized way (Börgers & Kopell, 2008; Tiesinga et al., 2008).

Acknowledging those basic physiological processes underlying the dynamic generation of selective synchronization seems to be pivotal to further elucidation of the mechanistic working principles of selective attention in the brain.

Introduction

J. ANTHONY MOVSHON AND BRIAN A. WANDELL

THIS IS THE FOURTH edition of *The Cognitive Neurosciences*. With each succeeding edition comes the same question: Why does a volume on cognition include sensation and perception—and a double dose at that? The answers to these questions lie in the chapters of this section.

For more than a century, there has been a systematic quest to understand what and how physical information is captured by the nervous system. A great gift of 20th-century neuroscience is a set of beautiful and definitive experiments that explain much about this peripheral encoding. Through the use of illusions and demonstrations, introductory textbooks rightly emphasize that these peripheral signals must be interpreted for their biological significance. For example, the signals encoded in the retina do not measure the distance to a predator; the signals encoded in the auditory nerve do not specify the significance of a sound. Rather, as Helmholtz taught us, the brain uses the receptor signals to make inferences about information. The ongoing work in sensation and perception has shifted to focus on questions about the brain's computational circuitry: What are the computations performed on raw sense data by the sensory systems? What quantities of interest are extracted by these computations? What neural circuits perform them, and how do these circuits work?

Science is frequently imprisoned by technology, and neuroscience is no exception. Our view of brain function has been conditioned and distorted by the methods that we have available. In sensory neuroscience, the dominant technique for most of the last quarter-century has been single-unit recording. Unit recording experiments offer unparalleled access to the details of neural computation and allow us to measure activity at a fundamental computational scale of the system. But the resolution of unit recording comes at a cost. Brain function depends on the organization and trans-

mission of information over distances far larger than a single electrode can sense, and we have had a difficult time obtaining a view of the nervous system's actions at long spatial scales. Our view is expanding on the basis of new methods for measuring neural signals at multiple length scales. There are noninvasive methods to measure the spatial organization of cone photoreceptors in the living human eye and new methods to measure spatially resolved activity in the human brain. Techniques for studying cells now measure dozens of cells at once and can even track important activation-related signals from local clusters of thousands of neurons. These advances all provide valuable information about the way in which sensory signals are encoded by populations of neurons and how these signals are interpreted within the brain. The new measurements are accompanied by developments in computational principles and tools that help us to understand how the nervous system extracts biologically relevant events from a complex array of environmental signals. The chapters in this section show how the combination of new measurements and analytic methods are being combined to create a deeper understanding of how the nervous system represents biologically relevant sensory events.

The topics in this section span vision, audition, olfaction, analysis, and theory. The reader will find a wide array of techniques, including anatomy, electrophysiology, optical imaging, neuroimaging, behavior, and computation. The close connection between computation and methods is nicely illustrated in the chapters concerned with peripheral encoding. Brainard considers how one might make unexpected inferences about object color from the encoding by the three types of cones; Carroll, Yoon, and Williams analyze the information contained in the cone spatial mosaic. The computational analysis of neural encoding is fundamental across sensation. Yeshurun and colleagues describe how psychophysical and computation methods are used to understand the organization of olfaction. Richards and Kidd introduce the reader to questions about how the auditory system disentangles sounds in a complex environment. Two theoretical chapters, by Simoncelli and Barlow, consider approaches to analyzing information in sensory arrays. Simoncelli offers a modern approach that builds on the fundamental work of important pioneers; Barlow, one of these pioneers, gives us a historical perspective and puts his current thinking in that context.

Much important work remains to be done at the single-neuron level, and each of the chapters by Connor and colleagues, DeAngelis, and Angelaki and colleagues offers a snapshot of the state of the art. Connor and colleagues show how the rigorous application of quantitative analysis methods can begin to offer an account of the transformation of information about visual sensory elements in V1 into a more subtle and sophisticated representation of object features in temporal cortex. DeAngelis considers area MT, best known

for its contributions to visual motion perception, and gives an account that combines unit recording and behavioral analysis to demonstrate that MT also plays a key role in the perception of depth. Angelaki and colleagues remind us that visual signals are processed in combination with information from other senses, and describes a series of experiments showing the coordinated role that vestibular and visual signals play in representing information about motion through the world in areas that used to be considered "purely" visual. There are intimate links between sensory and motor systems, none closer than the link between the visual system and the oculomotor system. Morrone and Burr review behavioral and functional imaging work, addressing the ways in which these systems work together to compute our stable perceptual experience from a highly unstable retinal signal.

Many researchers now seek to take data from the unit level and generalize it into a form that can be used to account directly for behavior. Ringach reexamines the specificity of neuronal response in the most-studied of all sensory areas—V1—and shows unexpected relationships between that specificity and the cortex's functional architecture. Seidemann and colleagues also start with the familiar visual representation in V1 but use optical imaging techniques to ask about population activity on a scale of millimeters rather than microns. Drawing on his recordings, on simultaneous behavioral measurement, on knowledge from unit work, and on the theory of encoding and representation, he constructs an account of simple visual performance.

The revolution in functional MRI, enabling scientists to make spatially resolved measurements of the awake-behaving human brain, has also played an important role in sensation and perception. The chapters by McKone, Griffiths, and Goebel and their colleagues describe approaches to interpreting signals in human visual cortex. Taking a developmental approach, McKone and colleagues seek to understand how the pathways that are needed to recognize and interpret faces develop. Griffiths and colleagues apply computational methods to understanding the structure of sounds and then further considers ideas about how the responses spread across cortex might interpret these sounds. Goebel and De Weerd examine the process of image interpolation (filling-in) in visual cortex. Notions of interpretation are often connected with neural plasticity (see Section II), which also plays a major role in sensory processing. Wright and Zhang document a series of behavioral studies showing how auditory information processing depends on training and experience, suggesting that much of the cortical machinery studied by others can adapt its function to suit the needs of the organism.

Taken together, these contributions show that sensation and perception are intertwined with cognition in two fundamental ways. First, the work in sensation and perception

crosses borders between many fields, integrating work in behavior, neuroscience, and computation. This field offers an excellent testing ground to evaluate many of the techniques that will be needed as we develop the field of cognitive neuroscience. Second, the chapters in this section show clearly that the information that sensory and perceptual pathways provide to cognition sets critical bounds on the

information that is available to the brain. These are limits that influence the thoughts we have, the decisions we make, and the emotions we experience. Perception provides three dimensions of color and three dimensions of space; there are molecules whose smell evokes pleasure or disgust. Sensation and perception serve the needs of cognition; cognition, in turn, works within the bounds set by perception.

21 Grandmother Cells, Symmetry, and Invariance: How the Term Arose and What the Facts Suggest

HORACE BARLOW

ABSTRACT By the late 1960s, recording from sensory pathways had shown that single neurons can be much more sensitive, selective, and reliable than had previously been recognized. The term *grandmother cell* started as a fanciful name for a high-level neuron that might enable us to experience complex perceptions and discriminate among them. The concept included invariance of response for changes in some variables as well as selectivity of response for others, together with the idea that these cells are created by processing at a hierarchy of levels. This chapter first outlines the discoveries that eventually led to the general acceptance that such cells really exist. It then discusses hierarchical processing, the evolution of the cortex, and ideas about the new behavioral faculties that evolved with it. Finally it points to the enormous, unaccounted for number of neurons in the cortex and suggests that this plays a major role in enhancing our ability to exploit symmetry and invariance in our environment.

The term *grandmother cell* suggests that there are particular neurons in the visual cortex that are activated by the sight of one's grandmother, and it implies that such neurons play an important part in generating high-level perceptions and discriminating between them. The term was introduced in 1969 by Jerry Lettvin (see Barlow 1995), and in the first part of this chapter, I shall present a brief history of the facts as they have been discovered since then. In the early years, many people thought that it was just a catchy term for an implausible idea that would lead nowhere, but by now, it is clear that neurons fitting this definition really exist and that advances in understanding their neurophysiology will constitute real progress in understanding the brain, particularly the conscious, thinking parts of it.

Even before Lettvin had coined the term, Konorski (1967) had championed the idea that what he called *gnostic neurons* were the end result of a hierarchical series of transformations along the lines that Hubel and Wiesel (1962, 1965) had suggested from the results of their single-unit recordings in the

visual cortex. Although this idea of a hierarchy has not completely crashed, it has had a bumpy ride and never specified a functional goal that the supposed hierarchy might help to achieve.

The second part of this chapter briefly considers some objections to the idea of a hierarchy, but we rapidly encounter the fact that the cortex contains vastly more neurons representing each location in the visual field than the retina or LGN, and the need for this vast excess has not been explained by any current computational model. This makes one suspect that the cortex performs computations that are different from those of earlier stages in the visual pathway or other parts of the brain, which adds a new slant to the problem. To help decide what these new computations might be, in the third part I look at the problem from a broader perspective, consulting other academic disciplines, and this leads to the idea that the cortex uses the symmetry and invariance present in its input to generate a more economical, sparser, representation of the environment.

A brief history

Charles Gross deserves at least as much credit as anyone else for the actual experiments on which claims about grandmother cells rest, and in his essay "Genealogy of the Grandmother Cell" (Gross, 2002), he tells how Jerzy Konorski's neuropsychological studies of visual agnosia, with evidence of the functional hierarchy of neurons in the visual cortex from Hubel and Wiesel, further helped by Jerry Lettvin's fertile imagination, may have guided his laboratory toward these discoveries. Gross gave the definition shown in box 21.1, and this will be adopted as an initial working definition, since it coincides well with most people's usage. However, one of the main points of the grandmother cell idea is that the cells' responses are largely unaffected by changes of grandma's position, pose, clothing, facial expression, and so on. Invariance has got lost in box 21.1's definition, but it is at least as important a property as selectivity is.

HORACE BARLOW Department of Physiology, Development and Neuroscience, University of Cambridge, Cambridge, United Kingdom

Box 21.1 Definition of Grandmother Cells by Charles Gross (2002)

A “grandmother cell” is a hypothetical neuron that responds only to a highly complex, specific, and meaningful stimulus, such as the image of one’s grandmother.

Konorski (1903–1973) was a psychologist who had worked with Pavlov and is best known for making the distinction between what are now termed *operant conditioning* and *Pavlovian conditioning*. He was also a clinical neurologist and was particularly interested in disturbances in the understanding and production of speech. In some patients, the disturbance is confined to a specific category of objects; for instance, one patient might confuse the names of small human-made objects (figure 21.1, line a), with little or no evidence of confusions within categories sketched on other lines, whereas another patient’s problems might be confined to animate objects (figure 21.1, line f). Konorski suggested this is because the relevant part of the cortex is subdivided spatially into distinct regions that he called *gnostic fields*, so local damage could affect one category without affecting others. For future reference, note the bottom line (figure 21.1, line i), suggesting there is a gnostic field that specializes in body parts.

Konorski was aware of the work of Hubel and Wiesel (1962, 1965) on the selective sensitivity of individual neurons in the visual cortex, and when they suggested that these neurons are arranged in a functional hierarchy, he took this up and proposed that his gnostic fields are populated by *gnostic neurons*, whose job it is to respond to images of particular objects within the semiological category for the gnostic field they are located in. For example, in the “small human-made objects” gnostic field, he thought that some neurons might respond when a key was shown to the patient and others when a pair of spectacles was shown and that these different responses would enable them to be distinguished and appropriately named by the patient.

Gross reviewed *The Integrative Action of the Brain* (Konorski, 1967) and was mightily impressed by it, so he started testing Konorski’s ideas in his lab, where he was recording from neurons in monkey inferotemporal cortex. Gross’s lab was then at the Massachusetts Institute of Technology, where Jerry Lettvin daily preached his inspired views in his own imaginative style. I was once accused of inventing grandmother cells and wrote to Jerry Lettvin to ask whether he was the real hero (or villain). He immediately confessed, explaining that in 1969, he had had to take over a lecture course at short notice and wanted to illustrate how a neuron might represent a rather complex concept. He therefore prepared the story sketched in box 21.2.

Box 21.2 Lettvin’s Story Illustrating the Grandmother Cell Concept

In the distant Ural mountains lives my second cousin, Akakhi Akakievitch, a great if unknown neurosurgeon. Convinced that ideas are contained in specific cells, he had decided to find those concerned with a most primitive and ubiquitous substance—mother. Starting with geese and bears . . . he progressed to Trotskyites under death sentence in Siberia. . . . He located some 18,000 neurons clustered in von Seelendonck’s area . . . that responded uniquely only to the animal’s mother, however displayed . . . animate or stuffed . . . offered by caricature, photograph, or abstraction . . . etc., etc.

The story went on for many more paragraphs and ended up with poor Akakhi, on the threshold of a Nobel Prize, having to start all over again with grandmother cells because, for reasons that are beyond me, mother cells with such properties would be politically unacceptable. (With his permission, Lettvin’s letter was reproduced in full in an appendix in Barlow, 1995.) Note particularly the last two lines of Lettvin’s story, emphasizing the invariance of the selectivity of the postulated neurons for many types of change in the stimulus.

It must surely have been the experimental results obtained by recording the activities of neurons in sensory pathways that gave Jerry Lettvin the idea that a complex concept could be represented by the firing of a single neuron, for by the late 1960s, this work had shown that single neurons were much more sensitive, reliable, and selective in their responses than had previously been supposed. The facts and arguments that led to this conclusion can be found in my review (Barlow, 1972), but three points about this early work deserve attention.

First, a lot of the early research came from outside the field of vertebrate neurophysiology, for example, work on insects and crustaceans (Wiersma, Waterman, & Bush, 1961; Hartline, 1949; Reichardt, 1961). Second, the field was fertilized by ideas from different, apparently unrelated, fields; I was myself much influenced by the idea of innate releasing factors and fixed action patterns from ethology and by the importance of signal-to-noise ratios from signal detection theory and feature detectors from early work on pattern recognition and computer vision. Third, the work of Lettvin and his colleagues on the frog visual system (Lettvin, Maturana, McCulloch, & Pitts, 1959), though not reported with enough detail to satisfy some of their colleagues, was certainly effective in spreading the important message that single neurons respond reliably, and in some cases invariantly, to complex and meaningful features in the visual field.

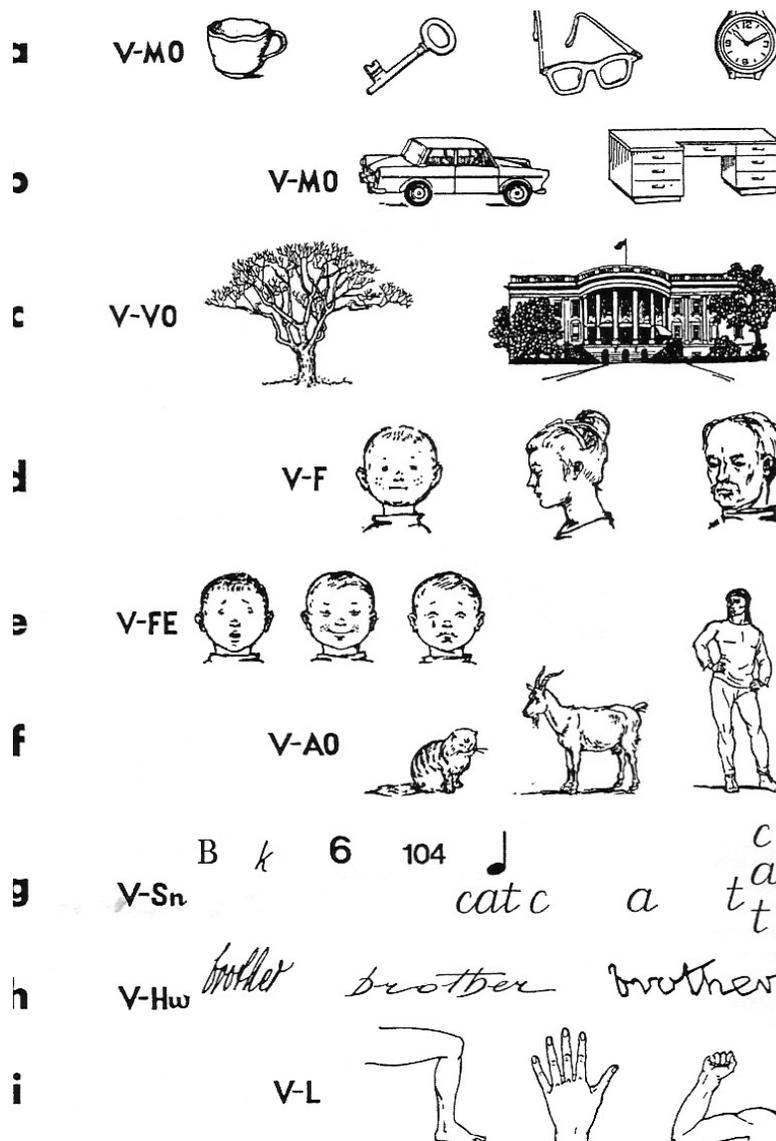

FIGURE 21.1 Konorski's gnostic fields and neurons. Clinical evidence suggests that aphasia is sometimes partial, affecting the ability to name or recognize objects in specific semiological categories, such as small human-made objects (line a), facial expression (line e), or body parts (line i). When Hubel and Wiesel (1962, 1965) put forward the hierarchical view of cortical processing, Konorski

suggested that single gnostic neurons within each gnostic field responded selectively to different items within the semiological category of that gnostic field. This is very similar to Lettvin's proposal (see box 21.2) but does not emphasize the invariance of their responses. (From Konorski, 1967; Gross, 2002.)

MIT lies across the Charles River from Hubel and Wiesel's lab at Harvard Medical School, from which the evidence for a hierarchical functional organization in the cortex had emerged. Hubel and Wiesel (1959) had discovered that neurons in V1 are selective for the orientation of visual stimuli, and I shall make a digression here to illustrate how difficult it was to make that step. This is based partly on my own experience somewhat later, when I was working with Bill Levick on retinal ganglion cells in the rabbit (Barlow, Hill, & Levick, 1964); these fall into many different categories whose high degree of selectivity for different, specific

patterns makes them, in some respects, like precortical grandmother cells.

Most people who have recorded from neurons in sensory pathways will have experienced the long periods of intense frustration that occur when you know that your electrode is near a cell, because you detect its action potentials when it fires spontaneously, but you are unable to find the visual stimulus, nicknamed its "trigger-feature," that reliably excites it. In such cases, one frequently relieves one's frustration by moving on to another neuron in the hope that one will find its trigger feature more easily, but in the following quotation,

David Hubel describes how he and Torsten Wiesel persisted and were rewarded.

They had initially assumed, like others before them, that a uniform field of light would stimulate most cells in visual cortex, but they did not find any significant responses to such general changes of illumination. They therefore started projecting small dark or light spots onto a screen, because these are very effective stimuli for retinal ganglion cells and LGN neurons, so they at least knew that the inputs to the cortical neurons would be strongly active. What happened next is described by David Hubel in box 21.3.

Gross and his colleagues, exploring a new part of the cortex, were in an even more unpromising position, and it might have been in some desperation that they resorted to testing responses to objects for which Konorski had postulated “gnostic neurons.” When they tried items for the “body parts” category (figure 21.1, line f), they obtained results such as those shown in figure 21.2, and many examples of neurons selective for the view of a monkey face were also found.

These amazing results initially evoked much skepticism, and many reasons for disbelieving them were advanced: Perhaps the view of another monkey’s face or hand aroused the interest of the monkey whose cells were being probed, and this general excitement spread to the particular cell being recorded from. Without actually being present and observing many responses to many different stimuli, one can certainly be forgiven for being skeptical and cautious, for there is an almost infinite range of stimuli that could have been tested, and there is real difficulty in describing the

range that was actually used and why these were selected. One wonders whether they ever heeded Lettvin’s voice and tried a real grandmother!

The neurophysiological world was slow to repeat these experiments, but more papers from Gross’s own lab (Gross, Bender, & Rocha-Miranda, 1969; Gross, Rocha-Miranda, & Bender, 1972; Desimone, Albright, Gross, & Bruce, 1984), from Perrett, Rolls, and Caan (1982) in Oxford, and from Yamane, Kaji, and Kawano (1988) in Japan convinced most of us that neurons are to be found in monkey inferotemporal cortex (and elsewhere) that respond better to monkey-like faces than to other visual stimuli (“better” here means simply that more spikes were produced during the few hundred milliseconds following the stimulus). These responses can be produced from a wide range of positions in the visual field and over a wide range of distances, so they show considerable invariance for retinal image position and size while remaining selective for pattern. Different neurons varied a great deal in how selective they were for the pose or orientation of the stimulus, and they responded to both monkey and human faces. In some cases, it seemed clear that a good response was reserved for a particular human individual’s face, among a dozen or so tested, regardless of pose, position, and distance. It also came to be appreciated that faces are peculiarly important for monkeys, and Perrett’s work in particular (Perrett, Heitanen, Oram, & Benson, 1992) showed that some cells were responsive to aspects of the image presented that had special behavioral significance, such as the direction of a monkey’s gaze.

One extraordinary development was the finding of face cells in humans (Kreiman, Koch, & Fried, 2000; Quiroga, Reddy, Kreiman, Koch, & Fried, 2005). Single neurons were recorded from the medial-temporal regions of patients whose brains were being explored in order to shed light on the origins of their epileptic attacks, and the researcher reported neurons that were responsive not only to images of the actresses Jennifer Aniston and Halle Berry, but also, in one instance, to the written name. It is amazing how this finding echoes the spirit of Lettvin’s imaginary neurons that “responded uniquely only to the animal’s mother, however displayed . . . animate or stuffed . . . offered by caricature, photograph, or abstraction.” One particularly wants to know how the experimenters selected the range of stimuli that were tested. How did they happen to have available the

**Box 21.3 David Hubel and Torsten Wiesel
Discover Orientational Selectivity (Hubel, 1988)**

After about five hours of struggle, we suddenly had the impression that the glass with the dot was occasionally producing a response, but the response seemed to have nothing to do with the dot. Eventually we caught on: it was the sharp but faint shadow cast by the edge of the glass as we slid it into the slot that was doing the trick. We soon convinced ourselves that the edge worked only when its shadow was swept across one small part of the retina and that the sweeping had to be done with the edge in one particular orientation. . . .

The discovery was just the beginning. . . .

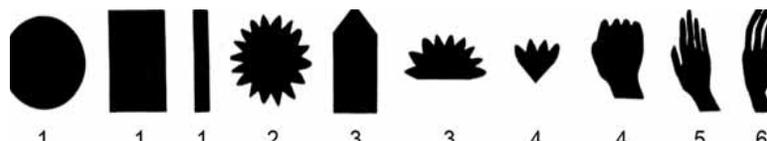

FIGURE 21.2 Examples of shapes used to stimulate a group TE unit apparently having a very complex trigger feature. The stimuli are arranged from left to right in order of increasing ability to drive the neuron from none (1) or little (2 and 3) to maximum (6). (From Gross, Rocha-Miranda, & Bender, 1972.)

picture of the right actress when testing a particular neuron? Although there are, inevitably, unanswered questions about such work, done under such very restrictive conditions, these results illustrate beautifully the property of selectivity for one characteristic of the stimulus (personal identity) while maintaining invariance for others (e.g. whether this identity is conveyed by a photograph or in writing).

Turning back to Gross's definition, we can see that he was perhaps overly modest, for by 2002, the existence of neurons that are very like "grandmother cells" was no longer hypothetical. We can also see that Gross was unfortunate in adopting the prototypical name Lettvin had chosen for explaining the concept of a class of cells that were selectively sensitive to "highly complex, specific, and meaningful stimuli"; no one has ever reported cells whose trigger feature was actually "grandmother." The term is flippant, incomplete, and not quite accurate, but it is widely understood, and I shall stick with it.

Although by the new millennium, the mere existence of grandmother cells could not seriously be doubted, their reported properties were very variable, and although they were known to be widely distributed, they were not thought to occur anywhere with high density. Furthermore, their functional roles and how they were wired up to produce their selective sensitivities and invariant responses remained unknown. But this was about to change.

The first important finding was that significant fMRI responses occur at several positions in scans of humans viewing whole faces but not fragmented faces or nonface objects (Puce, Allison, Gore, & McCarthy, 1995; Kanwisher, McDermott, & Chun, 1997). Apparently one of these face-sensitive patches, as they are called, the fusiform face area, even yields significant blood oxygen level dependent (BOLD) fMRI responses when the subject just thinks of faces (O'Craven & Kanwisher, 2000). Tsao, Freiwald, Knutsen, Mandeville, and Tootell (2003) showed that rhesus monkeys also have several face-selective patches, and detailed statistical analysis of the BOLD responses in different cortical positions to different stimulus objects showed that the pattern of activation produced by a stimulus object contained sufficient information to determine which of the objects was a face.

This is an intriguing finding that replicates similar analyses of human fMRI results (Haxby et al., 2001; Spiridon & Kanwisher, 2002). It shows that much information about the nature of a stimulus object can be derived from the distribution of activity in the cortex on the coarse spatial scale of voxels provided by the fMRI scans. It has also been shown that microstimulation in regions that are rich in face-selective neurons interferes with the correct categorization of noise-perturbed face images by awake, behaving monkeys (Afray, Kiani, & Esteki, 2006). Since microstimulation is thought to act on a spatial scale considerably coarser than that available to single neurons, this result fits in with that

of Haxby and colleagues (2001). However the fact that the object identification problem can be solved by using information segregated on a coarse scale and is interfered with by the coarse-scale interference of microstimulation by no means disproves the idea that the brain depends upon face-selective single neurons to recognize and discriminate between faces.

If the brain only uses the coarse-scale information revealed by fMRI, what part of the brain performs the complex statistical computation that Haxby and colleagues (2001) had to do on the fMRI data to get their result? But even though it can be interpreted in misleading ways, the fact that the coarse-scale localization of activity provides information for object identification remains important.

Kanwisher and colleagues (1997) also realized that fMRI scanning might open an opportunity for serious analysis of grandmother cells in monkeys, for it could perhaps tell neurophysiologists precisely where to place their electrodes to obtain a high yield of face-selective cells and thus make systematic examination of their varied properties possible, and perhaps it could also reveal the significance of there being several face-selective patches. Although such examination is still in its early stages, the technique is showing enormous promise.

In the first experiments in which they guided their recording electrode not just to the general region where previous investigators had found face cells, but to the region in a specific monkey where fMRI had revealed face-specific activity, Tsao and colleagues found 97% of neurons (out of about 400 recorded from) that showed greater response to pictures of whole faces than to nonface objects or to fragmented face images (Tsao, Freiwald, Tootell, & Livingston, 2006; Tsao, 2006). This compares with a figure no higher than 30% (and often much lower) for previous investigators who were not using fMRI guidance. Figure 21.3 shows three prominent face patches in the temporal lobe of a macaque, together with BOLD responses from a face patch as a function of time when stimulated by faces alternated with hands or other nonface objects. The third part of the figure compares the healthy responses to the faces with the insignificant or even weakly negative responses to all nonface objects, with the exception of an apple and a clock, which gave weak but significant positive responses that need no further comment.

It is interesting that the face stimuli that were used in these experiments were pictures of human faces, all presented in full-face, erect view. As might be expected, the monkeys' cortical neurons actually preferred monkey faces, consistently giving larger responses to them than to human faces. They also gave weak responses to a very crude face cartoon when it was erect but not when it was inverted, as shown in the bottom two lines in figure 21.3, and this was important, for it made possible a later, more detailed analysis of the

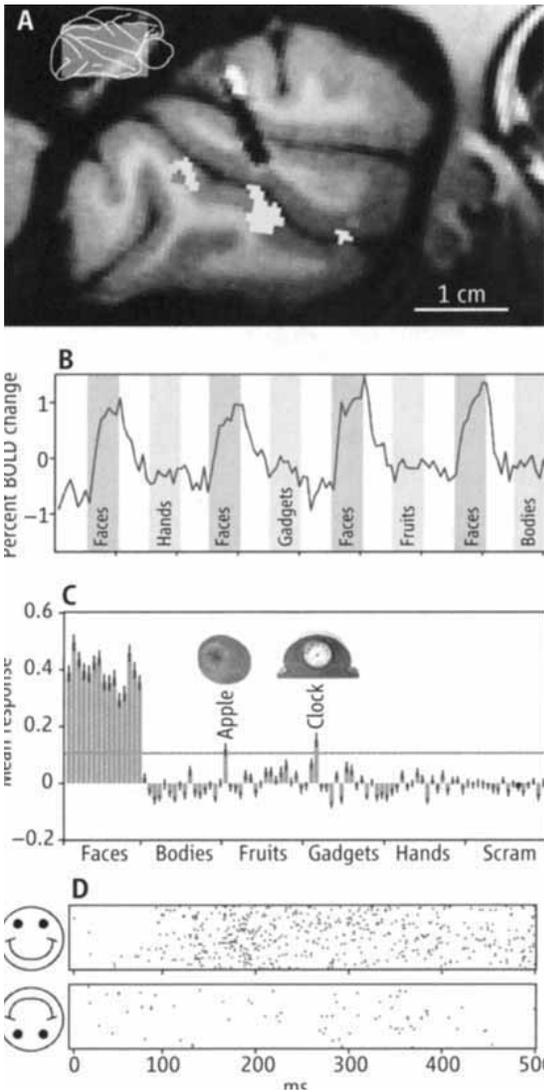

FIGURE 21.3 (A) Three patches of face-selective fMRI activation (yellow regions) in the macaque temporal lobe. (B) Time course from the face patches. Blood flows to these regions increase only when the monkey views faces. (C) Average response across 182 cells from the middle face patch of one monkey to 96 different images. The first 16 images are faces. (D) Responses of a face cell to repeated presentations of an upright and an inverted cartoon face. Each dot represents an action potential. (From Tsao, 2006.) (See color plate 21.)

basis for the pattern-selective properties of these neurons, using partial and complete face cartoons with graded feature properties. This part of their work is obviously based on a good knowledge of the face recognition literature, and the results are clearly described and thoroughly analyzed. The overall impression that is given is that different neurons respond to different snippets of information about faces, sometimes to single features such as iris size, sometimes to combinations of features. Whole faces usually give large responses, though these are never as large as the sum of the responses to individual features.

Many hypotheses about the nature of the selectivity were explored, and there is a lot of information against which one can test one's own individual theory of face recognition, but I think it is fair to say that clear models do not emerge, either for what the middle face patch and other face patches do or for how they may do it.

The good news, then, is that we have a system in which the pattern selectivity and invariance of face cells can be explored. The analysis of how neural mechanisms determine their selectivity for some features and invariance for others has not been solved, but it is on its way.

Cortex: *Hierarchy, origin, and new behavior*

Hubel and Wiesel's hierarchical proposal has been important for all our thinking about cortical function and is, for instance, a central feature both of the anatomical scheme of Felleman and van Essen (1991) and of the computational view of Riesenhuber and Poggio (1994), but it has also been criticized on a number of grounds. For example, hypercomplex cells are thought to be the same as what are now termed *end-stopped neurons*, and the details of the anatomical evidence do not coincide with the physiological evidence as nicely as Hubel and Wiesel would probably have liked; for instance, V1 has both simple and complex cells, which should not be the case, according to their scheme, if V1 is a single stage in the hierarchy. There is also good evidence that complex cells receive a direct input from the LGN, which again does not fit the suggested scheme exactly.

The agreed arrangement of the interconnected areas in the cortex is not obviously that of a hierarchy, for there is no "top area," and if one area connects directly to another, there is almost always a direct connection in the reverse direction as well. The term also introduces inappropriate implications from its everyday use to describe hierarchies of command in the army or of decision making in a commercial business, in which there are often very different numbers at different levels—one boss, many workers, for example—and the flow of command may be strictly unidirectional and may strictly avoid skipping levels. Also, the details often turn out to be different from those that were originally suggested; for example, there are orientationally selective ganglion cells in the retina (Levick, 1967), whereas this type of selectivity was initially not thought to occur before the primary visual cortex.

These may all be minor quibbles, but there is one fact suggesting that if there is a cortical hierarchy, it involves new methods or new principles not employed at earlier levels in the visual pathway. This is shown by doing counts of neurons at different levels in the visual pathway, for there is a large, abrupt rise on entering the cortex. Figure 21.4 shows the numbers of neurons in the precortical visual pathway and various parts of the cortex of the macaque. The main message stands out bold and clear: There is an enormous

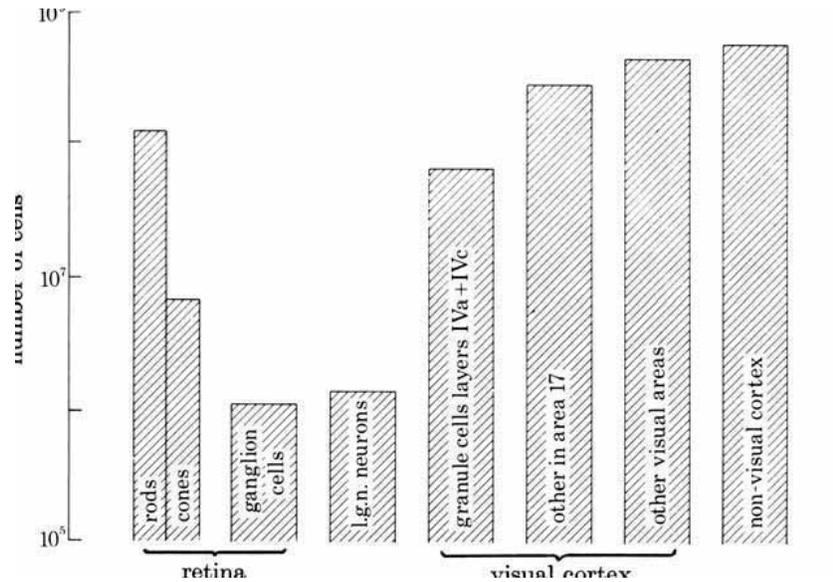

FIGURE 21.4 Estimated numbers of cells at various levels in the visual pathway of a macaque monkey. Note that the scale is logarithmic and that there are 55 times as many granule cells as LGN neurons. If one takes all the 250 million neurons in V1, this is 180

increase in the number of neurons involved in vision as the messages are passed from the LGN neurons to the granule cells in layer 4 of the primary visual cortex. The actual figures are interesting. Reading from the chart, this first stage of increase is by a factor of about 55, from 1.4 million to 75 million. If one includes all the 250 million neurons in V1, the factor increases to 180, and for the whole visual cortex (nearly 800 million neurons), the number of neurons is almost 600 times the number of LGN neurons.

That really establishes the point that the cortex has very many more cells at its disposal than do precortical levels, but the numbers in figure 21.4 represent averages over the whole visual field. It is estimated that in the foveal region, the density of neurons in V1 per unit solid angle of the visual field is 10,000 times the density of input fibers from the LGN (Hawken & Parker, 1991). This compares with the average over the whole visual field of 180 times, given above. The difference results from the fact that the cortical representation of the fovea has much more than its fair share of neurons, even after taking account of the overrepresentation of the fovea in the input from the LGN. The number of neurons available for computations on the input from the fovea is truly phenomenal.

Detailed accounting for the numbers shown in the left part of figure 21.4 is complicated by the fact that rods and cones behave differently, and the pattern of convergence and then divergence is very different at the fovea and in the periphery. Many of these matters are not relevant here, but there is one point that makes sense physically, and this is worth pointing out, lest the obvious message conveyed above be overshadowed by these complications.

times the number of LGN neurons, and for the whole visual cortex (nearly 800 million neurons), it is almost 600 times. (From Barlow, 1981; adapted from Chow, Blum, & Blum, 1950.)

The actual number of nerve fibers running in parallel from retina to LGN is not far from the number required for there to be one pathway per resolvable element of the optical image falling on the retina or one pathway per cone, provided that one confines one's attention to the foveal part of the pathway and takes into account that the image in the near periphery is undersampled (i.e., it has fewer nerve fibers serving it than the quality of the image deserves). The approximate agreement in the fovea means that with these cautions, the number of nerve fibers in the optic nerve roughly coincides with the number of degrees of freedom in the copy of the image that the optic nerve passes to the brain. Why, then, does the cortex need up to 10,000 times that number of neurons to perform its computations? The fact that we think we understand the limiting factors of foveal vision makes the huge numbers of neurons that are available in that part of the cortex even more impressive. Is there something about the computations it does that we have missed or paid insufficient attention to?

The next part of this chapter discusses this problem in light of the new behavior that the new part of the mammalian brain, the cerebral cortex, is thought to have brought about. Although this evidence is not very satisfying for a modern neurophysiologist, it is one of the few sources that can give useful hints about these new functions.

The cerebral cortex first appeared in the forebrain of mammals while dinosaurs were the dominant large, terrestrial vertebrates. Before mammals, the vertebrate forebrain had been dominated by its olfactory input, and in fact, olfaction is the only sensory modality that still has a direct input to the cortex; all the others pass through the thalamus. These

facts led G. Elliot Smith (1924) to suggest the following story of the evolution of the cortex. After the demise of the dinosaurs, mammals extended their range to different habitats, including forest trees. Here, they had to become more reliant on vision, and their good sense of smell, which had served them well when they were living on the ground, was no longer as useful, for the informative scents of soil and undergrowth would simply have been blown away. This, he said, freed up resources that could be used for the construction, maintenance, and further evolution of the forebrain. At the time, it was far from clear what these resources might be, but recent discoveries in olfaction suggest an intriguing possibility.

Consider these three facts: (1) In the mouse, more than 1200 genes are involved in coding for all the different olfactory receptor molecules; (2) each receptor cell's axon finds its way to a glomerulus that also receives axons from other receptor cells in the neighborhood containing the same type of receptor molecule, and Singer, Shepherd, and Greer (1995) concluded that this molecule must have a role in axon guidance, as well as in olfactory reception; and (3) in modern primates, many genes for olfactory receptors are not expressed in the olfactory mucosa. These three facts point to the possibility that these genes have retained an axon-guiding role and that this has helped the cortex to resolve its axon-guiding problems. As was emphasized earlier, cortex is characterized by having a vast number of neurons interconnecting its different parts, so it faces this axon-guiding problem on an unparalleled scale.

Whether or not there is any truth in this notion, what one really wants to know about is how their enlarging cortex allowed mammals to enlarge their behavioral repertoire: What could they do with a cortex that they could not do without it? Unfortunately, most of the suggested answers to this question are useless, because they depend upon words or phrases—such as *voluntary actions*, *free will*, or *consciousness*—that we do not understand. In contrast, C. J. Herrick (1926, 1928), a founding father of comparative neuroanatomy in the United States, penned three one-liners that were astonishingly prescient.

First, he said that cortex contained the “filing cabinets of the central executive.” He was mainly suggesting that cortex is the store-place of memory, but perhaps he was also anticipating the idea that determining, storing, and making use of the statistics of the environment are crucially important for everything we do, especially for those things that primates, and particularly humans, do better than other animals or computers.

Second, he called cortex the “organ of civilisation.” Here again, he anticipates understanding of the fact that civilization is possible because humans are adept at assimilating, disseminating, and using little associative facts, such as “Fanny likes bananas.” Substitute other, less trivial nouns

and verbs for those in this sentence, then allow that individuals collect and remember associations that are observed to be true, and you have a population with many shared beliefs that can, together with a system of intricately linked mutual benefits, make a civilized society possible.

Neither of these gives much idea of the actual operation cortical neurons perform, but Herrick's third one-liner was “cortex is the organ of correlation.” The ability to detect associations underlies the other two, for “Fanny likes bananas” proclaims that you have noticed a correlation between Fanny, the individual, and her manifestation of behavior that shows a liking for bananas; furthermore, most of the facts in those filing cabinets of Herrick's first one-liner are not just the means and current values of a host of variables, but also evidence for associations among them, most of them weightier than that just mentioned.

Correlation, symmetry, and invariance

Herrick did not specify exactly what he meant by calling the cortex the organ of correlation. He might have just meant that it detects the similarity between patterns in the external world and patterns held as templates in the brain. If a receptive field with a particular pattern of spatial sensitivity, say a Gabor function, calculates the point-by-point linear sum of sensitivity times luminance over its field, it becomes a matched detector for that same spatial pattern in an image falling on it. Such a matched detector can give the highest possible signal-to-noise ratio for detecting a precisely known stimulus pattern, and some of the properties of biological feature detectors can be well modeled in this way. Such models have two serious problems, however: They do not show the invariance of response for position, illumination, pose, or size that is typical of biological pattern recognition, and they do not form a good basis for hierarchical models, because the result of doing two (or more) template matching operations in sequence can be expressed as a single template matching operation. There are ways of ameliorating these problems (see Heeger, 1992; Carandini, Heeger, & Movshon, 1997; Simoncelli & Heeger, 1998; Rust, Mante, Simoncelli, & Movshon, 2006), but there is also a more radical solution.

An “organ of correlation” should be able to reveal more about an image than which templates best match its different parts. Autocorrelation is an operation that is related to template matching but differs from it in that it compares parts of an image with other parts of the same image rather than with a fixed template. This has been used to follow the motion of planetary atmospheres (Luz, Berry, & Roos-Serote, 2008), and it allows the symmetries in sensory messages to be actively sought out.

The most appropriate definition of symmetry that we have found is “the property of remaining invariant under

certain changes” (Merriam-Webster online dictionary). For example, a circular object has circular symmetry because it does not change when you rotate it about its center, and a line or edge has translational symmetry because it does not change when you move it in the direction of its orientation. In popular usage, the word *symmetry* most often refers to bilateral, or mirror, symmetry, meaning that if one half of an image is flipped over, it will exactly match the other half onto which it has been flipped, provided that the axis of the flipping has the right position and orientation (i.e., if it is the mirror axis).

The responses of retinal ganglion cells to image contrast are little changed by altering the mean level of illumination. One might call this “contrast symmetry” or “invariance to mean illumination,” but note that such changes of mean illumination are passively experienced, not actively sought out. It is not like rotating an object and finding its appearance unchanged, for that involves the active application of the “certain changes.”

A way to bring out the importance of symmetry is to point out that it tells you how to find more of the same; it tells you that if symmetry is present and you apply the changes for which invariance holds, you will find more evidence of the same type, to be likely from the same object. Take displacement symmetry, which is closely related to translational symmetry; it is present if you move across an image through a specified distance and direction and find that the region at which you arrive has properties similar to those of the region from which you departed. That can easily be tested for by rotating the eye through the specified distance and direction, when any small patches over the whole image that are unchanged by the eye movement must have the specified symmetry. However it is obvious that at only three saccades per second, the eye cannot quickly determine the displacement symmetries that are present in a whole scene using this method.

From what we know about the brain’s computing powers, it is hard to think of any simple alternative to the following brute force general scheme for detecting symmetries: Determine the properties, such as luminance, color, and texture, of each small region, using a limited number of local characteristics; transmit their values to all the neighboring regions for which displacement symmetry might exist; and test the similarities of the received values with those in the receiving small regions. At first, this might seem absurdly extravagant in the use of neurons and likely to require far too many of them, but recall that in the foveal region of V1, there are some 10,000 cortical neurons per input fiber from the LGN. There are a lot of neurons available for the task, but I do not think that the evidence is yet available to make even a crude estimate of whether there are enough.

From the definition, it is clear that searching for symmetry is the same as searching for ordered modifications to the

image that leave certain parts of it unchanged. Rotation, translation, and reflection were mentioned above, and there are many other tasks in perception that can be easily framed in terms of symmetry and invariance. For example, when a small region in an image moves, the pixel values of all points in the small region are displaced through the same distance and direction and are also delayed in time, so the displaced and undisplaced small regions of the image have spatiotemporal displacement symmetry; this is the symmetry involved in motion detection. Similarly, the binocular disparity that gives rise to stereoscopic depth perception occurs when a small region of one eye’s image is displaced horizontally relative to its position in the other eye’s image, and this is the symmetry involved in stereoscopy. It is an interesting exercise to go through the features in images that the Gestalt school pointed to as promoting grouping or segregation, asking, “How are symmetry and invariance involved here?” In most cases, it is not hard to see that there is a connection, though it is sometimes hard to find exactly the right words to express it.

We need to consider with particular care Adelson and Movshon’s (1982) plaid paradigm, for this is perhaps the only perceptual phenomenon that has not only been shown to be generated in the cortex (Movshon, Adelson, Gizzi, & Newsome, 1985) but for which there is also a neurophysiological model that works (Rust et al., 2006).

To generate a plaid, two moving gratings that have different spatial frequencies, orientations, contrasts, and velocities are superimposed. Sometimes you see just what you might expect, namely, two different gratings, each moving in its own direction. However, if the two gratings are not too different from each other, you often experience something new, namely, a single plaid rather than two separate gratings, and its direction of movement is obviously different from that of either of the original gratings. In the second of the three papers cited above, the authors reported finding neurons in area MT of macaques that showed the type of directional selectivity required to signal the direction of the plaids. By contrast, in V1 itself, they found no such neurons, only ones that had the type of directional tuning expected for signaling the motion of each component by itself.

In the third paper, Rust and colleagues (2006) show how the plaid type of directional selectivity can be generated by appropriate interactions among inputs from primary visual cortex (V1) that have the normal directional tuning of V1 neurons and cover a wide range of optimal directions and velocities. Both the input neurons from V1 to MT and the neurons in MT itself had linear/nonlinear characteristics and normalization processes based on previous evidence (Heeger, 1992; Carandini et al., 1997). If symmetry and invariance are important in understanding what cortex does, they should also help us to understand this remarkable sequence of observations, experiments, and modeling, and I think they do.

The merging could be described as the ability to perceive the true direction of motion of a textured region in an image, invariantly for differences of texture. This new description does not much help one to understand the mechanism—indeed, it does not even hint at the intersection of constraints idea that Adelson and Movshon (1982) pointed to as the key to how it must be done. Nor does it enable one to predict the interactions Rust and colleagues (2006) discovered or the model by which they explained them. On the other hand, it does neatly summarize the functional role of the merging mechanism, and it points to two other merits of using invariant symmetries as the “words” that a neuron signals, rather than other more or less arbitrary features.

The region where the merging occurs is MT (Movshon et al., 1985), which receives input largely from V1 and transmits output largely to MST. These three areas are all strongly responsive to motion and often strongly selective for its direction, but the V1 neurons give potentially misleading information, because the velocity vector to which they respond best is not invariant for the spatial frequency composition (i.e., texture) of the stimulus. MT corrects for this lack of invariance, and one can see why it is needed by looking at the properties of neurons in MST. These respond maximally to motions in different directions in different parts of their receptive fields, and the patterns of motion that fulfill the requirements all over the receptive field are the patterns of motion, called *optic flow*, that occur when an observer moves through a textured environment. Now with optic flow, the textures of different parts of the scene are likely to be very different, so direct information from V1 to MST would often be misleading. The invariance for texture differences of the MT neurons would not only avoid this, but also allow these neurons to combine information appropriately from a larger number of V1 neurons, thus improving the reliability and signal-to-noise ratio of the messages from MT neurons.

It requires the concepts of symmetry and invariance to understand this neat and economical system, and these concepts might also be needed to explain how the model of Rust and colleagues (2006) is set up in the monkey’s area MT. The constraints on patterns of apparent motion in the image that result from geometric optics and a single observing instrument moving through a structured three-dimensional environment are constantly present in the inputs to a monkey’s eye. Could the monkey’s visual cortex seek out the symmetries and invariances that result from these constraints and use them to adjust the parameters of a genetically prewired skeleton of the model? Einstein plucked his scientific laws from the confusing and sometimes contradictory evidence of contemporary physicists, and we generally accept that his genius lay in his cerebral cortex. Why should not monkey cortex be using a touch of Einstein’s genius to generate an economical model of its motion environment?

Such economy has long been thought desirable for sensory systems and perception (Attneave, 1954; Barlow, 1959; Watanabe, 1960); in particular, it can make possible a sparser representation of a scene. The advantages that this brings for improving the reliability and sensitivity of learning and economy of metabolic costs are explained elsewhere (Olshausen & Field, 1997; Gardner-Medwin & Barlow, 2001; Attwell & Laughlin, 2001; Lennie, 2003).

The importance of symmetry in perception and in psychology at all levels needs more attention. At one extreme, rhetoric often uses analogy to strengthen a case, and that depends upon recognizing the symmetry between two arguments, one already accepted and the case for acceptance of the other supposedly being strengthened by the postulated symmetry. At the other extreme, we have the starburst amacrine cells of the retina, which are believed to be the means by which knowledge of the image at one point is transmitted to another point to provide evidence for spatiotemporal displacement symmetry, the symmetry underlying motion detection (Vaney & Taylor, 2002; Euler, Detwiler, & Dent, 2002).

Symmetry appears to be something that is widely exploited by the brain, and it probably has a role in the mechanisms underlying grandmother cells and face detection. This carries the immediate lesson that it is at least as important to define and puzzle over the invariances of grandmother cells’ responses as it is to study their pattern selectivity.

Conclusions

Neurons that respond to “a highly complex, specific, and meaningful stimulus” (Gross, 2002) exist and can now be recorded from and studied reliably. But grandmothers are not among the specific stimuli to which they respond, and their ability to respond invariantly is as important as their pattern selectivity.

An abrupt change in the anatomy of the visual pathway occurs as it enters the cerebral cortex. The total number of neurons in V1 over the whole visual field is about 250 times the total number of LGN neurons, and if one considers the foveal region alone, there appear to be 10,000 cortical neurons per LGN afferent. If cortical computations require this number of neurons, they are likely to be accomplishing more than we currently expect of them. Although the idea of grandmother cells must have been based largely on the recognition that subcortical single neurons are much more pattern selective and reliable than had previously been supposed, it could be misleading to assume that the cortex can do no more than subcortical mechanisms.

Most cortical models have been based on the summed cross-product of the pattern of activity in a group of input messages with the pattern of sensitivity of a receptive field, which thus acts as a weighting function or template. So far,

this has failed to provide an adequate model of the selectivity and invariance of face cells.

It has been suggested that the cortex is “the organ of correlation” (Herrick, 1928) and can detect the invariances of symmetries by autocorrelation. Autocorrelation involves the comparison of two patterns, as with template matching, but both patterns are from the image, instead of one being from the image and the other from an internally stored template.

Autocorrelation would require the transmission of information from one region of an image to other regions on a massive scale, but as was emphasized above, phenomenal numbers of neurons are available to meet this demand.

The ranges of invariance that symmetries define increase the range of stimuli that excite a neuron and thus can improve its signal-to-noise ratio and reliability. Achieving maximum invariance with minimum loss of needed selectivity must be a principle that operates at most, if not all, stages in the successive operations that determine the properties of grandmother cells.

22 Olfaction: From Percept to Molecule

LEE SELA, AHARON WEISBROD, REHAN KHAN, AND NOAM SOBEL

ABSTRACT Despite major progress in elucidating the anatomical and molecular foundations of olfaction, the rules underlying the link between the olfactory stimulus and the olfactory percept remain unknown. We argue that this lack is a reflection of visual primacy in human perception and thinking, primacy that has prevented the development of a perception-based approach to studying olfactory coding. With this in mind, in this chapter, we first provide a tutorial on the organization of the mammalian olfactory system and then describe our recent efforts to generate a perception-based olfactory metric. The primary olfactory perceptual axis revealed by this effort was odorant pleasantness. We found that pleasantness is a perceptual representation of the physical axis that best explains the variance in molecular odorant structure. That the most important dimension in olfactory perception should be the best correlate of the most discriminating physicochemical measures suggests that, as with other senses, the olfactory system has evolved to exploit a fundamental regularity in the physical world. In this respect, olfactory pleasantness can be likened to visual color and auditory pitch. Finally, we review our use of this olfactory metric in predicting odor perception in humans and odorant-induced neural activity in the olfactory system of nonhuman animals.

Our lab has a pet cat named Diesel. We found Diesel at the age of about four weeks, when he was suffering from severe feline herpes that had invaded both his eyes. Despite significant veterinary efforts, both his eyes had to be removed, and Diesel has since been a blind cat. That said, any naïve visitor to our lab will not notice Diesel's blindness. Diesel runs and jumps around the lab following an internal spatial mental map he has constructed, and he negotiates changes in this landscape, such as a chair that has been moved, with surprising speed, thanks to rapid processing of information from his whiskers, which are always a step in front of him when he is in motion. However, the most astonishing aspect of Diesel's behavioral repertoire is his ability to catch flies in flight. Diesel will identify the sound of a fly seemingly despite any level of background noise, will follow the fly seemingly tracking the fly with his eyes (which are not there), and at

the correct moment will leap several feet into the air, catching the fly between his clapped paws (figure 22.1).

Observing this marvelous demonstration of sensory substitution (audition for vision) is a lesson to us in our studies of olfaction. We humans are visual animals, and this has shaped not only how we negotiate the world around us, but also how we think about it. Vision dominates our conscious perception. We intuitively think that information about the outside world that is naturally provided to us through vision is inherently *visual information*. This is not necessarily true, however, as is so powerfully shown in Diesel's fly hunting. In other words, all distal senses have evolved to maximize the amount and types of information they can extract from the environment. It follows from this that if we pay careful attention to our sensory perceptions in each domain, we can learn much about how that domain is physically organized in the world around us, and in our brain. This simple truth was elegantly stated by Helmholtz (1878): "Thus, even if in their qualities our sensations are only signs whose specific nature depends completely upon our make-up or organization, they are not to be discarded as empty appearances. They are still signs of something—something existing or something taking place—and given them we can determine the laws of these objects or these events. And that is something of the greatest importance!"

Neurobiologists have internalized this lesson for vision and audition but not for olfaction. In vision, we learned that what appears to us as perceptually similar in color is in fact similar in the physical dimension of wavelength; and in audition, we learned that what appears to us as perceptually similar in pitch is in fact similar in the physical dimension of frequency. We further learned that the physical dimensions of wavelength and frequency are represented at various stages of the nervous system. But what physical dimension is common to similarly smelling odors? And how is this dimension represented in the brain? These questions remain unanswered. In this chapter, we will first provide a basic tutorial on the organization of the mammalian olfactory system and then describe our initial efforts to generate a perception-based approach for probing the neurobiology of olfaction.

FIGURE 22.1 Diesel, a blind cat, aged six months, hunts flies in flight using audition only. Here, Diesel jumps to swat at the slightly moving hand of coauthor N.S.

The olfactory system

What is an odor? Any volatile (molecular weight < 294 daltons) molecular species with surface activity, low polarity, some water solubility, high vapor pressure, and a high lipophilicity will probably be detectable and discriminable by the mammalian olfactory system (Ohloff, 1986). Nobody knows exactly how many discrete odorants this amounts to. Estimates have ranged from thousands to tens of thousands to hundreds of thousands, yet we know of no computed theoretical upper limit to this number. The human olfactory system can detect these molecules with astonishing sensitivity, outperforming analytical instruments (Cain, 1977) and performing on par with monkeys (Laska, Trolp, & Teubner, 1999) (figure 22.2). The transformation from molecule to percept occurs along an hierarchically organized system that in mammals is summarized as follows: Following transduction at olfactory receptor neurons in the olfactory epithelium, odor information is projected ipsilaterally via the olfactory nerve to the olfactory bulb. Following bulbar processing, the signal is projected ipsilaterally via the lateral olfactory tract to primary olfactory cortex within the ventral portions of the temporal lobe (figure 22.3).

In this manner, olfaction differs from the distal senses of vision and audition, where peripheral input projects to contralateral cortex initially via a thalamic relay. In contrast, olfactory information projects to the thalamus from primary olfactory cortex. Additional primary olfactory cortex projections relay odor information to multiple brain regions, including what has been referred to as secondary olfactory cortex in the orbitofrontal region and flavor integration regions in the insula (Small & Prescott, 2005).

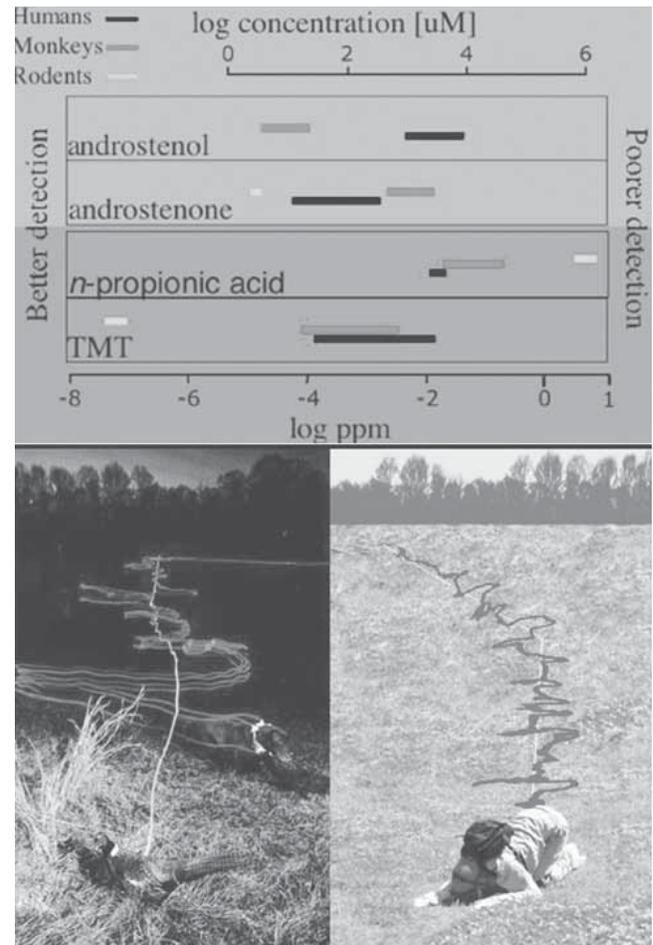

FIGURE 22.2 Olfaction in humans and other animals. *Top panel:* Detection thresholds across species. The data are amassed from studies by Laska and colleagues (1999) and are for detection of the fox odor TMT, *n*-propionic acid, and the two steroidal compounds androstenol and androstenone. The two shades of gray distinguish the units in which results were reported, dark gray in log concentration of the vapor, and light gray in log concentration of the odorant liquid. The extent of the lines reflects the reported variance across studies. The important point illustrated is that each species excels at detecting particular odorants. For example, humans outperform rats and monkeys at detecting *n*-propionic acid. That said, one must keep in mind the limitation of comparing across studies that used different methods of delivery and statistical criteria. *Bottom panel:* Human subject's path following a scent trail, as compared to a dog's path. *Left:* Path of a dog following the scent trail of a pheasant dragged through a field (scent trail in yellow, dog's path in red) (Gibbons, 1986). *Right:* Path of a human following a scent trail of chocolate essential oil through a field (scent trail in yellow, human's path in red). (The background trees were pasted in for esthetics and are part of the data.) (From Porter & Sobel, 2005.) (See color plate 22.)

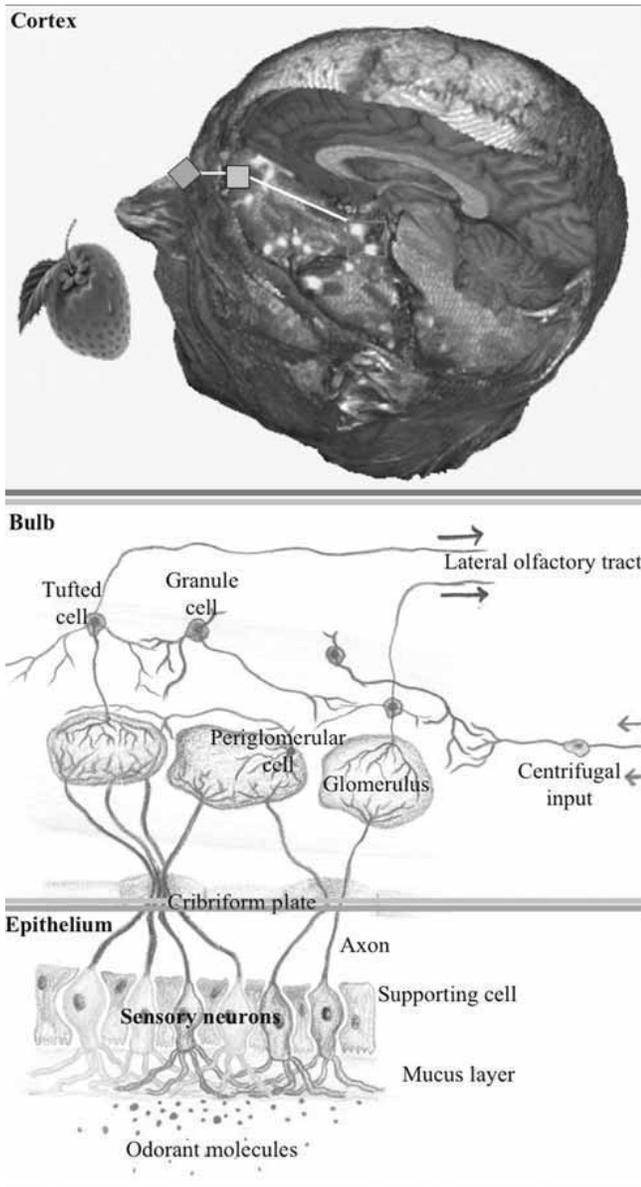

FIGURE 22.3 Structure of the human olfactory system. The human olfactory system can be segregated into three primary compartments: (bottom) epithelium, (middle) bulb, and (top) cortex. Olfactory epithelium: Each olfactory sensory neuron expresses on olfactory receptor gene. Like receptor project to one or a small number of glomeruli. Organization of the olfactory bulb: Glomeruli receive input from olfactory sensory neurons and cortical olfactory regions. Mitral and tufted cell dendrites contact receptor axons within glomeruli. The axons of the mitral and tufted cells project widely to higher brain structures. Lateral processing in the olfactory bulb occurs across two types of interneurons: periglomerular cells and granule cells. A sagittal view of the human head. The olfactory epithelium is in green, bulb in blue, and primary cortex in pink. (Drawing courtesy of Christina Zelano.) (See color plate 23.)

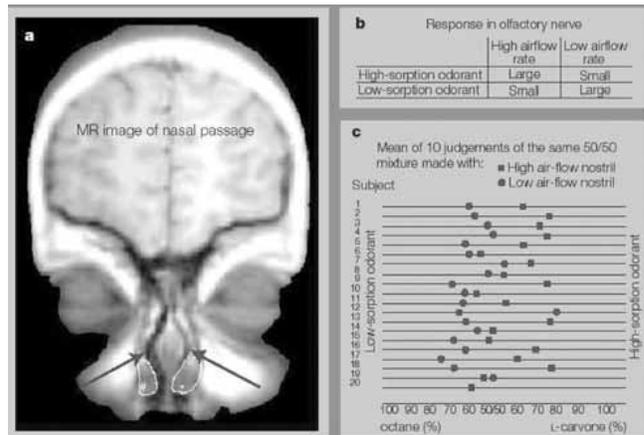

FIGURE 22.4 Different nostrils convey different olfactory information to the brain. (A), Magnetic resonance image of the nasal passages. The swollen (*) and relaxed (#) turbinates, outlined in white, result in an occluded right nostril (red arrow) and a clearer left nostril (green arrow). (B), The size of the response in the olfactory nerve (large or small) as a function of the interaction between airflow rate and odorant sorption (Mozell & Jagodowicz, 1973). (C), On each of 10 trials, subjects were asked to smell an identical mixture of 50% octane and 50% L-carvone using either the left or right nostril. They were then given each individual odorant component to smell separately and judged the composition of the mixture by marking the line. Using the high-flow-rate nostril (green), the average judgment was that the mixture consisted of 55% L-carvone and 45% octane. Using the low-flow-rate nostril (red), the judgment was that it consisted of 61% octane and 39% L-carvone ($t(19)43.74$, $p = 0.001$). (From Sobel et al., 1999.) (See color plate 24.)

The above is a unilateral description of what is a bilateral system. As in other distal senses, mammals have two olfactory systems, a left and a right nostril, each connected to their respective epithelia, bulbs, and cortices. Also as in other distal senses, there is an asymmetry of input across sides, whereby the left and right nostril are tuned to slightly different aspects of the olfactory content (Sobel, Khan, Saltman, Sullivan, & Gabrieli, 1999). Whereas this asymmetry may contribute to spatial localization of odors (Porter, Anand, Johnson, Khan, & Sobel, 2005; Rajan, Clement, & Bhalla, 2006; Porter et al., 2007), any contribution of this sensory offset to olfactory discrimination remains unknown (figure 22.4).

Airborne chemicals are concurrently transduced by at least two additional mammalian neural subsystems: the vomeronasal system (Halpern, 1987; Meredith, 1991; Keverne, 1999; Dulac, 2000), the trigeminal system (Doty, 1995; Hummel, 2000; Hummel & Livermore, 2002), and possibly the Grüneberg organ, a septal subsystem of the main olfactory system (Roppolo, Ribaud, Jungo, Luscher, & Rodriguez, 2006; Storan & Key, 2006). However, to maintain a manageable scope in this chapter, we will focus on the main olfactory system only. We will first briefly summarize

the structure and events at each of the olfactory anatomical processing stages; then we will review the current understanding of how odor is encoded within this neuronal infrastructure.

Olfactory epithelium

For a molecule to be transduced into a neural signal, it must reach olfactory receptors within the olfactory epithelia. The human epithelia are located bilaterally about 7 cm up the nasal passage, lining the cribriform plate and extending to the nasal turbinates (Clerico, To, & Lanza, 2003). These turbinates are convoluted to increase the surface area of the epithelium to about 1–10 cm² in humans (Moran, Rowley, Jafek, & Lovel, 1982) and 170 cm² in some dogs (Moulton, 1977). An odorant molecule may reach the epithelium in three different ways. The first is by diffusion from an area of higher concentration (the environment) to an area of lower concentration (the nares). The second is by a process termed *retro-nasal olfaction* (Hornung & Enns, 1986), whereby an odorant enters the mouth in food or drink and propagates back up the throat into the nose. The third and most common route by which a molecule reaches the olfactory epithelium is transportation by either ongoing nasal inhalation or a sniff—a vigorous contraction of the diaphragm leading to rapid nasal airflow (often exceeding 100 liters per minute in humans) (figure 22.5). Sniffs are a rapidly modulated mechanism of sensory acquisition that profoundly influence patterns of neural activity throughout the olfactory system and have a significant impact on the olfactory percept (Kepecs, Uchida, & Mainen, 2006, 2007; Mainland & Sobel, 2006; Schoenfeld & Cleland, 2006).

The epithelium consists of many cell types (Carr, Farbman, Colletti, & Morgan, 1991; Huard, Youngentob, Goldstein, Lauskin, & Schwob, 1998), but most fall into four primary categories: olfactory receptor cells, sustentacular or supporting cells, basal cells, and duct cells of Bowman's glands. The latter are the secretory source of a mucus layer that lines the olfactory epithelium. This mucus layer plays a role in immune function (Getchell & Getchell, 1991) and

various enzymatic processes (Lewis & Dahl, 1995) but also directly affects olfaction by selectively modulating the passage of odorants to the receptors and possibly by further modulating the later removal of odorants from the receptors (deactivation) (Lewis & Dahl, 1995). In addition to the passive mucosal effect on olfaction, the mucosa contains an odorant-binding protein that assists in actively transferring hydrophobic odorants across the largely hydrophilic mucosa (Pevsner, Trifiletti, Strittmatter, Sklar, & Snyder, 1985; Pelosi, 2001).

The olfactory receptor cells are bipolar neurons that are unique in at least two ways: (1) They constantly regenerate from the basal cell layer (Graziadei, Levine, & Monti Graziadei, 1979; Graziadei & Monti Graziadei, 1983), with a typical life span in mammals ranging from a month to a year (Hinds, Hinds, & Mcnelly, 1984; Mackay-Sim & Kittel, 1991), and (2) they are in direct contact with the external environment. This direct link of the brain to the outside world has been postulated as a path of entry for pathogens from the environment directly to the brain (Roberts, 1986). Humans have about six million receptor cells in each epithelium (Moran et al., 1982). Each of these olfactory receptor neurons sends one dendrite into the mucus layer, terminating in an olfactory knob that contains between 3 and 50 nonmotile olfactory cilia, each about 5 μm long (Morrison & Costanzo, 1990, 1992). It is these cilia that contain the site of olfactory transduction. Various lines of evidence suggested that this transduction was similar to transduction of light in retinal rods and cones. Doron Lancet and colleagues found that odorants induce activation of adenylate cyclase (Pace, Hanski, Salomon, & Lancet, 1985), and Nakumara and Gold (1987) found a cyclic nucleotide-gated conductance in olfactory receptor cilia. Randy Reed and colleagues later found this adenylate cyclase to be olfactory-specific (Bakalyar & Reed, 1990) and activated by an olfactory-specific G protein (Jones & Reed, 1989). In 1991, Linda Buck and Richard Axel culminated this line of research by identifying a large multigene family that encodes the olfactory receptors. The olfactory receptors indeed belonged to the family of G-protein-coupled receptors of the seven-helix type, that, surprisingly, contained around 1000

FIGURE 22.5 Airflow visualization using Schlieren imaging in dogs (Settles, 2001) and humans (Porter & Sobel, 2005). *Left panel:* Before sniffing inward, dogs may also sniff outward in a lateral trajectory distributing particles so that they can be inhaled and

smelled. As this image clearly depicts, sensation is an active process, and olfaction is a good case in point. *Remaining panels:* Imaging of the human nose clearly reveals an asymmetry in airflow into each nostril.

different olfactory receptor genes, the largest known gene family in the mammalian genome (Buck & Axel, 1991). This work has generated the following current view of olfactory transduction: When an odorant molecule binds to an olfactory receptor, it triggers the activation of the specific olfactory G-protein G_{olf} that releases a subunit $G_{\alpha olf}$ that stimulates adenylyl cyclase III. Adenylyl cyclase III increases intracellular cAMP, which opens a cyclic nucleotide-gated cation channel, depolarizing the cell and ultimately resulting in an action potential in the sensory neuron (figure 22.6). John Ngai and colleagues demonstrated that blocking this cascade causes anosmia—a total loss of olfaction (Brunet, Gold, & Ngai, 1996).

A second transduction cascade has also been suggested whereby activation of the G-protein and phospholipase C lead to the production of IP_3 , which directly opens calcium channels that depolarize the cell (Boekhoff, Tareilus, Strotmann, & Breer, 1990). Following transduction, odorant-induced action potentials propagate down the axons of

olfactory receptor neurons that join to form the olfactory nerve, pass through the cribriform plate, and synapse at the olfactory bulb.

Olfactory bulb

The mammalian olfactory bulb consists of six cellular layers, which are, from superficial to deep, the (1) olfactory nerve layer, (2) glomerular layer, (3) external plexiform layer, (4) mitral cell layer, (5) internal plexiform layer, and (6) granule cell layer (Kratskin & Belluzzi, 2003). These layers are arranged in a concentric manner reminiscent of an onion (Shepherd, 1972; Greer, Stewart, Kauer, & Shepherd, 1981). The bulb contains functional elements primarily consisting of an input neuron, an interneuron, and an output neuron. The inputs are from two sources: peripheral input from the olfactory receptors and centrifugal inputs from cortical olfactory regions (see figure 22.3). These centrifugal inputs are very extensive, are from various olfactory regions, and,

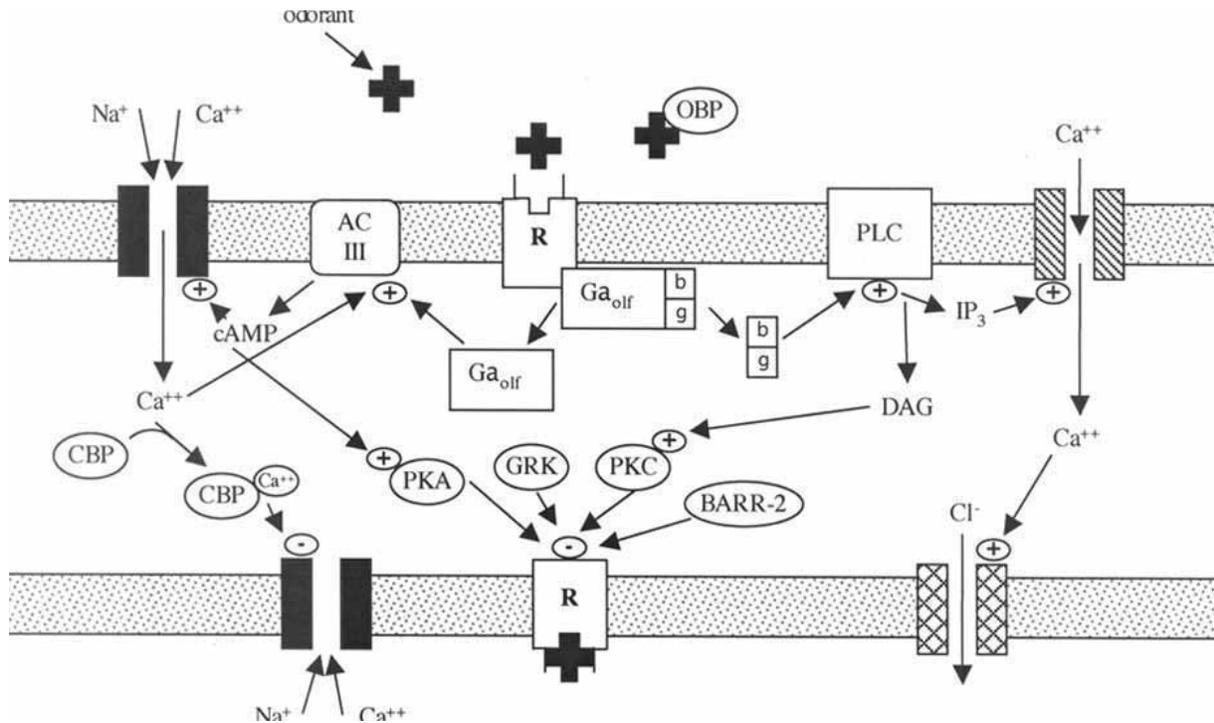

FIGURE 22.6 Odorant molecules bind to olfactory receptors (R) embedded within the olfactory epithelium. The binding causes the associated G-protein complex to release its two subunits (α and β). The α subunit stimulates the integral membrane protein adenylyl cyclase (AC III), which in turn increases the concentration of cAMP. Cyclic-nucleotide-gated (CNG) channels open with cAMP, leading to membrane depolarization; if there is sufficient depolarization an action potential is generated in the sensory axon. The $\beta\gamma$ complex released from the G protein stimulates phospholipase C (PLC) leading to higher intracellular inositol triphosphate (IP_3) and diacylglycerol (DAG). IP_3 opens Ca^{++} channels, allowing Ca^{++} to enter the neuron. The Ca^{++} ions have multiple effector path-

ways. Ca^{++} stimulates Cl^- channels, allowing Cl^- ions to exit the cell (intracellular Cl^- concentration is greater than extracellular concentration). This ion exchange further depolarizes the membrane. Calcium also inhibits the transduction by combining with Ca^{++} -binding protein (CBP) that closes the CNG channels, ending signal transduction. Signal termination is also mediated by a variety of protein kinases (PKA, GRK, PKC) that phosphorylate the olfactory receptor and by β -arrestin-2 (BARR-2) interacting with the olfactory receptor. Odorant-binding proteins (OBP) in the nasal mucosa may increase odorant solubility and/or receptor-binding affinity, aiding transduction, or may assist in odorant clearance, aiding signal termination. (Image after Buck, 1996.)

although not yet fully understood, are thought to play a significant role in olfaction (Gray & Skinner, 1988; Singer, Kim, Zochocski, 2007). The peripheral input consists of axons of olfactory receptor neurons. These project unbranched from the epithelium to the olfactory nerve layer of the bulb, where they terminate in spherical neuropil structures 50–200 μm in diameter, called *glomeruli*. These form the glomerular layer, which is one or two glomeruli thick. In humans, each olfactory bulb contains approximately 8000 glomeruli (Meisami, Mikhail, Baim, & Bhatnagar, 1998), and in a striking case of neural convergence, all the axons of same olfactory receptors converge to one glomerulus. (Convergence is even greater in macrosmatic mammals.) Within the glomeruli, the receptor axons contact dendrites of either mitral or tufted output neurons and periglomerular interneurons. The bulb is the site of extensive olfactory processing modulated by interneurons consisting of short-axon cells, inhibitory periglomerular cells, and inhibitory axonless granule cells. Granule cells make inhibitory dendrodendritic reciprocal synaptic connections with mitral and tufted cells. Periglomerular cells project a primary dendrite into glomeruli, where they synapse with sensory axons, and additional dendrites make inhibitory dendrodendritic synapses with mitral and tufted cells. The mitral and tufted cell axons join to form the lateral olfactory tract, which is the output from the bulb to primary olfactory cortex in the ventral portions of the temporal lobe (see figure 22.3). Similar to the olfactory epithelium, the olfactory bulb is characterized by relatively high levels of neurogenesis (Pagano et al., 2000; Bedard & Parent, 2004), mainly in the glomerular layer (Ninkovic, Mori, & Gotz, 2007).

Olfactory cortex

By current definition, primary olfactory cortex consists of all brain regions that receive direct input from the mitral and tufted cell axons of the olfactory bulb (Allison, 1954; Price, 1973, 1987, 1990; de Olmos, Hardy, & Heimer, 1978; Carmichael, Clugnet, & Price, 1994; Shipley, 1995; Haberly, 2001). These make up most of the paleocortex, including (by order along the olfactory tract) the anterior olfactory cortex (also referred to as the *anterior olfactory nucleus* [Brunjes, Illig, & Meyer, 2005]), the ventral tenia tecta, the anterior hippocampal continuation and indusium griseum, the olfactory tubercle, the piriform cortex, the anterior cortical nucleus of the amygdala, the periamygdaloid cortex, and the rostral entorhinal cortex (Carmichael et al., 1994). In rodents, the anterior olfactory cortex may play a role in interhemispheric communication between olfactory bulbs (Cleland & Linster, 2003), but in humans, both the anterior olfactory cortex and the olfactory tubercle are poorly defined. Piriform cortex, the largest component of primary olfactory cortex in mammals, lies along the olfactory tract at the junction of

temporal and frontal lobes and continues onto the dorsomedial aspect of the temporal lobe. Piriform cortex is three-layered allocortex, with a superficial plexiform layer I and pyramidal cells densely packed in layer II and less so in layer III. Projections from the bulb synapse onto dendrites of pyramidal cells within layer I of piriform cortex. Caudally, piriform cortex fuses into the anterior cortical nucleus of the amygdala. Olfactory bulb projections terminate densely on the periamygdaloid cortex, which inhabits the medial surface of the amygdala, and less so on the rostral portions of the entorhinal cortex. The entorhinal cortex is the only portion of primary olfactory cortex that is six-layered and is thus considered transitional between olfactory allocortex and neocortex. The entire cortical complex that forms primary olfactory cortex is extensively interconnected by association fibers projecting across regions to synapse at layer I and within regions traversing the three cortical layers (Shipley, 1995). Furthermore, as was previously noted, the primary olfactory cortical regions project extensive centrifugal input back to the olfactory bulb (Carmichael et al., 1994). Beyond these primary regions, olfactory information is projected throughout the brain, most prominently to orbitofrontal gyri and the insular cortex.

As can be appreciated by both the sheer area and the diversity of cortical real estate that is considered primary olfactory cortex, this definition is far from functional. The term *primary* typically connotes basic functional roles such as early feature extraction, yet as can be expected, a region comprising piriform cortex, the amygdala, and the entorhinal cortex is involved in far more complex sensory processing than mere early feature extraction. It is for this reason that this definition is nearing abandonment (Haberly, 2001; Sobel, Johnson, Mainland, & Yousem, 2003). Indeed, in a thorough review of central olfactory structures, Cleland and Linster (2003) simply shifted the definition by referring to the classical primary olfactory structures as secondary olfactory structures, noting that as Haberly (2001) suggested, the definition of mammalian primary olfactory cortex may better fit the olfactory bulb than piriform cortex.

Odor encoding: From molecule to percept

The anatomy described above consists of three primary compartments: epithelium, bulb, and cortex (see figure 22.3). Some aspect of odor encoding occurs at each one of these processing stages, and it is the combination of activity across these regions that gives rise to the complex percept of odor.

As noted earlier, the number of discrete odorants that mammals can discriminate is unknown. That said, there is uniform agreement that it is more than 1000 (the estimated upper limit number of mammalian olfactory receptor types),

and therefore odorants are probably not encoded in a simple one-receptor-to-one-odorant scheme. There are several lines of evidence suggesting that each olfactory receptor neuron expresses only one (Nef et al., 1992; Strotmann, Wanner, Krieger, Raming, & Breer, 1992; Ressler, Sullivan, & Buck, 1993; Vassar, Ngai, & Axel, 1993; Chess, Simon, Cedar, & Axel, 1994) or two (Goldman, Van der Goes van Naters, Lessing, Warr, & Carlson, 2005) types of olfactory receptors. Furthermore, each individual receptor neuron will respond to multiple odorants, and a given odorant will activate several different olfactory receptor types (Sicard & Holley, 1984; Firestein, Picco, & Menini, 1993; Raming et al., 1993; Sato, Hirono, Tonoike, & Takebayashi, 1994; Krautwurst, Yan, & Reedy 1998; Zhao et al., 1998; Malnic, Hirono, Sato, & Buck, 1999). Thus odor encoding may be the result of a combinatorial scheme in which different receptors respond to different molecular aspects of an odorant and a given odorant is then represented by the subset of receptors that it activates (Axel, 1995; Buck, 1996; Mombaerts, 1999; Firestein, 2001). Such a scheme would enable the encoding of a very large number of different odorants within what is potentially a 1000-dimensional space.

Under the assumption that this is indeed the manner in which the peripheral olfactory system initially transduces odorants, one may ask how this high-dimensional information is organized by the brain to enable odor discrimination. Some unique principles may apply to odor encoding. First, odor coding appears to be synthetic (Wilson & Stevenson, 2006; Stevenson & Wilson, 2007). Most environmentally relevant odorants are complex mixtures of molecules yet are processed as a whole. Indeed, the identification of specific odorant molecules or molecular features is far less behaviorally relevant than is the ability to distinguish the complex odor of a ripened fruit or of a predator from background odors. Anterior piriform cortex may play a role in this process, as it acts as a filter that is driven most strongly by changing stimuli, providing a potential mechanism for olfactory figure-ground segmentation and selective reading of olfactory bulb output (Kadohisa & Wilson, 2006a). Consistent with this, mammals are quite bad at determining the composition of mixtures when the number of components reaches four or higher (Livermore & Laing, 1996; Linster & Smith, 1997). Second, in comparison to vision and audition, odor transduction is relatively slower, because molecules must sorb across the mucosa, a process that takes about 150 ms (Firestein & Werblin, 1989). That the neural substrates of olfaction do not have to fire continuously to keep up with peripheral transduction (in contrast to vision and audition) may enable the system to use the temporal encoding domain to encode complex odorant features. The brain can then combine temporal encoding with spatial encoding in the construction of odor space.

Spatial coding

Several lines of evidence point to spatial encoding in odor discrimination. This spatial coding may take form at the level of the epithelium, at the level of the bulb, and perhaps at the level of cortex. The olfactory epithelium is spatially segregated into four zones roughly along the longitudinal axis of the cribriform plate (Buck, 1996). Although some olfactory receptors are randomly represented across these four zones (Strotmann et al., 1992, 2000; Sullivan, Adamson, Ressler, Kozak, & Buck, 1996), most neurons that express a given olfactory receptor type are restricted to one of the four zones, where they are interspersed with other receptors in a seemingly unordered manner (Ressler et al., 1993; Vassar et al., 1993; Strotmann et al., 1994). Thus a rudimentary spatial map of odor identity is generated across these four zones of the epithelium (Mustaparta, 1971; Moulton, 1976; Thommesen & Doving, 1977; Mackay-Sim, Shaman, & Moulton, 1982; Edwards, Mather, & Dodd, 1988; Kent & Mozell, 1992; Scott, Shannon, Charpentier, Davis, & Kaplan, 1997; Scott & Brierley, 1999). Whereas the epithelium may offer crude spatial ordering, the nature of convergence from epithelium to bulb (Miyamichi, Serizawa, Kimura, & Sakano, 2005) enables a much more detailed spatial map of odor at the bulbar level (figure 22.7). Receptor neurons expressing the same type of receptor typically converge onto two individual glomeruli in the bulb, one on the lateral surface and one on the medial surface, in a manner that is symmetrical between bulbs and similar across individuals within a species (Ressler, Sullivan, & Buck, 1994; Vassar et al., 1994; Mombaerts et al., 1996; Tsuboi et al., 1999). Thus a strict relationship is maintained whereby a single receptor type is represented by a two glomeruli. Considering that different receptors may be sensitive to different aspects of odor molecules (termed *odotopes* or *pharmacophores*), a given odorant may then be represented by a spatial pattern of glomerular activity (Lancet, Greer, Kauer, & Shepherd, 1982; Shepherd, 1985; Johnson & Leon, 2007). Furthermore, lateral inhibition between glomeruli may serve to further sharpen this glomerular spatial map of odor (Mori & Shepherd, 1994; Yokoi, Mori, & Nakanishi, 1995). Several lines of evidence support this notion of odor maps on the olfactory bulb, including 2-deoxyglucose uptake (Stewart, Kauer, & Shepherd, 1979; Jourdan, Duveau, Astic, & Holley, 1980; Johnson, Woo, & Leon, 1998; Johnson, Woo, Hingco, Pham, & Leon, 1999; Johnson & Leon, 2000a, 2000b), electrophysiology (Shepherd, 1985; Mori & Yoshihara, 1995), gene expression (Guthrie, Anderson, Leon, & Gall, 1993; Guthrie & Gall, 1995; Johnson, Woo, Duong, Nguyen, & Leon, 1995; Sallaz & Jourdan, 1996; Inaki, Takahashi, Nagayama, & Mori, 2002), and optical imaging (Kauer, 1988; Rubin & Katz, 1999; Uchida, Takahashi, Tanifuji, & Mori 2000; Meister & Bonhoeffer, 2001).

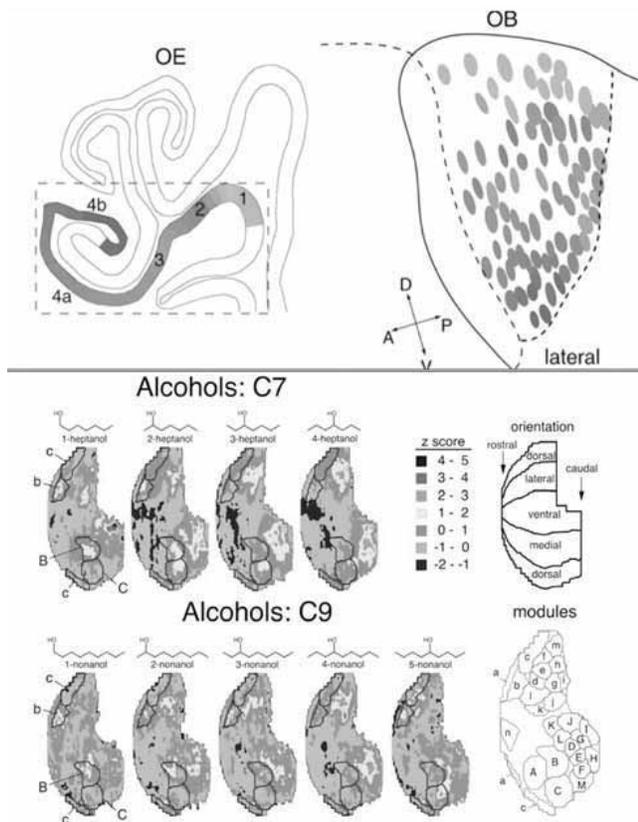

FIGURE 22.7 Spatial mapping from epithelium to bulb. *Top panel:* Color-coded zonal distribution of receptor types in the olfactory epithelium and their projection pattern to glomeruli in the olfactory bulb (Miyamichi et al., 2005). *Bottom panel:* Patterns of 2DG activation on the surface of the rat olfactory bulb as a reflection of odorant identity. For detailed maps, see <http://leonservers.bio.uci.edu/>. (See color plate 25.)

If a rudimentary spatial map of odorant identity is formed at the level of the epithelium and then sharpened at the level of bulb, one may ask whether this map is maintained at the level of cortex. Early anatomical studies suggested that the topography of projections from bulb to cortex was disordered and that cortical representation did not maintain the spatial ordering of bulbar representation (Price & Sprich, 1975). However, several functional studies point to spatial axes of representation in primary olfactory cortex. Optical recording of activity in the rat cortex suggest that the piriform cortex is divided into several functionally heterogeneous regions (Litaudon, Datiche, & Cattarelli, 1997). Electrophysiological recordings suggest piriform cortex has at least four spatial receptive fields specialized for odors delivered to the ipsilateral nostril, contralateral nostril, either nostril, or both nostrils (Wilson, 1997, 2001). Furthermore, a converging finding across rats (Kadohisa & Wilson, 2006b) and humans (Gottfried, Winston, & Dolan, 2006) suggests a dissociation whereby odorant structure is represented primarily in anterior piriform cortex, and odor quality is rep-

resented primarily in posterior piriform cortex. Although these findings suggest some relationship between the spatial organization of piriform cortex and odor input, rules underlying this organization remain unknown. Finally, work using single-cell recordings in monkeys found a high degree of odorant-specific responses at an even later stage of olfactory processing, namely, prefrontal and orbitofrontal cortex (Tanabe, Iino, Oshima, & Takagi, 1974; Rolls, Critchley, & Treves, 1996). Taken together, these findings suggest that odor identity may be spatially encoded at the level of cortex, but additional studies are needed to fully address this question.

Under the assumption of spatial mapping of odor at the olfactory epithelium, bulb, and cortex, a key question is what is the metric of smell that governs olfactory perception and hence this map. To date, scientists have been probing for this metric by systematically varying known aspects of molecular odorant structure while imaging the glomerular layer of the bulb. On the basis of work on the 17 receptor in mice and rats (Ivic, Zhang, Zhang, Yoon, & Firestein, 2002), the most commonly probed structural axis is that of carbon chain length. For example, Johnson and colleagues (1999), using 2-deoxyglucose uptake, and Rubin and Katz (1999), Uchida and colleagues (2000), and Meister and Bonhoeffer (2001), using optical imaging, all stimulated with an homologous series of n-aliphatic aldehydes varying in carbon chain length as a possible odor metric. They found that each individual odorant could be represented by a unique spatial distribution of glomerular activity and that the difference between these unique distributions or maps was greater for odorants that differed by increased length of carbon chain. In other words, odorants that differed by one carbon in chain length produced similar glomerular maps, and odorants that differed by several carbons produced increasingly different glomerular maps. Johnson and Leon (2000a, 2000b) defined clusters of glomeruli with similar response specificities as *glomerular modules* and found that in addition to carbon chain length, modular glomerular maps also encode for hydrocarbon branch structure and oxygen-containing functional group. These glomerular module maps were sufficiently consistent to allow Johnson and colleagues (2002) to predict both odorant structure based on patterns of glomerular activity and patterns of glomerular activity in response to novel odorants. The optical imaging studies also found that higher odorant intensities activated increased overall numbers of glomeruli, thus producing a somewhat smeared, yet retained, odorant identity map. This increased recruitment of glomeruli with increased odorant concentration was not always seen with 2-deoxyglucose uptake.

Although the emerging picture of spatial odor encoding at all levels of the olfactory system is quite convincing, this view does have some significant caveats. First, as noted by Laurent (2002), even if the current view of encoding at the

bulb is correct, this is not spatial encoding per se. In audition and vision, spatial ordering in the neural system represents spatial ordering in the physical world. For example, neighboring locations on the basilar membrane encode for neighboring frequencies. This was not the case in the aforementioned studies of activity in the olfactory bulb (Luo & Flanagan, 2007). Second, extensive lesions both at the level of olfactory bulb (Hudson & Distel, 1987; Lu & Slotnick, 1998; Slotnick & Bodyak, 2002) and at the level of the olfactory cortex (Slotnick & Berman, 1980; Slotnick & Rissler, 1990; Slotnick & Schoonover, 1993) do little to distort olfactory perception. If this perception were strongly linked to spatial representation within this neural architecture, one would expect these lesions to have far greater impact. Third, odor discrimination can be achieved at a rate that precedes full development of bulbar spatial maps (Wesson, Carey, Verhagen, & Wachowiak, 2008). Finally, patterns of activity throughout the olfactory system in general, and specifically in the olfactory bulb, are constantly modified through experience (Kauer, 1974; Meredith & Moulton, 1978; Di Prisco & Freeman, 1985; Harrison & Scott, 1986; Wellis, Scott, & Harrison, 1989; Eeckman & Freeman, 1990). Pure spatial mapping is an encoding scheme that would probably not lend itself to rearrangement within short time frames. By contrast, temporal encoding of information, namely, encoding of odor within the temporal order of neural activity, may be far more plastic on short time scales and conceivably less susceptible to anatomically restricted lesions.

Temporal coding

Olfactory behavior and therefore neural activity within the olfactory system are marked by rhythmic events. Since the pioneering work of Adrian (1942) and Freeman (1960), it has been known that two particular frequency domains dominate activity throughout the olfactory system. The first is the slow θ rhythm (typically 3–12 Hz) related to sniffing, and the second is the γ rhythm (typically 30–100 Hz), an odor-related oscillation that rides on the respiratory wave. These oscillations

occur in both the olfactory bulb and in primary olfactory cortex in a correlated manner (Eeckman & Freeman, 1990) and are present in rodents (Adrian, 1942; Ueki & Domino, 1961; Bressler & Freeman, 1980; Ketchum & Haberly, 1993; Protopapas & Bower, 2001) and perhaps in humans (Hughes, Hendrix, Wetzell, & Johnston, 1969; Sobel et al., 1998). Although it is clear that these oscillations are key to the process of olfaction, the exact functional significance of these patterns remains unclear. Several researchers have suggested that the γ frequencies, coupled with the exceedingly large number of backprojecting pyramidal axons from anterior piriform cortex to the bulb, categorize olfactory stimuli in an increasingly specific fashion over successive sniff cycles (Bressler, 1990; Freeman & Barrie, 1994; Bhalla & Bower, 1997). Consistent with this, single-cell recording revealed that ensemble activity of mitral cells in the olfactory bulb contains information at different time-scales that could be separately exploited by downstream brain centers to make odor discriminations (Bathellier, Buhl, Accolla, & Carleton, 2008). Although temporal ordering of neural activity is a well-described encoding strategy in the olfactory system of insects (Laurent, 2002), the suggestion of temporal coding in the mammalian system was met with hesitation by a field that has been dominated by the notion of spatial encoding. That said, studies by Hartwig Spors (Spors & Grinvald, 2002; Spors, Wachowiak, Cohen, & Friedrich, 2006) begins to bridge the gap between these two schools (Friedrich, 2002). Spors and Grinvald (2002) combined optical imaging with voltage-sensitive dyes to obtain high spatial (10–20 μm) and temporal (50–200 Hz) resolution measurements from the olfactory bulbs of rodents. Using these methods the authors found odorant-specific glomerular modules of activity similar to those previously described with optical imaging. However, the added temporal resolution revealed a highly dynamic spatial representation across the glomeruli that was constantly modified both within a sniff and across consecutive sniffs (figure 22.8). In other words, odor was represented by a combined spatio-temporal pattern of activity. This notion is consistent with

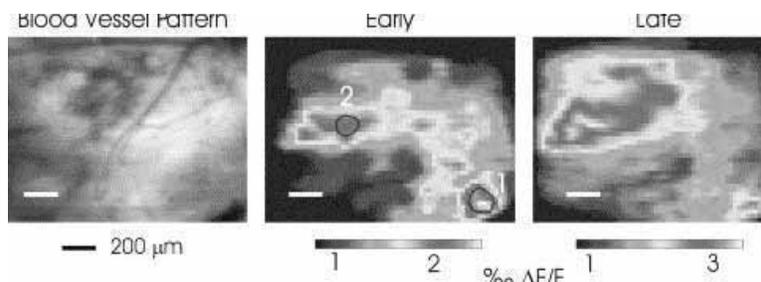

FIGURE 22.8 Temporal development of odor-induced activity. Data from Spors and Grinvald (2002) showing the temporal development of the bulbar response to the odorant ethylbutyrate. The early response is data obtained 150–300 ms following stimulus

onset, and the late response is data obtained 300–500 ms following stimulation. The spatial pattern of response is clearly modified over time. (See color plate 26.)

measurements obtained in cortex as well (Rennaker, Chen, Ruyle, Sloan, & Wilson, 2007). The brain may then read this spatiotemporal pattern as a sequence of discreet spatiotemporal events like frames in a movie (Hopfield & Brody, 2001; Friedrich, 2002). By contrast, these successive representations may represent stages of an ongoing computation in the bulb, in which case “time” is a computational variable in the construction of the odor representation at the bulbar level (Bhalla & Bower, 1997; Friedrich & Laurent, 2001). In both cases, the temporal information on odor may be carried by the intrinsic oscillations whereby it would alter the phase of activity in a specific manner (Hopfield, 1995).

In addition to directly participating in encoding of odorant content, the rapid oscillations may reflect the organization of network activity (Wilson & Bower, 1992; Protopapas & Bower, 2001). Specifically, current source density analysis suggests that each γ oscillation decomposes each inspiratory cycle into temporal bins of about 20-ms duration (Ketchum & Haberly, 1993). Haberly (1998) suggested that the olfactory system uses these temporal bins to pair afferent input from the olfactory bulb with intrinsically generated associational activity and inhibition in piriform cortex in order to subserve this region’s primary function as odor association cortex (Haberly, 1985, 2001).

Odor encoding: From percept to molecule

Although it is quite clear that odor is reflected in unique spatial and temporal patterns of neural activity in the olfactory system, odor encoding is far from understood. This is primarily evident in what remains the key unanswered question in olfaction: There is not a perfumer or scientist who can predict the odor of a novel physicochemical structure or predict the physicochemical structure of a novel smell. In our view, olfactory coding has not been solved because the stimulus space is poorly understood. To probe neural coding in vision and audition, neurobiologists varied stimuli along known primary perceptual axes such as color and pitch that were clearly linked to physical dimensions of wavelength and frequency, but what is a primary axis of olfactory perception? And to what physical dimension might it be linked? It is these two questions that we recently set out to ask, and we went about this by shifting from the typical approach of “from molecule to percept” to one “from percept to molecule.”

Constructing a perception-based odor space

To build a perception-based odor space, Rehan Khan and colleagues in our lab (Khan et al., 2007) used a previously published data set known as Dravnieks’ *Atlas of Odor Character Profiles*, in which approximately 150 experts (perfumers and olfactory scientists) ranked (from 0 to 5, reflecting “absent”

to “extremely” representative) 160 odorants (144 monomolecular species and 16 mixtures) against each of the 146 verbal descriptors (Dravnieks, 1985). Dravnieks had demonstrated that this type of data was stable across a large pool of subjects and across a large geographic span (Dravnieks, 1982). Using the data in the atlas, we applied principal components analysis (PCA), a well-established method for dimension reduction that generates an orthogonal basis set for the profile space in which each successive dimension has the maximal possible variance. In simple terms, PCA generates a new set of features, each of which is a weighted linear combination of the input feature space, such that the new features are (1) orthogonal and (2) ordered so that the first new feature is the single feature that captures the most variability among the objects in the feature space, the second is the single feature that captures most of the remaining variability, and so on. Thus the first principal component (PC), the first new feature or dimension, is the “best” one-dimensional reflection of the data, the first and second PCs are the “best” two-dimensional reflection, and so on. Figure 22.9A shows the percentage of the variance in the perceptual feature space explained by each of the first 10 PCs. As can be seen, the effective dimensionality of the odor profile space was much smaller than 146, with the first two dimensions or PCs accounting for 40.1% of the total variance in the odor profiles and the first four accounting for 54%. Using these four PCs that explained more than half of the variance, we generated a subspace into which we projected the 144 odorants (figure 22.9B). In other words, by applying PCA, we reduced the 146-dimensional feature space into a relatively low-dimensional perceptual space.

To test whether the space formed from the odor profile data can be thought of as a perceptual space, we tested whether distances in the space reflected perceptual odor similarity. We pseudo-randomly selected nine odorants that span the space (figure 22.9B) and then compared pairwise perceptual similarity between all odorant pairs to pairwise Euclidean distances within the space. Euclidian distance in the space was a powerful predictor of odor perceptual similarity (figure 22.9C). In a second experiment, we tested our perceptual space using an implicit similarity task. Using a subset of five odorants from the nine previously used, we presented subjects with a forced choice speeded reaction time task in which subjects were presented with two odorants in succession and required to indicate as quickly as possible whether they were the same or different. In such tasks, the time to respond correctly is expected to be longer for more similar odorants and shorter for more dissimilar odorants (Wise & Cain, 2000; Abraham et al., 2004; Khan & Sobel, 2004; Rinberg, Koulakov, & Gelperin, 2006). As we expected, subjects took longer to make correct judgments for more similar odorant pairs than for dissimilar odorant pairs (figure 22.9D), where similarity was derived from our

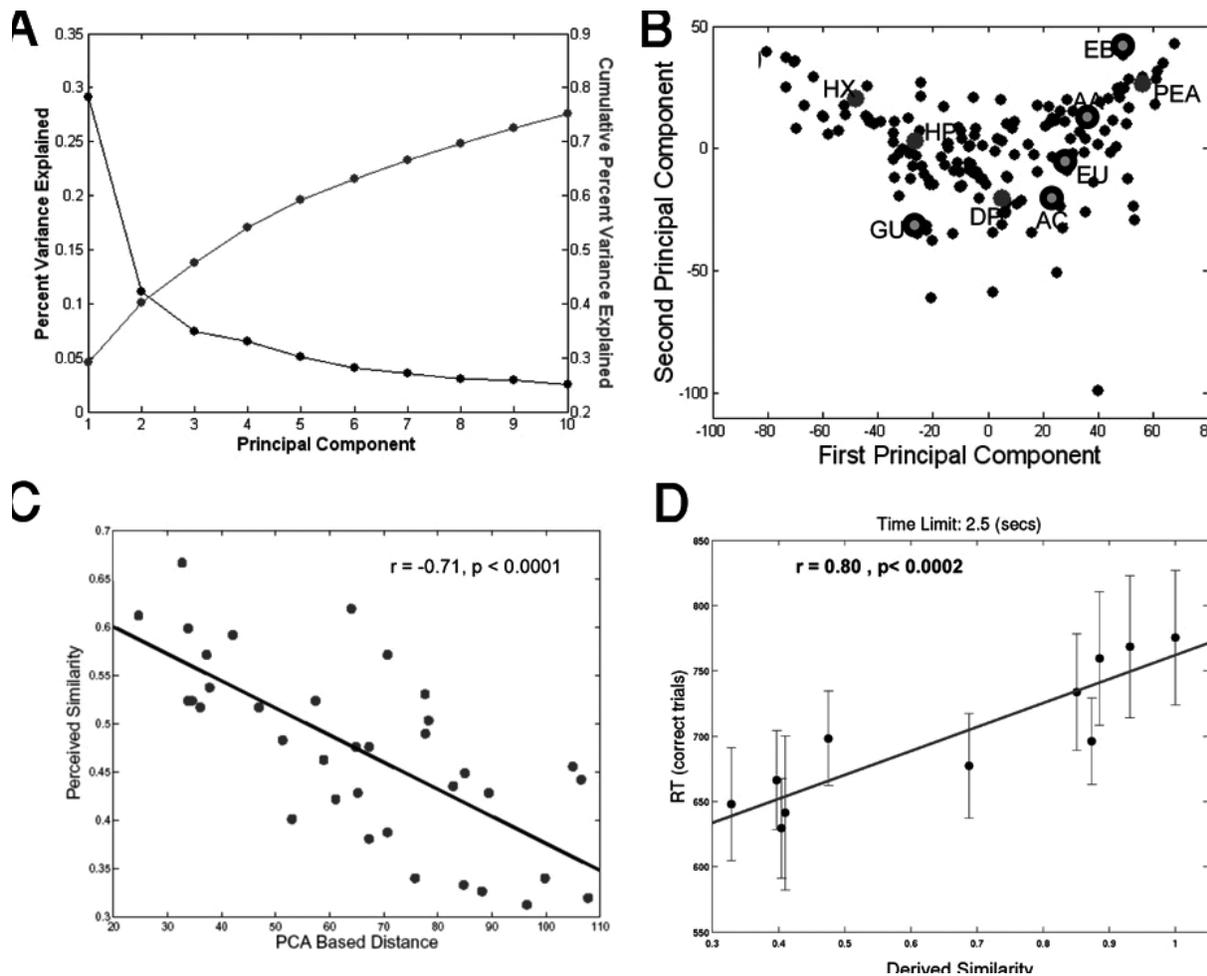

FIGURE 22.9 Olfactory perceptual space. (A) The proportion of variance in perceptual descriptions is explained by each of the PCs (starting at 0.3), and the cumulative variance is explained (starting at 0.05). (B) The 144 odorants projected into a two-dimensional space made of the first and second PCs. The nine odorants used in experiment 1 (acetophenone (AC), amyl acetate (AA), diphenyl oxide (DP), ethyl butyrate (EB), eugenol (EU), guaiacol (GU), heptanal (HP), hexanoic acid (HX), and phenyl ethanol (PEA) are in enlarged circles, and the five odorants used in experiment 2 (ace-

tophenone, amyl acetate, ethyl butyrate, eugenol, guaiacol) are in further enlarged circles. (C) For the nine odorants, the correlation between explicit perceived similarity ratings and PCA-based distance for all pairwise comparisons. Odorants closer in the perceptual space were perceived as more similar. (D) Reaction time for correct trials in a forced choice same-different task using five of the nine odorants. Error bars reflect SE. The reaction time was longer for odorant pairs that were closer in PCA-based space, thus providing an implicit validation of the perceptual space.

perceptual space. Thus in both explicit and implicit similarity tasks, our derived perceptual space corresponded to subjects' judgments of similarity. Odorants near each other in our space were perceived as similar, and odorants distant from one another were perceived as dissimilar.

Having validated the space, we set out to identify its principal axis. A first indication to the identity of PC1 is in the descriptors that flank it, that were SWEET, PERFUMERY, AROMATIC, FLORAL, and LIGHT on one end and SICKENING, PUTRID-FOUL-DECAYED, RANCID, SHARP-PUNGENT-ACID, and SWEATY at the other (figure 22.10A). An intuitive name for an axis spanning these descriptors is *perceptual pleasantness* (we use the term *pleasantness* for the sake of simplicity, yet we are referring to the contin-

uum from unpleasant to pleasant, also referred to as *perceptual valence* or *hedonic tone*). To test this intuitive label, in a separate experiment, we asked subjects to rank the pleasantness of the odorants, and then compared the difference in pleasantness to distances along PC1. The two measures were strongly correlated (figure 22.10B), indicating that our intuitive label of *pleasantness* for PC1 was valid.

Our characterization of the first PC as pleasantness is in agreement with previous research (Richardson & Zucco, 1989). Pleasantness is the primary perceptual aspect humans use to discriminate odorants (Schiffman, 1974; Godinot & Sicard, 1995) or combine them into groups (Berglund, Berglund, Engen, & Ekman, 1973; Schiffman, Robinson, & Erickson, 1977). Pleasant and unpleasant odorants are

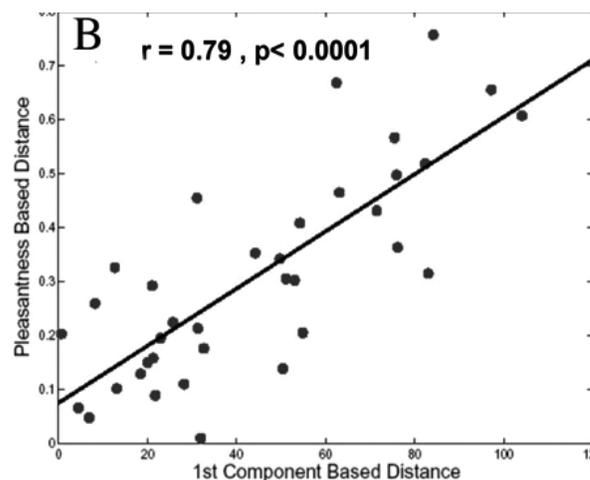

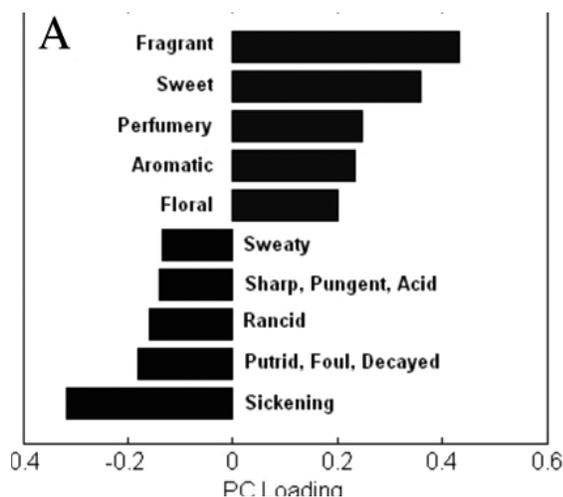

FIGURE 22.10 Identifying pleasantness as the first PC of perception. (A) The five descriptors that flanked each end of PC1 of perception. We should stress that here we show the five extreme descriptors only to help give a sense of the PC. This does not reflect a cutoff in any stage of the analysis, but only an esthetic cutoff for

the figure. (B) For the nine odorants, the correlation between the pairwise difference in pleasantness and the pairwise distance along the first PC. Distance along the first PC was a strong predictor of difference in pleasantness.

evaluated at different speeds (Bensafi et al., 2002) and by dissociable neural substrates, as evidenced in both electrophysiological recordings (Kobal, Hummel, & Vantoller, 1992; AlaouiIsmaïli, Rubin, Rada, Dittmar, & Vernet-Maury, 1997; Pause & Krauel, 2000; Masago, Shimomura, Iwanaga, & Katsuura, 2001) and functional neuroimaging studies (Zald & Pardo, 1997; Royet et al., 2000; Gottfried, Deichmann, Winston, & Dolan, 2002; Anderson et al., 2003; Rolls, Kringelbach, & de Araujo, 2003; Grabenhorst, Rolls, Margot, da Silva, & Velazco, 2007). Finally, studies with newborns suggest that at least some aspects of olfactory pleasantness may be innate (Steiner, 1979; Soussignan, Schaal, Marlier, & Jiang, 1997). Thus our findings are consistent with the view that “it is clearly the hedonic meaning of odor that dominates odor perception” (Engen, 1982).

Building a physicochemical molecular descriptor space

Having identified the primary perceptual axis of olfaction, we set out to ask whether any physicochemical dimension may be linked with it. Using structural chemistry software (Dragon), we obtained 1514 physicochemical descriptors for each type of odorant. These descriptors were of many types, for example, atom counts, functional group counts, counts of types of bonds, molecular weights, topological descriptors, and so on. We then used the same PCA procedure to reduce the dimensionality of the physicochemical space. Applying PCA revealed that the effective dimensionality of the space of descriptors was much lower than the apparent dimensionality of 1514. Figure 22.11A shows the percent variance explained by each of the first 10 PCs. The first PC accounted for approximately 32% of the variance, and the first 10

accounted for approximately 70% of the variance. Figure 22.11B shows the five descriptors that anchored the first PC of the space. The full names of these physicochemical descriptors are listed in the legend of figure 22.11.

Characterizing the primary dimensions of the PCA space of the physicochemical descriptors is more challenging than the task for the perceptual space, because of both the set size and the variety of descriptors involved. Nevertheless, giving them a coherent general character is possible and useful for providing a sense of what information they might capture. The first physicochemical PC was weighted at one end by factors that are reasonable proxies for molecular size or weight: the sum of the atomic van der Waals volumes is essentially a crude count of atoms, as is the count of the number of nonhydrogen atoms and the self-returning walk count of order one for nonhydrogen atoms (which is actually identical to a count of the nonhydrogen atoms). The characterization of these descriptors as indices of “weight” is borne out by a very high weighting that “molecular weight” itself has on this side of the first PC.

At the other end of the dimension are a series of topological descriptors that vary with the “extent” of a molecule. In fact, all five of the descriptors are average eigenvectors of distance or adjacency matrices, normalized in slightly different ways: average eigenvector coefficient sum from electronegativity-weighted distance matrix, and average eigenvector coefficient sum from Z-weighted distance matrix (Barysz matrix), average eigenvector coefficient sum from mass-weighted distance matrix, and average eigenvector coefficient sum from distance matrix, average eigenvector coefficient sum from adjacency matrix. Each of these measures increases as the denseness of the atomic connections

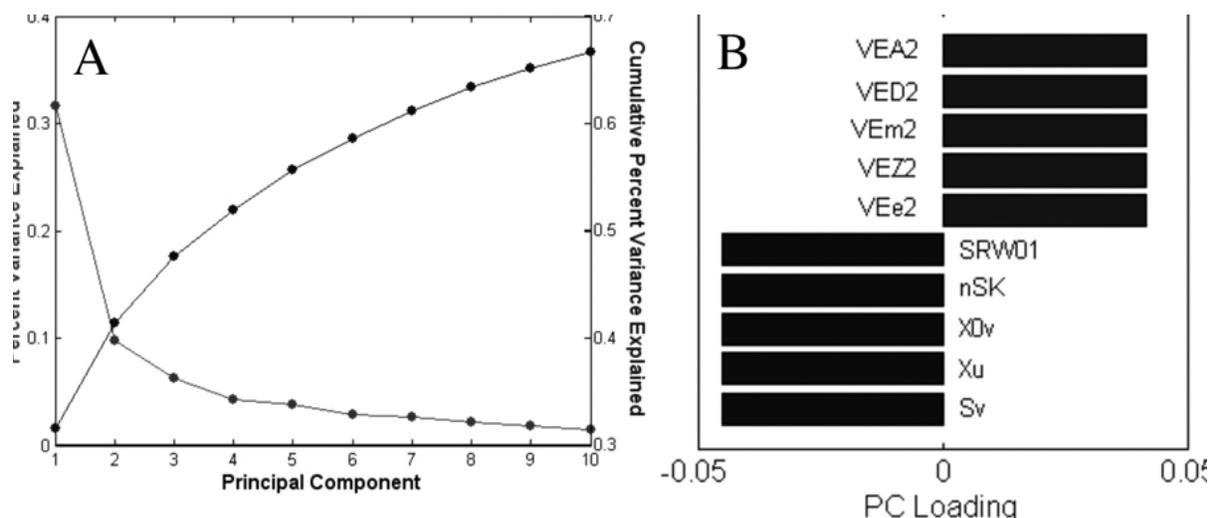

FIGURE 22.11 Reducing dimensionality of physicochemical space. (A) The proportion of variance in physicochemical descriptors is explained by each of the PCs (starting at 0.32), and the cumulative variance is explained (starting at 0.01). (B) The five descriptors that weighted most heavily at the ends of PC1 of physicochemical space. The descriptors are as follows: Sv, sum of atomic van der Waals volumes (scaled on carbon atom); Xu, Xu index; X0v, pleasantness connectivity index; nSK, number of non-H atoms; SRW01, self-

returning walk count of order 01 (number of non-H atoms, nSK); VEe2, average eigenvector coefficient sum from electro-negativity weighted distance matrix; VEZ2, average eigenvector coefficient sum from z -weighted distance matrix (Barysz matrix); VEm2, average eigenvector coefficient sum from mass weighted distance matrix; VEA2, average eigenvector coefficient sum from adjacency matrix; VED2, average eigenvector coefficient sum from distance matrix.

increases, that is, as the number of atoms is packed more closely together. In combination, then, these two extremes anchor a dimension that characterizes the amount and distribution of mass within a molecule. Thus the first PC can be thought of as a measure of the “compactness” of a molecule.

Building a model from physical to perceptual space

We used the same procedure to construct two spaces: a perceptual space that was derived from an initially high-dimensional odor descriptor space and a physicochemical space that was derived from an initially high-dimensional molecular descriptor space. Both spaces were constructed by using PCA, which generates ordered sets of orthogonal axes, constructed to maximize the variance they capture in the original feature space. Because the axes are orthogonal by construction, that is, uncorrelated using a linear Pearson correlation statistic, we can compare them independently.

For each of the first four perceptual PCs, we asked whether they were correlated with any of the first seven physicochemical PCs. Strikingly, we noted that the strongest correlation that we observed was between the first perceptual PC and the first physicochemical PC (figure 22.12A). In other words, the single optimal axis for explaining the variance in the physicochemical data was the best predictor of the single optimal axis for explaining the variance in the perceptual data. That the most important dimension in olfactory per-

ception should be the best correlate of the most discriminating physicochemical measures suggests that, as with other senses, the olfactory system has evolved to exploit a fundamental regularity in the physical world.

Having established that the physicochemical space maps onto the perceptual space, we next built linear predictive models through a cross-validation procedure. We then split the Dravnieks data in half, modeled one half, and used this to predict PC1 of the other half. We repeated this 1000 times and obtained a modest but significant prediction of PC1 (odorant pleasantness) based on physicochemical attributes (figure 22.12B). To test the generality of this finding, we predicted the pleasantness of 104 odorants that we had never smelled before and that were not used by Dravnieks or us at any stage. We then obtained these odorants and collected pleasantness estimates from three culturally diverse groups of subjects (Americans in Berkeley, California, in the United States; Israeli Jews in Rehovot in Israel; and rural Israeli Muslim Arabs in the village of Dir El Asad in the Northern Galali in Israel), each tested with more than 20 odorants. In each case, we obtained a similarly accurate and significant prediction of odorant pleasantness based on odorant structure (figure 22.13).

Using odor space to predict neural activity in the olfactory system

PC1 of physicochemical structure, or compactness, is a single axis. However, it is multidimensional in the sense

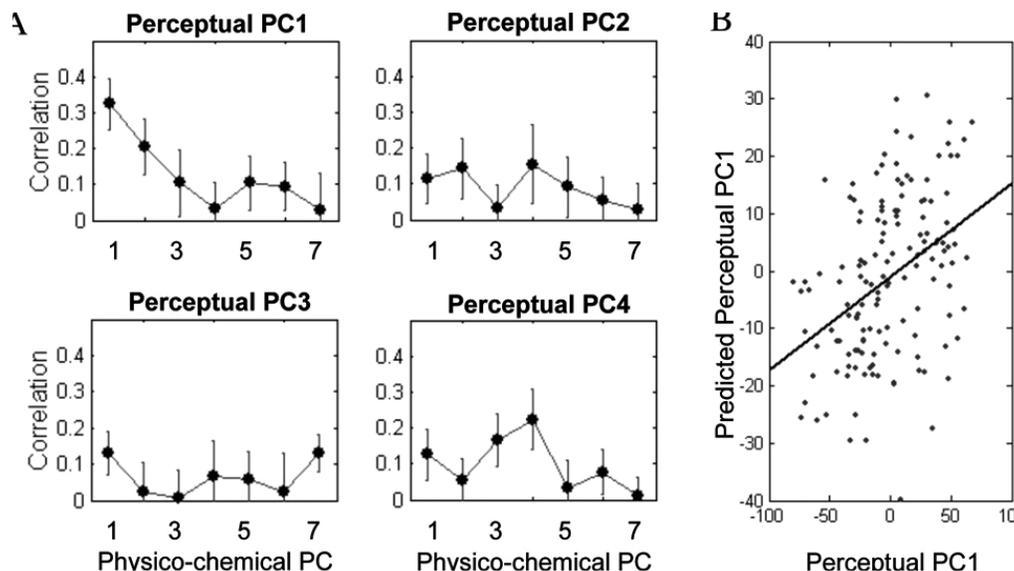

FIGURE 22.12 Relating physicochemical space to perceptual space. (A) The correlation between the first to fourth (descending in the figure) perceptual PC and each of the first seven physico-chemical PCs for the 144 odorants. Error bars reflect the SE from 1000 bootstrap replicates. The best correlation was between the

first PC of perception and the first PC of physicochemical space. This correlation was significantly larger than all other correlations. (B) For the 144 odorants, the correlation between their actual first perceptual PC value and the value our model predicted from their physicochemical data ($r = 0.59$; $F(1, 136) = 10.62$; $p = 0.0001$).

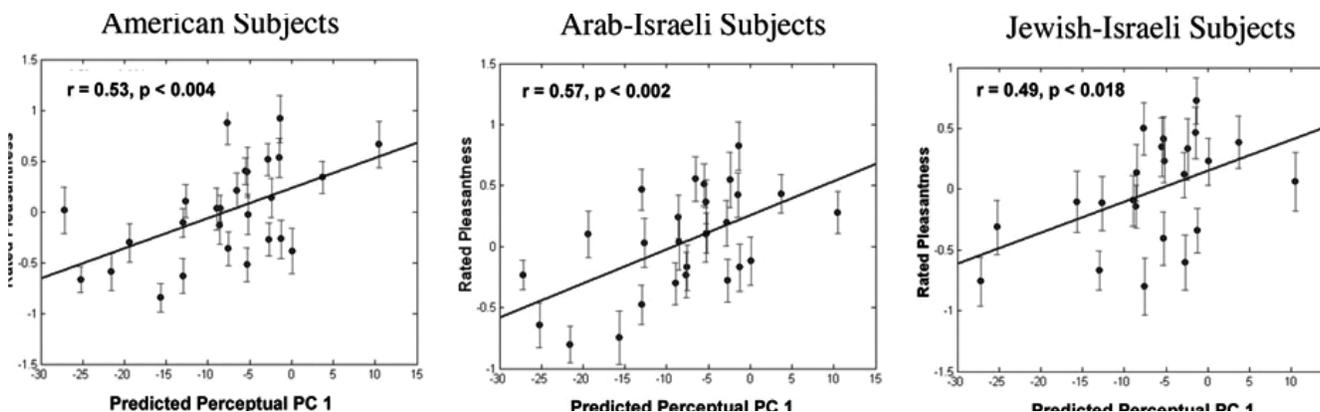

FIGURE 22.13 Cross-cultural validation. Twenty-seven odorous molecules not commonly used in olfactory studies and not previously tested by us were presented to three cultural groups of naïve

subjects: Americans (23 subjects), Arab Israelis (22 subjects), and Jewish Israelis (20 subjects). In all cases, our predictions of odorant pleasantness were similar and significant.

that more than 1500 known features contributed to it with known weights. In other words, we can represent each odorant as a single value reflecting its compactness (its PC1 score), or we can represent each odorant as a vector of more than 1500 values (although PC1 was generated with 1514 values, Dragon software will generate up to 1664 values). When using the former approach, the distance between two odorants is the difference in PC1 values. When using the latter approach, one can compute the distance between any two odorants by the square root of the sum of squares of the differences between descriptors.

Given that we have generated an olfactory metric, we can reanalyze previously collected data by reordering the studied odorants using the above described vector-type representation. With this in mind, Rafi Haddad and colleagues in our lab revisited nine previously published data sets as well as one novel data set for which we knew the odorants used but did not know the neural response (Haddad et al., 2008). We found that our novel metric was always better at accounting for neural responses than the specific metric used in each study (e.g., carbon chain length). Moreover, this single metric was applicable across studies that used different olfactory neurons, different model systems, and different neuronal

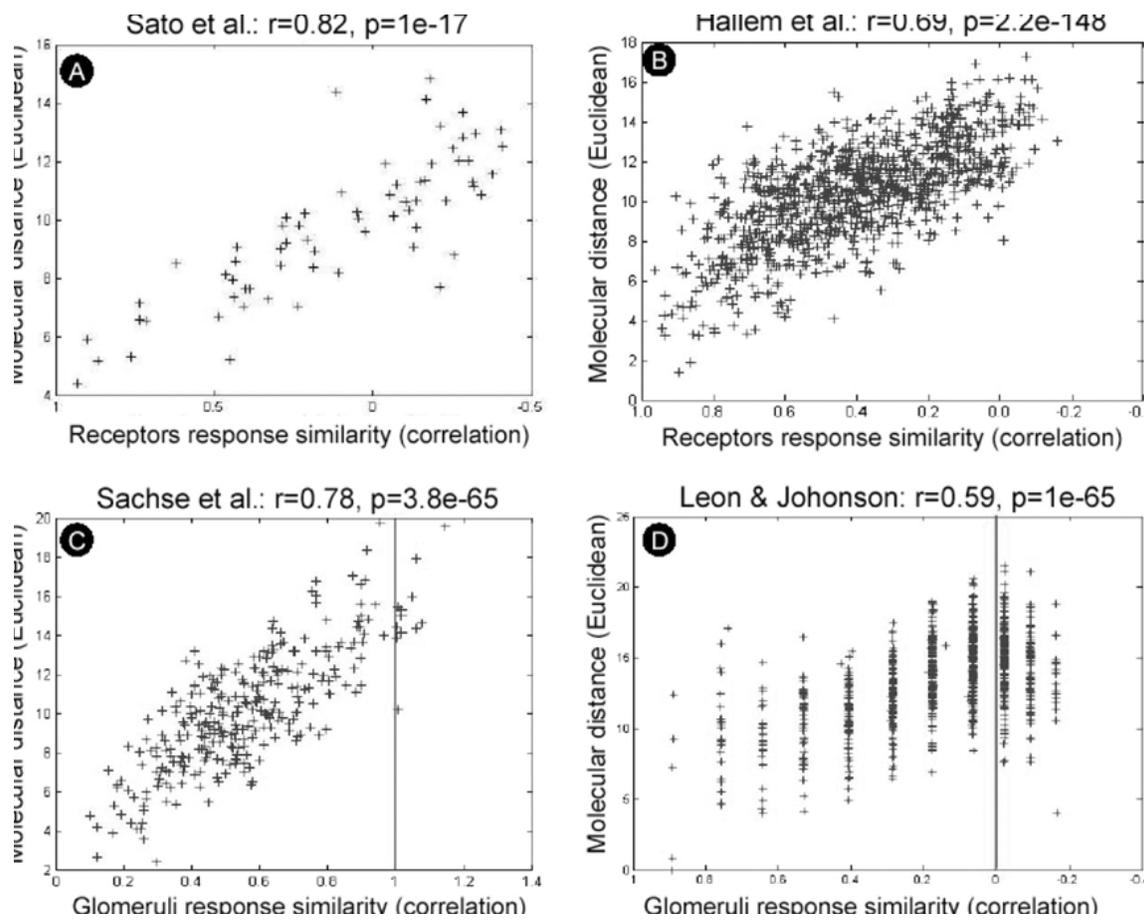

FIGURE 22.14 Correlation plots for unrelated data sets. The graphs demonstrate the ability of the multidimensional olfactory metric to predict neural activity in the olfactory system. Graphs *A* and *B* are from data set reporting RN responses (the similarity was the measured Pearson correlation and thus can range from 1 to -1). Graphs *C* and *D* are from data sets reporting GLO responses.

response measurement techniques and odorants varying along different feature types. In other words, our approach enabled us to use odorant structure to predict olfactory perception in human subjects (Khan et al., 2007) and odor-induced neural activity in nonhuman animals (Haddad et al., 2008) (figure 22.14).

Conclusions

Although the neuroanatomy of the olfactory system is well described and the molecular mechanisms of olfactory transduction are well understood, overall coding of olfaction remains a mystery, in the sense previously noted whereby an olfactory percept cannot be predicted from an olfactory stimulus structure. Our recent efforts have, in our view, made a step in this direction. However, this remains an initial step in what is a long path. To reiterate, we first reduced the dimensionality of olfactory perception

and joined others (Engen, 1982) in observing that pleasantness is the principal perceptual aspect of olfaction. We next reduced the dimensionality of physicochemical properties, and identified a primary axis of physicochemical structure. We found that 144 molecules were similarly ordered by these two independently obtained principal axes: one for perception and one for physicochemical structure. In other words, when measures useful to chemists with no a priori connection to any particular percepts were analyzed, those physicochemical measures that were best at discriminating a set of molecules were found to be precisely those that were most correlated with the perception of olfactory pleasantness. It is in identification of this privileged link that we add to the work of Schiffman, Amoore, Dravnieks, and others, who together laid the groundwork for this approach between the early 1950s and the late 1970s (Amoore, 1963; Laffort & Dravnieks, 1973; Schiffman, 1974).

As this link between physicochemical organization and perceptual organization is a key concept in this chapter, we think that it worth reiterating more plainly: Imagine that you were given 1514 physicochemical descriptors (but no perceptual descriptors) for each of 144 molecules, about which you were told nothing else, not even their names, and were instructed to order these descriptors on a single axis that best captures the variance observed in the full set of molecular descriptors. Now imagine that having produced such an axis, you were to arrange all of your 144 odorants on it, those with the lowest scores at one end and those with the highest scores at the other. Now imagine that you walk down your line and smell the odorants in turn. What we have found is that the odorants at one end of your line will smell relatively unpleasant and those at the other will smell relatively pleasant.

That perceptual pleasantness is a reflection of optimal physicochemical discrimination might at first appear at odds with the notion that olfactory pleasantness is variable across both individuals and cultures (Moncrieff, 1966; Pangborn, 1975; Wysocki, Pierce, & Gilbert, 1991; Ayabe-Kanamura et al., 1998), as well as malleable within individuals over time (Cain & Johnson, 1978; Hudson, 1999; Stevenson & Repacholi, 2003). In our own cross-cultural experiments, we found that judgments of pleasantness were less culturally variable than one might expect. We propose that the notion of large cultural variability in pleasantness may be overstated, owing to the salience of exceptions to the rule. Those cases in which one person finds an odorant pleasant and another finds the same odorant unpleasant are in such contrast to our usual experience (“How in the world can you find *THAT* smell to be pleasant?”), that they attain increased salience in our view of olfaction. Whereas it is true that these exceptions exist, there is nevertheless overwhelming agreement on gross olfactory pleasantness. Individuals may differ in the extent to which they find one perfume more pleasant than another or one rotting substance more disagreeable than another, but rarely will they find the rotting odor decidedly pleasant or the perfume decidedly unpleasant.

This is not to say that all of olfactory perception is common or innate. As in other senses, the perception of odor and of pleasantness is a complex process involving both innately tuned and learned components. The olfactory system is known for plasticity at multiple levels (Graziadei et al., 1979; Wilson, Best, & Sullivan, 2004; Barkai, 2005; Mandairon, Stack, Kiselycznyk, & Linster, 2006) and is characterized by experience-dependent learning (Keverne, 1995; Wilson, 2003; Wilson & Stevenson, 2003; Davis, 2004; Wilson & Stevenson, 2006) that reflects an advantageous evolutionary mechanism. Olfactory perception and subsequent neural representations are significantly influenced by several aspects that are clearly unrelated to physicochemical structure, such as context (Schoenbaum & Eichenbaum, 1995; Kay &

Laurent, 1999; Herz & von Clef, 2001; Djordjevic et al., 2008), expectation (de Araujo, Rolls, Velazco, Margot, & Cayeux, 2005; Zelano et al., 2005), multisensory convergence (Haberly, 2001; Gottfried & Dolan, 2003; Rolls, 2004), conditioning (Stevenson, Borakes, & Prescott, 1998; Li, Howard, Parrish, & Gottfried, 2008), and various top-down state-dependent modulatory influences (Pager, 1983; Critchley & Rolls, 1996; Kay & Freeman, 1998; Murakami, Kashiwadani, Kirino, & Mori, 2005). For example, an unfamiliar odor will smell sweeter after pairing with sweet taste (Stevenson et al., 1998), a cherry odor may smell smoky following previous association with a smoky odor (Stevenson, 2001a, 2001b), and the same test odor will smell more pleasant when labeled “cheddar cheese” than when labeled “body odor” (de Araujo et al., 2005). Experience-dependent neural representations of odor quality may be rapidly updated through perceptual experience, such as prolonged exposure to a target odorant (Li, Luxenberg, Parrish & Gottfried, 2006), aversive conditioning (Li et al., 2008), or congruent semantic information (Gottfried & Dolan, 2003).

The dynamics of this plastic aspect of olfactory perception will obviously not be reflected in physicochemical structure. However, a portion of olfactory perception is innate and hard-wired (Blanchard et al., 1989; Zangrossi & File, 1992; Dielenberg, Hunt, & McGregor, 2001; Dielenberg & McGregor, 2001), and our results concern this portion. Innately, the olfactory system evolved to maximize discrimination between molecules, and as with other senses, its perceptual organization has evolved to reflect the axis of maximal variance in stimulus space. Thus in perceiving pleasantness, the olfactory system may be understood to be a programmed widely tuned discriminator of molecules rather than a haphazard or arbitrary translator of molecular properties. In other words, what is on one hand surprising is on the other hand inevitable.

23 Auditory Masking with Complex Stimuli

VIRGINIA M. RICHARDS AND GERALD KIDD, JR.

ABSTRACT The detection of a target sound embedded in a chaotic acoustical environment is a basic yet poorly understood component of auditory perception. This chapter reviews three aspects of such auditory masking, building toward the important problem of the perception of hearing a speech signal in the presence of competing speech sounds. First, the history of psychoacoustic masking experiments and the development of energy-based models to account for the resulting data are described. Then experiments and models of the detection of a tonal signal masked by randomly drawn maskers, an example of informational masking, are described. Informational masking experiments such as these are important because they reveal masking phenomena that are mediated more centrally than the masking associated with traditional masking studies. Finally, the roles of peripheral and central masking for the detection of speech masked by other speech sounds are discussed.

Imagine the following: You and a friend are standing on the corner of 34th and Chestnut Streets in Philadelphia, awaiting a bus to take you to Monks, a local pub known for Belgian-style beers. It is just after 5:00 P.M., and the traffic is heavy. And as it happens, a garbage truck is clearing public trash bins along Chestnut Street. Needless to say, you have to yell to be heard over the din of activity. This is an example of masking.¹ To communicate your message acoustically, you must broadcast your signal at a high intensity. Sound pressure waves superimpose, or add, in space, and what enters the ear is the accumulation of the sound in the environment. In enclosed environments—a classroom, for example—superposition includes not just the noise of students, audiovisual equipment, and so on, but also the sounds reflected off of walls, chalkboards, tables, and other surfaces. It is as though we live in an acoustical hall of mirrors. The auditory system has adapted to this din, allowing the segregation of a target sound away from the masking sounds. Efforts to understand this fundamental aspect of auditory perception form the basis of modern research in auditory masking.

In 1958, Tanner suggested that the intuitive sense of masking conveyed in the scenario described above is a vastly

incomplete description of auditory masking. Tanner began with Licklider's (1951) description of masking: "Masking is thus the opposite of analysis; it represents the inability of the auditory mechanism to separate the tonal stimulation into components and discriminate between the presence or absence of one of them" (Tanner, 1958, p. 191; Licklider, 1951, p. 1005). This definition reflects the fact that the auditory system represents sounds *tonotopically*, such that the different frequencies of impinging sounds are encoded and represented by different populations of neurons. The failure of analysis noted by Licklider, then, essentially equates masking with limitations in the frequency resolution of the auditory system. When the signal and masker share common frequencies, the overlap of signal and masker energy makes the detection of the signal difficult because the shared energy is represented by the same population of neurons. Tanner noted that when the frequency of the tone to be detected is not fixed but chosen at random, the detectability of the signal decreases (Tanner & Norman, 1954). It is unlikely that this reduction in sensitivity reflects a failure of analysis at the auditory periphery. Should this decline in sensitivity be considered a form of masking? Tanner further pondered the detection of a tone of known frequency masked either by another tone or by Gaussian (white) noise. Should masking be defined independently of the properties of the masker? Regardless of whether the frequency of the tone to be detected is uncertain or the characteristics of the masker are varied, the end result is the same: A listener's ability to detect the signal changes. Should all of these examples be described by using the single term *masking*?

Tanner's point might be described in a slightly different way: As the sound stream is processed by the ascending auditory pathway, what information is lost and where in the processing is it lost? With regard to what masking tells us about the auditory system, the question becomes: How is it that biological systems effortlessly detect and follow an ongoing target sound under the pressure of multiple acoustical distracters? While not directly addressed in the current chapter, it is important to appreciate that for many individuals with compromised auditory capabilities, there is a decline in the ability to detect a target sound in the presence of other sounds especially when the listening situation is

VIRGINIA M. RICHARDS Department of Psychology, University of Pennsylvania, Philadelphia, Pennsylvania

GERALD KIDD, JR. Department of Speech, Language and Hearing Sciences, Boston University, Boston, Massachusetts

complex and uncertain. Presumably, when a more complete understanding of masking is achieved, advances in prosthetic devices such as hearing aids will follow.

In the current chapter, the answers to the complex question Tanner posed are not wholly addressed. Rather, the goal is to provide an update, asking: What are the peripheral and central constraints that yield auditory masking? Following the tradition in which Tanner worked, this chapter considers psychophysical data in which quantitative models associated with signal detection theory (cf. Green & Swets, 1974) are used to link the physical description of sounds with behavioral measurements. Thus, the scientific questions that are addressed are: (1) What are the peripheral constraints for the detection of a target among distracters? (2) What is known of the central constraints for the detection of a target among distracters? and (3) Given the large amount of masking associated with central processing, how does this affect our ability to recognize a target speech sound among competing speech? These questions are addressed in sequence, with an emphasis on the latter two.

Traditional masking studies: Energetic masking

Wegel and Lane (1924) provided empirical estimates of detection thresholds for a signal tone that is masked by

another tone of different frequency. They described their results in terms of the *amount of masking*. The amount of masking is the increase in sound pressure level that is required to detect a target tone (the signal) in the presence of a second tone (the masker) compared to the detectability of the target tone in quiet. Figure 23.1 shows the results of a similar experiment by Egan and Hake (1950). Although the results of Egan and Hake (1950) and those of Wegel and Lane (1924) are quite similar, Egan and Hake's data are displayed because they are less influenced by factors such as auditory "beats" that distort the masking pattern. In this experiment, a narrowband noise masker was centered at 410 Hz, and the amount of masking, in dB, was plotted as a function of the signal frequency. The three functions are for three different masker levels: 40, 60, and 80 dB sound pressure level. Wegel and Lane's and Egan and Hake's results revealed several important features of auditory masking. First, they found that when the masker is distant in frequency from the signal, there is little masking. Consistent with the tonotopic organization of the auditory system, it is only when the masker is near in frequency to the signal that masking occurs. Second, when the masker level is increased, the signal level too must be increased to maintain equal detectability. Third, when the masker has a frequency lower than the signal frequency, there is more masking than occurs for the converse

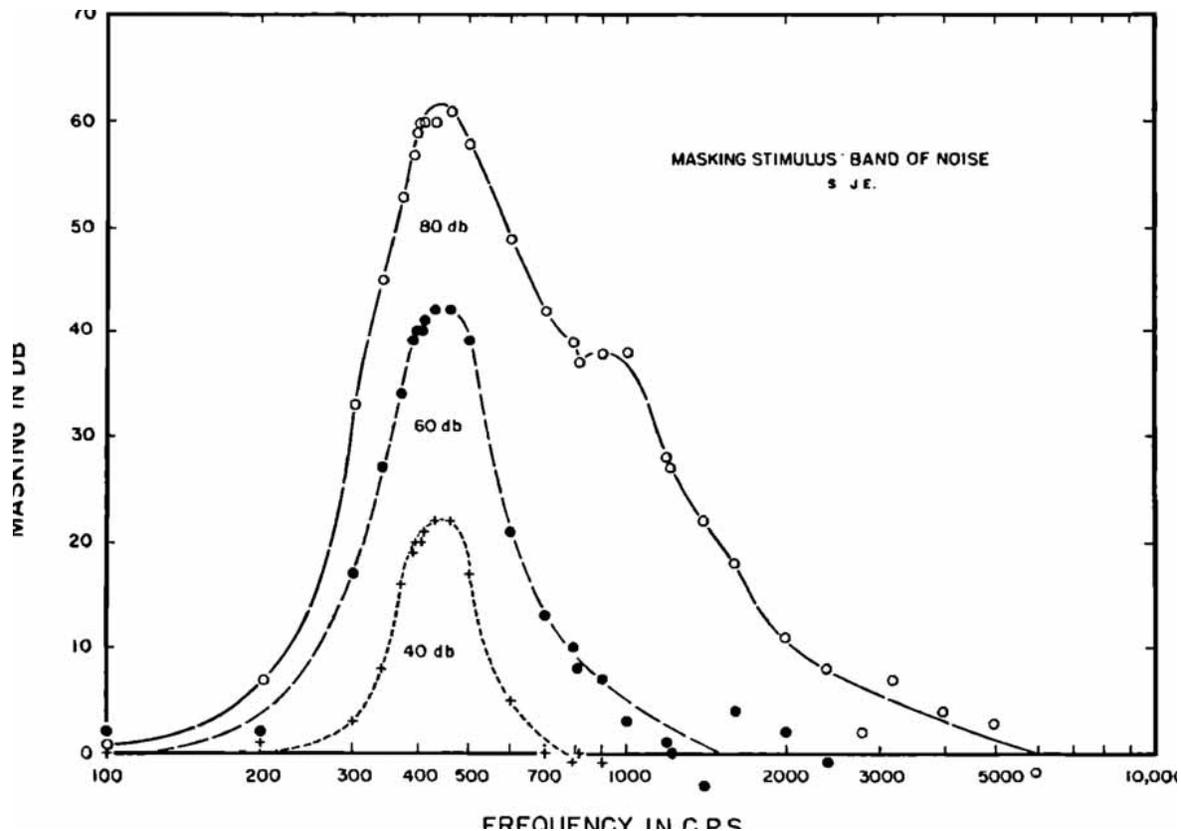

FIGURE 23.1 The amount of masking for a tonal signal masked by a narrowband noise centered at 410 Hz is plotted as a function of signal frequency. The level of the narrowband noise was 40, 60, and 80 dB sound pressure level. (From Egan & Hake, 1950.)

situation; for example, to detect a midfrequency signal, a low-frequency masker produces more interference than a high-frequency masker does. Fourth, they found that as the frequency of the masker increased, the frequency range over which the masker interfered with signal detectability increased. This work and many other related studies have provided psychoacoustical evidence corresponding to the frequency selectivity that is found at the level of the basilar membrane within the cochlea as well as suggesting the potential that the transduction chain includes nonlinearities.

Fletcher (1940) provided early estimates of the effective bandwidth of interaction at the auditory periphery. In one of his experiments, the task was to detect a tone added to a noise masker. The bandwidth of the masker, which was centered at the signal frequency, was systematically broadened. The idea was that as the noise bandwidth increased, the detectability of the added tone should decrease. This is because the masker power passed through the *internal* bandpass filter² (currently referred to as the *auditory filter*) would increase with increasing masker bandwidth, causing more and more masking of the signal tone. Once the bandwidth exceeded the bandwidth of the internal filter, no further increase in masking would be expected. As such, when the bandwidth of the masker increased, Fletcher expected the detectability of the added tone to first decrease and then level off. This prediction held true, allowing Fletcher to estimate the bandwidth of the effective internal filter.

Subsequent work has refined the assumptions upon which Fletcher's model was based, and this contemporary model is referred to as the *power spectrum model of masking*. By this model, for the detection of a tone added to any masker, noise or otherwise, a listener monitors the output of the single auditory filter. Work by Patterson and colleagues and Moore and colleagues (e.g., Patterson, 1976; Patterson, Nimmo-Smith, Weber, & Milroy, 1982; Glasberg & Moore, 1990; Moore, 1995; Unoki, Irino, Glasberg, Moore, & Patterson, 2006) has provided computational/psychophysical approaches that allow for the estimation not only of the bandwidth but also the shape of auditory filters. The assumptions associated with the power spectrum model of masking include the following: (1) Listeners monitor the output of a single auditory filter, the filter with the highest signal-to-noise ratio; (2) the auditory system can be modeled as a set of contiguous overlapping bandpass (and notably, nonlinear) filters²; (3) listeners detect the added tone at a constant signal-to-noise ratio; and (4) there is variance in the listener's auditory/decision-making system. The last assumption groups together all possible sources of error, including neural jitter, uncertainty regarding the true characteristics of the signal to be detected, variations in motivation, and so on. The resulting estimates of auditory filter characteristics provide a convenient psychophysical tool for studying peripheral interactions. The masking associated with limitations in analysis at the auditory

periphery is often referred to as *energetic masking*, a term coined by Pollack (1975) as a contrast to *informational masking*.

Informational masking: Simultaneous multitone maskers

Different from energetic masking, central masking, or *informational masking*, occurs when there is an elevation of threshold due to stimulus uncertainty (cf. Leek, Brown, & Dorman, 1991; Neff, 1995). An alternative description is that informational masking is the amount of masking above and beyond energetic masking or the masking that occurs even when there is insufficient interaction between the signal and masker at the auditory periphery to explain the results (see Durlach et al., 2003a, for a discussion).

One means of inducing informational masking is to use maskers composed of several tones, with the frequencies of the tones chosen at random on each presentation. This procedure was introduced by Neff and Green (1987). The signal to be detected was fixed in frequency (e.g., 1000 Hz), and the number of tones that composed the masker ranged, in different blocks, from 1 to 100. Critically, the frequencies of the masker tones were drawn at random prior to each stimulus presentation, creating masker uncertainty. To understand the difficulty that this task poses, imagine trying to hear a 1000-Hz tone embedded in a masker, but the masker's timbre varies vastly from presentation to presentation. As a simple example, the masker might shift randomly from a piano to an oboe to an organ from trial to trial. There is little basis for comparison among the sounds, making it difficult to detect the added tone. This is the core of informational masking: Under pressures of masker variation, listeners fail to *selectively attend* to the known signal frequency.

An empirical example relating the amount of informational masking to the number of masker tones composing the masker is shown in figure 23.2 (Neff & Green, 1987). Two aspects of this graph deserve note. First, even when the masker was a single sinusoid (one masker component), thresholds were on average 20 dB higher than those when no masker was present. Second, thresholds were highest when the masker was composed of 10–30 or so components. With regard to understanding this function, it should be noted that energetic masking is expected to increase as the number of tones increases. This reflects the statistics of the masker. The more masking tones there are, the more likely it is that one or more of the masker tones' frequency will be close to the signal frequency. With regard to the nonmonotonicity of the function, Oh and Lutfi (1998) have developed a model that captures this general shape. As a brief description, their model suggests that the more variance there is at the output of each auditory filter, computed across trials, the larger is the amount of informational masking. When there are few masker components or many masker components, the variance in any one auditory filter is modest.

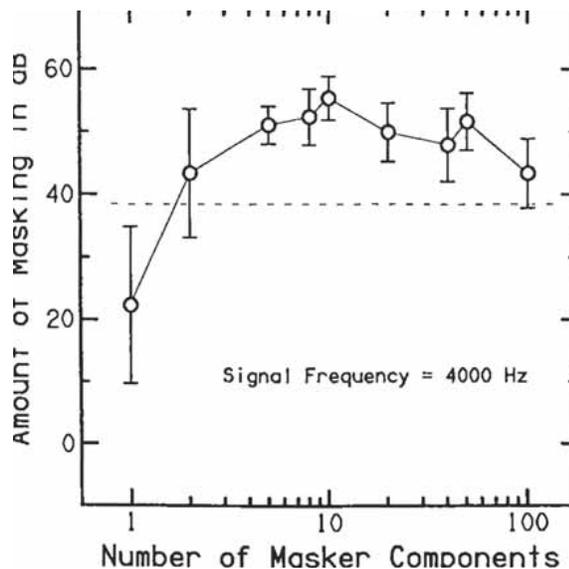

FIGURE 23.2 Amount of masking is plotted as a function of the number of tones comprising the masker. The dashed line is the amount of masking for Gaussian noise. (From Neff & Green, 1987.)

An additional common finding in informational masking experiments is large individual differences in levels of performance. In many instances, the range in the amount of masking approaches 50–60 dB (Neff & Dethlefs, 1995). This range represents approximately one-half of the dynamic range of the auditory system, which, depending on the way in which it is computed, typically is greater than 100 dB. Currently, the reasons for this enormous range of performance across individual subjects are poorly understood.

Even when individual differences are noted, it is clear that random multitone maskers are tremendously effective maskers of tonal signals. Additionally, it is apparent that informational masking reflects limitations in central processing. As a result of the large amount of masking, modest changes in cognitive processing can be reliably probed. For this reason, researchers have come to ask, in essence, how informational masking can be reduced, or *released*. To answer this question, it is critical that tools exist to separate peripheral from central processing (cf. Brungart, Chang, Simpson, & Wang, 2006).

With regard to potential means of releasing informational masking, an initial step is to recognize that informational masking must surely reflect, to a significant degree, the auditory system's grouping together of the signal and masker. That is, the signal and masker are, to a large degree, perceived as emanating from a single sound source. The factors that are associated with this grouping mechanism contribute to the failure of the auditory system to "hear out," or potentially selectively attend to, the signal tone. Consistent with this result is that listeners with superior sensitivity rely most

heavily on information in the region of the signal, whereas listeners with poorer sensitivity tend to integrate information from frequency regions that are distant from the signal frequency (e.g., Alexander & Lutfi, 2004; Oh & Lutfi, 1998; Richards, Tang, & Kidd, 2002; Richards & Neff, 2004; Tang & Richards, 2003). Drawing a rough parallel with Treisman and colleagues' feature integration theory (e.g., Treisman & Gelade, 1980), one potential description is as follows. When the masker is composed of relatively few masker tones (say, 10), the masker tones and the signal are separately analyzed at the auditory periphery, yielding several tones with common characteristics or features. Because the auditory system cannot distinguish an increase from 10 tones (masker alone) to 11 tones (masker plus signal), the signal is very difficult to detect. By this notion, introducing differences in the characteristics of the signal compared to the masker components ought to allow the signal to be segregated from the masker, thereby releasing masking. In fact, this result has been obtained (e.g., Neff, 1995; Kidd, Mason, & Arbogast, 2002; Durlach et al., 2003b). For example, if the signal to be detected starts shortly after the masker or is a frequency glide rather than a simple tone, then informational masking is substantially reduced. At present, the relationship between the amounts of release from informational masking due to changes in the characteristics of the signal versus the masker (and masker components) is not well understood.

The amount of informational masking can also be reduced by providing listeners with a cue that reduces stimulus uncertainty. Several types of cues have been tested: signal cues, masker cues, and signal-plus-masker cues (e.g., Richards & Neff, 2004; Richards, Huang, & Kidd, 2004). These cues are exact replicates of the stimuli tested on each trial. A signal cue reminds the listener of the signal's frequency thereby reducing signal-frequency uncertainty. The available data indicate that when signal cues are tested, listeners tend to rely on or heavily weight the region near the signal frequency (Richards & Neff, 2004). Similarly, masker cues would be expected to reduce masker frequency uncertainty, while signal-plus-masker cues would be expected to reduce uncertainty for both. Note that masker and signal-plus-masker cues reduce stimulus uncertainty nearly equally, so they might be expected to provide approximately equal amounts of release from masking. The data, however, which are discussed below, indicate otherwise.

Richards and colleagues (Richards & Neff, 2004; Richards et al., 2004) have completed several experiments examining the efficacy of different cue types in their ability to release informational masking. Richards and Neff examined the impact of providing a cue, both signal and masker cues, before the detection trial. The signal, when present, was either a 1000-Hz tone or a randomly drawn tone for each signal trial, depending on the condition that was tested.

The masker was composed of six tones whose frequencies were randomly drawn. Masked thresholds (signal level required for a d' of approximately 1) were estimated both with and without pretrial cues, and data collection was blocked to allow listeners to take full advantage of the cue. Listeners were highly trained and were provided with feedback following each trial.

First consider the results with a signal cue. Regardless of whether the signal frequency was fixed or random, thresholds were lower (superior sensitivity) when a cue preceded a trial than when there was no cue. Moreover, cued thresholds were only slightly poorer when the signal frequency was random than when it was fixed. Surprisingly, there was no correlation between the informational masking threshold and the amount of release from informational masking. That is, although there were substantial individual differences in the amount of informational masking, the release from informational masking provided by the signal cue was approximately equal across listeners.

Next consider the results with a masker cue. A preview of the masker provides information as to which frequency regions (masker tones) *not* to pay attention to on the subsequent trial. The results indicated that a masker cue was as effective as the signal cue in releasing informational masking. In one direct comparison, both signal and masker cues provided 10–15 dB of release from informational masking. Additional data showed that the benefit of both signal and masker cues lasts a substantial length of time. For example, delays between the cue and the trial ranging from 50 to 500 ms were equally effective. To summarize, the results of Richards and Neff (2004) indicated that a preview of either the signal or the masker can provide a substantial release from informational masking. However, neither a signal nor a masker cue fully released informational masking. It was estimated that on average, approximately 30 dB of informational masking still remained.

The fact that a preview of the masker allows a release from informational masking is consistent with the phenomenon of auditory enhancement, which in turn is consistent with the general finding that the auditory system is adept at detecting when something “new” is added to the sound stream (i.e., the introduction of new sound sources). Auditory enhancement is a term that describes the fact that the detection of a signal can be *enhanced* when energy “flanking” the signal frequency precedes the signal (e.g., Viemeister, 1980; Viemeister & Bacon, 1982; Wright, McFadden, & Champlain, 1993). Whether cueing effects in informational masking experiments reflect the same mechanisms as for the auditory enhancement reported in these studies remains to be determined. However, the results that are considered next suggest that they do contribute.

The importance to the auditory system of “new” information can be evaluated by measuring the release from infor-

mational masking for *pretrial* cues versus *posttrial* cues. The logic is as follows. If a masker cue is effective in releasing informational masking, regardless of whether it precedes or follows a trial, it would suggest that the release from informational masking reflects a reduction in uncertainty. In contrast, if the pretrial cue is much more effective than the posttrial cue then, for the masker-only cue at least, there would be support for the hypothesis of auditory enhancement. By the same token, a signal-plus-masker cue should also reduce uncertainty and thus should release informational masking but would not produce auditory enhancement. Figure 23.3 shows the results of two informational masking experiments that examine these predictions (Richards et al., 2004). First consider the open symbols to the left. The open square shows the average value of d' for a signal of fixed frequency and fixed level when a masker cue preceded each trial. The open circle (hidden by the solid symbols) shows d' for the same signal but with a preview of the signal-plus-masker stimulus. The masker cue provides substantially more release from masking than the signal-plus-masker cue does, consistent with the idea that the detection of something new (i.e., when the following trial has a signal) is enhanced by the auditory system.

Second, consider the open symbols to the right in figure 23.3. In this case, the cue followed the detection trial. As such, it is the signal-plus-masker cue that provides something “new” to be detected (i.e., a masker trial followed by a signal-plus-masker cue). The values of d' for the signal-plus-masker and masker posttrial cues are approximately the same. Moreover, the values of d' are approximately intermediate between the values that were obtained for the pretrial cues.

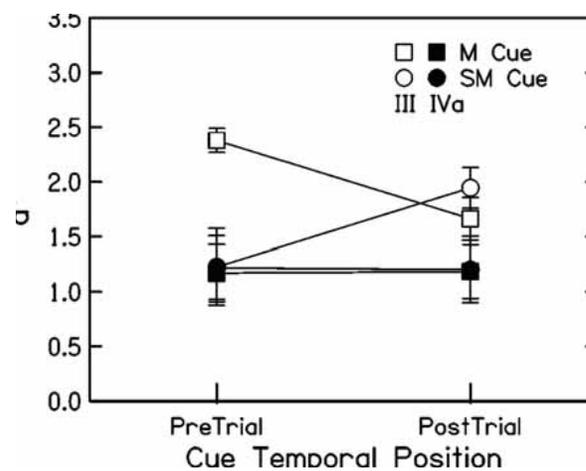

FIGURE 23.3 The index of detectability, d' , is plotted for two informational masking experiments. For one experiment, the signal frequency was fixed (open symbols), and for the other, the signal frequency was random (solid symbols). The cue was either a copy of the masker (square) or signal-plus-masker (circle), and the cue was presented either before or after the trial (abscissa). (From Richards et al., 2002.)

Across several experiments, data such as these indicate that a preview of the masker provides substantial release from informational masking, while the three remaining cue conditions (pretrial signal-plus-masker, posttrial masker, and signal-plus-masker) provide approximately equal, but less, release from informational masking. This result suggests that the larger release from informational masking does not simply reflect the temporal introduction of a “new” sound; pretrial masker cues and posttrial signal-plus-masker cues introduce an equal number of “new” sounds to be detected. This result contrasts with visual search studies in which pretrial and posttrial cues can be equally effective (cf. Kinchla, Chen, & Evert, 1995), potentially a situation in which the cue effectively reduces uncertainty.

Next consider the solid symbols in figure 22.3. In this case, the signal frequency was random but of the same level as for the conditions described above. When the signal frequency is random, all four types of cues (masker and signal-plus-masker by pretrial and posttrial positions) are equally effective.

Clearly, cues do provide a release from informational masking, but the pattern of results is complex. The dominant advantage of a masker cue is restricted to situations in which the signal frequency is *known* and the cue precedes the detection trial, at least for the temporal parameters tested by Richards and colleagues. These results are not wholly consistent with the hypothesis that the release from informational masking associated with a masker pretrial cue reflects the auditory systems ability to detect a new sound source. Nor are they consistent with the notion that masker and signal-plus-masker cues simply reduce uncertainty.

These results and others indicate the complexity of forms of masking that occur even for relatively simple psychoacoustic tasks. Indeed, informational masking is likely to be very prevalent in many psychoacoustic tasks. For example, Lutfi (1990) estimated that even for the traditional task of detecting a tone added to Gaussian noise, some 20% of the total masking is informational masking. Next, we discuss the ways in which research concerning informational masking contributes to an understanding of masking in a far more complex environment: the recognition of target speech sounds in the presence of competing utterances.

Informational masking and speech recognition

The acoustic signals that we use to communicate with most frequently are speech sounds. Other sounds may interfere with our ability to understand speech, and this interference may also be considered in terms of energetic and informational masking. Early studies of the masking of speech—similar to the early studies of the masking of tones mentioned above—often used Gaussian noise or filtered Gaussian noise as a masker. The interpretation of the results of speech rec-

ognition studies in the presence of noise was straightforward: The noise obscured or covered up portions of the speech sounds, and this loss of information had effects on intelligibility that were quite predictable. High-frequency noise, for example, might mask the high-frequency parts of a word such as the fricative consonant /s/. In such a case, the errors that would occur were likely to be errors involving the masked speech sound. In fact, the errors that occur from energetic masking can be accounted for by articulation index theory (French & Steinberg, 1947), which predicts how intelligible a speech signal will be on the basis of the signal-to-noise ratio in a number of frequency bands (cf. Allen, 2005). However, in contrast to the rather straightforward effects of noise (and some other types of energetic maskers) on speech intelligibility, sounds that produce informational masking—especially other talkers that are similar to the talker one wants to listen to—produce interference that might be difficult to predict and may have effects that are less straightforward than simple noise masking. The speech signal itself is complex and time-varying with frequency components that often change from moment to moment. When there are multiple sources of speech occurring simultaneously, the extent to which they overlap acoustically—and subsequently in the neural representations in the auditory system—also may vary from moment to moment. This time-varying overlap of the frequency spectra of multiple speech signals means that quantifying the amount of energetic masking that is present can be challenging, especially in natural listening situations.

It has long been appreciated that the effect of one speech signal on the intelligibility of another speech signal can go well beyond energetic masking. Broadbent (1952) provided an early and clever demonstration of this. In his study, a target sentence was broken up into individual words, and irrelevant words from another talker were interspersed in between the target words. Thus the words from the two talkers alternated in time. No energetic masking occurred because the target and masker words did not overlap. However, significant interference was observed in subjects’ ability to report the target speech. Broadbent considered this result to reflect a failure of selective attention. However, not all possible intervening sounds produce this type of informational masking. Recently, Kidd, Best, and Mason (2008) demonstrated that playing bursts of noise or time-reversed masker speech in between the target speech has only minor effects on intelligibility. Thus the meaningfulness of the masker speech and its similarity to the target speech are crucial for producing informational masking.

Carhart, Tillman, and Greetis (1969) concluded that some types of maskers—specifically, modulated noise or speech—produced masking of target speech that went beyond energetic masking. They found that combining these complex maskers produced masking that could not be reconciled with

the individual effects of each masker separately and termed the extra masking *perceptual masking*. To account for this extra masking, they speculated that more than one process was necessary and noted other examples involving the masking of simpler stimuli in which “excess additivity” was observed. Although the terms *energetic* and *informational masking* were not introduced until later (Pollack, 1975), these speech masking results—similar to the multitone masking results above—seemed to require the actions of separate mechanisms, one peripheral and the other central. Furthermore, the central factors contributing to masking likely involve multiple processes. Even though each may be considered a type of informational masking, there is a need to understand and distinguish among these processes (cf. Kidd, Mason, Richards, Gallun, & Durlach, 2008).

As was described above, one means for demonstrating masking effects in speech recognition in the absence of any peripheral overlap of target and masker was devised by Broadbent (1952) using the alternating-word paradigm. A more recent experiment used signal processing to achieve similar, if not as complete, isolation of informational masking in speech identification. This study by Arbogast and colleagues (2002) will be discussed in some detail because it illustrates clearly the distinction between energetic and informational masking of speech, and the stimuli resulting from the signal processing they employed provide some interesting parallels to the multitone masking stimuli discussed above.

Figure 23.4 illustrates the steps in processing target and masker speech. The speech materials used were developed

by Bolia, Nelson, Ericson, and Simpson (2000) and are referred to as the coordinate response measure (CRM). The CRM is a closed-set speech identification test in which the observer must report certain key words that are colors and numbers. As shown in figure 23.4, these recorded sentences were first given a gradual high-frequency emphasis, then filtered into 1/3-octave bands, half-wave rectified and low-pass filtered. This process extracts the amplitude envelope within each band. These envelope functions are then used to modulate pure-tone carriers corresponding to the center frequencies of each of the bands. Only a few such envelope-modulated carrier tones need to be combined to form intelligible speech. Thus a target sentence and a masker sentence may be composed of mutually exclusive frequency bands, but each retains a high degree of intelligibility.

Figure 23.5 shows two such sets of bands for two different sentences. These magnitude spectra, which are averaged over the length of each sentence, are characterized by sets of very narrow frequency bands that overlap only many decibels below the peaks. The effect of this processing is to render highly intelligible target and masker sentences into sets of narrow frequency bands that interact minimally with respect to energetic masking. This latter assertion was supported by a control condition in which one of the sentences was replaced by sets of matched narrow bands of noise (not shown in figure 23.5; see Arbogast et al., 2002). The difference in the amount of masking produced by processed speech and by the noise control was taken to be an estimate of the amount of informational masking produced by the speech. Figure 23.6 illustrates this result.

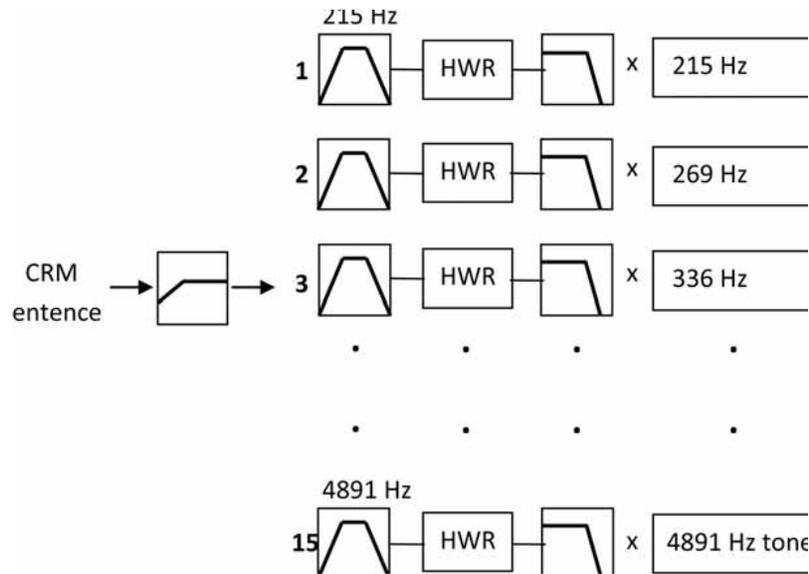

FIGURE 23.4 A schematic illustration of the steps in processing the target and/or masker speech into sets of narrow bands. The various stages include (left to right): (1) gradual high-frequency emphasis, (2) filtering the speech into one-third-octave bands, (3) half-wave

rectifying the filtered speech, (4) low-pass filtering of the rectified waveforms to extract the envelopes, and (5) multiplying the envelope functions with pure-tone carriers centered in each frequency band. (Adapted from Arbogast, 2003.)

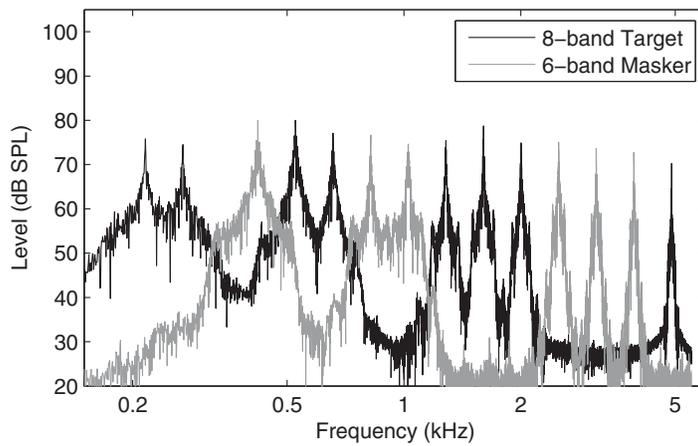

FIGURE 23.5 Magnitude spectra of target (black) and masker (gray) speech processed as shown in figure 23.4 into mutually exclusive frequency bands.

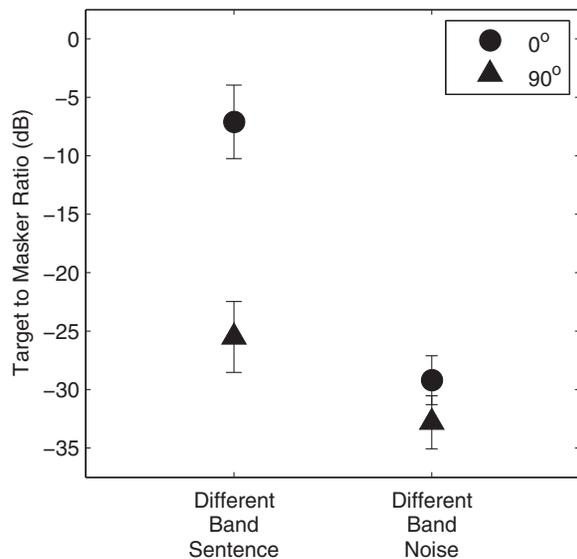

FIGURE 23.6 These are a portion of the results from Arbogast and colleagues (2002) replotted to emphasize the difference between energetic (different band noise) and informational (different band sentence) maskers. The values plotted are the level of the target relative to the level of the masker at speech reception threshold (50% correct identification).

The data plotted in this figure are group mean speech reception thresholds that indicate the level of the target relative to the level of the masker that allowed the listeners to correctly identify the key words in the target 50% of the time (chance performance is 3% correct). The two values on the left side of the graph represent the thresholds for the speech masker (called *different band sentence* because the frequency bands of the masker sentence are different from those of the target sentence), while the two values on the right side of the graph represent the thresholds for the noise masker control (called *different band noise*). For each masker, the higher of the two points indicates a threshold that is obtained when the

target and masker were both played from the same loudspeaker, which was located directly in front of the listener (0° spatial separation). The lower of the two points in each case indicates a threshold that is obtained when the target was presented from a loudspeaker directly in front of the listener while the masker was presented from a second loudspeaker located directly to the right of the listener (referred to as a spatial separation of 90°).

There are two main points to be made regarding the design of this experiment and the results shown in figure 23.6. First, the goal in the processing of speech in this case is very similar to the goal in the design of the multitone masking experiment discussed above. The masker energy is positioned in frequency regions that are remote from the target energy to reduce the peripheral overlap of excitation of the two minimizing energetic masking. The assumption is that a large proportion of the masking that occurs is informational masking that is not due to peripheral overlap of excitation. For both types of maskers—multitone and multiband speech—control conditions have been examined that support this interpretation (for the multitone masker, see Durlach et al., 2005). In the present case, the different band noise is the energetic masking control for the different band sentence masker and the difference in masking each produces is an estimate of the amount of informational masking. In this case, there are two comparisons: one when the target and masker are colocated and the second when they are spatially separated. From figure 23.6, the former comparison (circles) yields about 22 dB of informational masking, while the latter (triangles) yields about 7 dB. Second, when large amounts of informational masking are produced, stimulus manipulations that cause or strengthen the perceptual segregation of the target from the masker reduce the observed masking. In figure 23.6, it is obvious that spatially separating the speech target and speech masker produced a large decrease in the amount of masking (approximately 18.4 dB)

primarily through a reduction in informational masking. Although some energetic masking release could be produced by spatial separation of sources, the control condition of multiband noise (right side of figure) indicates that this was a minor factor in the experiment. This prominent role of perceptual segregation in reducing informational masking, but not energetic masking, has been reported in several other studies (cf. Neff, 1995; Kidd, Mason, Rohtla, & Deliwalla, 1998; Freyman, Helfer, McCall, & Clifton, 1999).

Concluding comments

The study of masking over the past century has provided important information regarding the functional organization of the auditory system. Consistent with this history, in recent years, studies of informational masking have provided a potent tool for an understanding of the relative contributions of peripheral and central processing in auditory perception. The ultimate goal is clear: to more fully understand *why* we hear *what* we hear in the cluttered acoustical environment. While the psychoacoustics research summarized above is incomplete—there are many fundamental questions to be answered, including a comprehensive answer to that posed by Tanner (1958)—studies of masking continue to offer a framework in which questions regarding the cognition of hearing can be addressed.

NOTES

1. It might happen that you are wearing a new rain hat with a wide brim. This hat leads to reflections of the sounds as they enter your ear, reflections that you have not experienced before. Alternatively, an impending head cold might clog your right Eustachian tube, providing an imbalance in the sounds transmitted by your right and left ears. These challenges, which point to the efficiency with which the auditory system recalibrates, are beyond the scope of the current chapter.
2. A bandpass filter is a device that allows a range of frequencies to pass but attenuates, or rejects, other frequencies. As an illustrative concept, a bandpass filter centered at 1000 Hz with a passband (or bandwidth) of 300 Hz would allow all frequencies between 850 and 1150 Hz to pass unimpeded yet would attenuate frequencies lower than 850 Hz or higher than 1150 Hz. For a hypothetical rectangular filter, the frequencies between 850 and 1150 Hz would pass with no change in level or phase. Moreover, the output of a linear filter for two tones would be equal to the sum of the output of the filter for each tone alone. Realistic biological, analog, and digital filters do not match this ideal. Typically, bandpass filters are not rectangular. For the example provided above, a rectangular filter would com-

pletely attenuate a 849-Hz tone but would pass a 851-Hz tone without attenuation. Instead, filters have “skirts” such that there is a gradual change in attenuation as a function of frequency from unattenuated to fully attenuated. Realistic filters also alter the phase of tones that pass through the filter, a phase shift that depends on the frequency of the tone. Finally, nonlinear filters, which are used to describe the auditory periphery, might not have unity gain. Depending on the intensity of the incoming sound, the filter might amplify the sound.

There are many examples of filters in everyday life. The telephone, for example, does not pass all frequencies; low and high frequencies are vastly attenuated. Our auditory system provides another example: Try as one might, the system does not pass/represent very high frequencies (e.g., above 20 kHz or so).

24 Insights into Human Auditory Processing Gained from Perceptual Learning

BEVERLY A. WRIGHT AND YUXUAN ZHANG

ABSTRACT Many auditory skills improve with practice, indicating malleability of the underlying neural system. Here we consider the effect of training on the human perception of basic sound attributes such as frequency, intensity, and duration. We first compare learning patterns across multiple tasks, in each of which listeners discriminate changes in a different sound attribute. These patterns differ markedly for different tasks and sometimes even for different stimuli within the same task, in terms of both how performance changes over training sessions and how learning generalizes to untrained conditions. The differences suggest that training on different tasks affects different neural processes. We then describe in more detail sets of training experiments on auditory-timing and spatial-hearing skills and make inferences about the underlying neural processes affected by the training. Finally, we speculate about the neural underpinnings of auditory learning. This chapter thus illustrates that the examination of auditory learning can provide unique insights into the human perception and neural processing of sounds.

A remarkable and often unrecognized characteristic of human perceptual abilities is that they can be improved with practice. Such perceptual learning indicates that the underlying neural processes are malleable. Investigations of the circumstances that yield this learning and of the patterns with which this learning occurs have both theoretical and practical value. On the theoretical side, this information provides insight into the architecture and plasticity of the neural processes that govern perceptual performance. On the practical side, it can guide the development of more effective and efficient perceptual training regimens to aid individuals with perceptual disorders as well as others who desire enhanced perceptual skills. To date, perceptual learning has been examined primarily in the visual system. Here, we instead describe select aspects of perceptual learning in the auditory system.

BEVERLY A. WRIGHT and YUXUAN ZHANG Department of Communication Sciences and Disorders and Interdepartmental Neuroscience Program, Northwestern University, Evanston, Illinois

To help establish the principles of auditory learning, we and others have focused our investigations on basic auditory skills and simple training regimens. In such cases, during training, listeners are asked to discriminate between small variations in only one attribute of a relatively simple sound, such as to determine which of two tones has a higher frequency or a longer duration. Establishing the learning patterns under these circumstances forms a baseline for interpreting improvements on more complex tasks and with more complex training regimens. Suggesting that this is a reasonable approach, we have recently seen that phenomena we first observed in learning on simple auditory tasks occur on speech-perception tasks as well. Similar reasoning has also guided a large number of investigations in the visual system (Rust & Movshon, 2005).

In this chapter, we begin with a brief review of differences across different trained tasks in the pattern of performance improvement resulting from training and argue that these differences constitute evidence for the involvement of different neural processes in these different cases. We then consider in more detail the learning patterns on auditory temporal and spatial tasks to illustrate how these patterns can be used to make inferences about the particular neural processes that were modified through training. We conclude with a brief discussion of the neural bases of auditory learning itself.

Evidence that different neural processes contribute to learning on different auditory tasks

The behavioral evidence that auditory learning involves different neural processes on different tasks arises primarily from examination of three aspects of the learning patterns: learning on the trained condition, across-task generalization, and across-stimulus generalization. This evidence rests on the basic assumption that the pattern of learning and generalization is determined by the particular neural circuitry that is being modified as well as by the particular type of modification that is occurring (e.g., Hochstein & Ahissar,

2002; Karni & Sagi, 1991). Given this assumption, differences in learning and generalization patterns across different tasks suggest that training on different tasks induced the same modifications in different neural circuitry, different modifications in the same circuitry, or different modifications in different circuitry. We typically cannot distinguish among these three types of differences at the behavioral level. Therefore we use the phrase *different neural processes* to refer to all three possibilities.

LEARNING ON THE TRAINED CONDITION One indication that training on different tasks affects different neural processes is that the pattern of learning on the trained condition differs across tasks. The specific assumption here is that the pattern of learning during the training itself differs across different trained conditions only if different neural processes are affected by the training. Such differences are evident in several aspects of learning on the trained condition, including the time frame of learning, the shape of the learning curve, the pattern of performance within each training session, and the amount of daily training required to yield improvement across sessions.

First, the time frame of learning differs markedly across different tasks. In perhaps the clearest demonstration of such differences, we trained five different groups of listeners each on a different basic auditory discrimination task, using similar training and testing regimens in all five cases. In addition, in three of the five cases, we used the same standard stimulus, against which all discrimination comparisons were made. Despite these similarities, the time frame of learning differed across the tasks (figure 24.1). For the discrimination of the sound intensity of brief tone pips (Wright & Fitzgerald, 2005) and of interaural time differences (a sound localization cue) in longer pure tones (Wright & Fitzgerald, 2001), learning appeared to be complete following an approximately two-hour pretraining test, because listeners who received an additional 6–10 hours of training showed no more improvement than controls who participated only in pretraining and posttraining tests. In contrast, for the discrimination of the frequency of (Wright & Sabin, 2007), and temporal interval between (Wright, Buonomano, Mahncke, & Merzenich, 1997), brief tone pips and of interaural level differences (a sound-localization cue) in longer pure tones (Wright & Fitzgerald, 2001), the listeners who received the multiple-hour training improved more than controls did. In general, learning on auditory tasks appears to be complete after times ranging from less than approximately 20 minutes (e.g., interaural-time-difference discrimination) (Ortiz & Wright, 2009) to more than 20 hours (e.g., learning of tone sequences) (Leek & Watson, 1984, 1988) (for a review, see Watson, 1980). Interestingly, while there is some indication that the amount of training that is needed to reach asymptotic performance on auditory tasks increases with increases in task

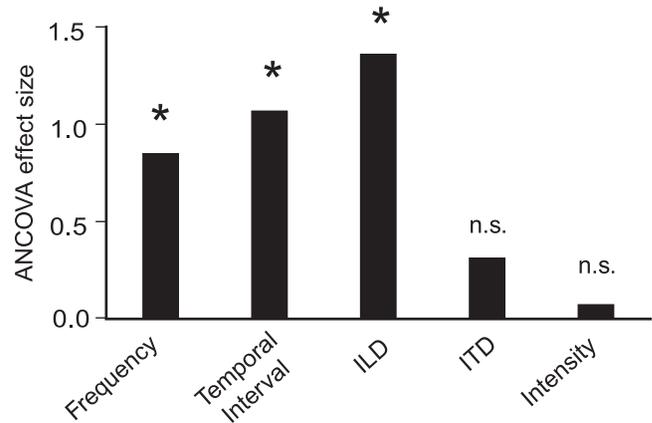

FIGURE 24.1 Different effects of multiple-hour training on five basic auditory tasks. Each bar shows the effect size of an analysis of covariance conducted on the posttraining thresholds for a given task, with the pretraining thresholds as the covariate. Asterisks indicate that the listeners who practiced 6–10 hours on that task ($n = 6-20$) had significantly lower posttraining thresholds (better performance) than did controls ($n = 6-16$) who participated only in pretraining and posttraining tests but received no intervening training; n.s. indicates that the posttraining thresholds did not differ significantly between the groups. Results are shown for frequency, temporal-interval, interaural-level-difference (ILD), interaural-time-difference (ITD), and intensity discrimination.

and stimulus complexity (Watson, 1980), the current cases illustrate that it can differ markedly even among tasks with similar levels of complexity. Rapid improvements on perceptual tasks have been attributed to cognitive processes such as familiarization with the testing procedure and recognition of the sound attribute that is key to performing the task, while more gradual improvements have been attributed to changes in the perceptual systems themselves (e.g., Recanzone, Schreiner, & Merzenich, 1993; Robinson & Summerfield, 1996; Wright & Fitzgerald, 2001). However, this interpretation should be treated with caution because of evidence that perceptual changes can occur quite early in training (e.g., Fiorentini & Berardi, 1980; Ortiz & Wright, 2009; Rubin, Nakayama, & Shapley, 1997).

Second, even when the time frame of learning is similar, in some cases, the shape of the learning curve differs across tasks. For example, of the three tasks described above for which learning continued over multiple daily sessions, the learning curves had different shapes (figure 24.2A). For temporal-interval and interaural-level-difference discrimination, the learning rate was most rapid over the first three days of training and slower thereafter. In contrast, for frequency discrimination, the learning rate was approximately constant across the 10 training days. Further, even on the same task, the learning curve sometimes differs in shape for different trained stimuli. For instance, for interaural-level-difference discrimination, learning was initially rapid and then slowed for a pure-tone stimulus but occurred at an

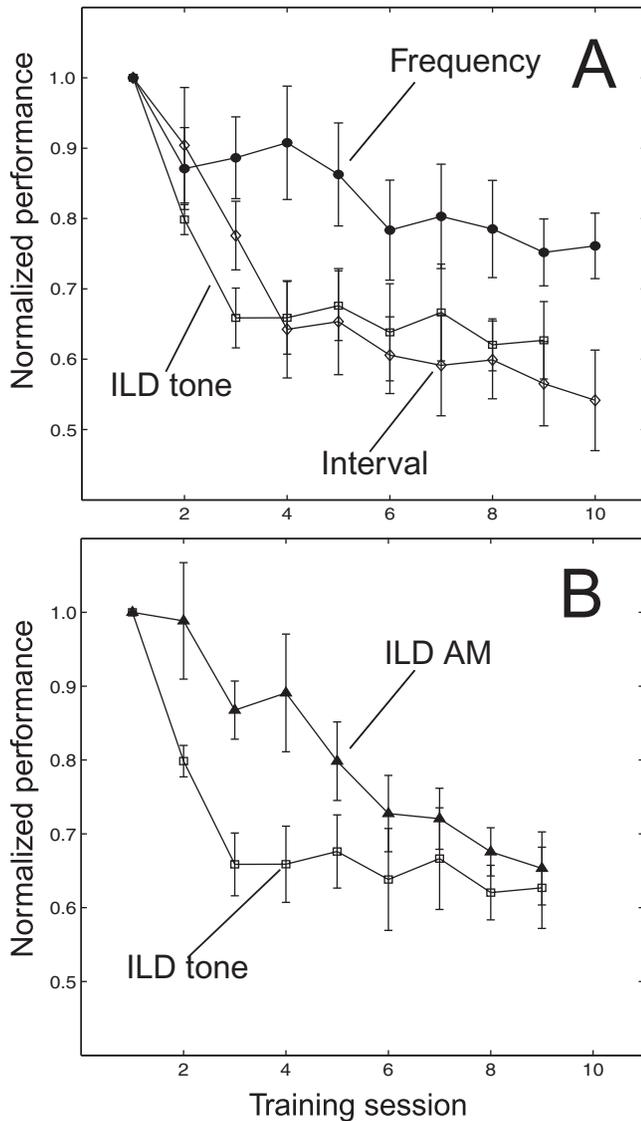

FIGURE 24.2 Different learning-curve shapes for different trained tasks and for different trained stimuli on the same task. Mean thresholds for each training session, normalized as a percentage of the first-session performance, for frequency (A, solid circles) and temporal-interval (A, open diamonds) discrimination with the same pair of brief tone pips and for interaural-level-difference (ILD) discrimination with a longer pure tone (A, B, open squares) and an amplitude-modulated (AM) tone (B, solid triangles). Each symbol represents the average of 6–10 trained listeners.

approximately constant rate for a sinusoidally amplitude modulated stimulus (figure 24.2B). Similarly, for the discrimination of the fundamental frequency of harmonic complexes, the slope of the learning curve was significantly steeper when the individual harmonics could be resolved by the peripheral auditory system than when they could not (Grimault, Micheyl, Carlyon, & Collet, 2002).

Third, in addition to the differences in across-session improvement, the pattern of performance within each training session also differs across tasks. We recently reported

that listeners who improved on either temporal-interval or frequency discrimination across multiple daily training sessions showed no systematic improvement in performance within each session (Wright & Sabin, 2007). That is, the improvement appeared to occur between, rather than within, sessions. However, we have seen different within-session patterns for other tasks. For example, although listeners improved across sessions on the detection of a brief tone that was presented immediately before a masking noise (backward masking), their performance tended to worsen from the beginning to the end of each training session (unpublished data). That the within-session performance patterns differ across tasks, despite across-session improvements in all cases, is consistent with the idea that there are at least two distinct stages of perceptual learning. One, acquisition, is the period during which the task is actually practiced. The other, consolidation, is the period during which performance stabilizes or further improves without additional practice, presumably through the transfer of what has been learned during acquisition from short- to long-term memory. The different within-session patterns suggest that the mechanisms that are involved in the acquisition stage are task dependent but nevertheless all are able to lead to consolidation.

Fourth, a related observation is that the amount of training in each daily session that is required to yield improvement across sessions differs for different tasks and possibly even for different stimuli (Wright & Sabin, 2007). We trained four groups of listeners, two on frequency discrimination (figure 24.3A) and two on temporal-interval discrimination (figure 24.3C), each for six days, with the same standard stimulus. For each task, one group was trained for 360 trials per day, and the other group was trained for 900 trials per day. The listeners who were trained on temporal-interval discrimination showed similar improvements regardless of the amount of daily training (figure 24.3D). In contrast, for frequency discrimination, only the listeners who were trained for 900 trials per day improved (figure 24.3B). Thus at least for the particular standard stimulus that we used, learning on frequency discrimination required more trials of training per day than did learning on temporal-interval discrimination. Note, however, that performance on frequency discrimination with a different standard stimulus improved over eight 350-trial sessions (Roth, Amir, Alaluf, Buchsenspanner, & Kishon-Rabin, 2003), suggesting that the amount of daily training required for learning may be stimulus dependent as well as task dependent (Wright & Sabin, 2007). In the context of the two learning stages, these results suggest that different amounts of training during acquisition are required to trigger consolidation for different tasks and even for different stimuli.

ACROSS-TASK GENERALIZATION Another line of evidence that auditory training affects different neural processes for

Frequency Discrimination

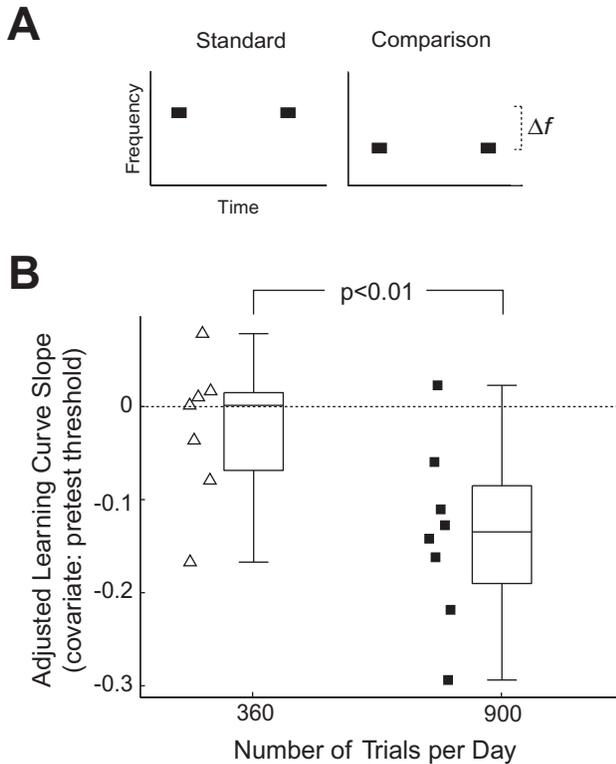

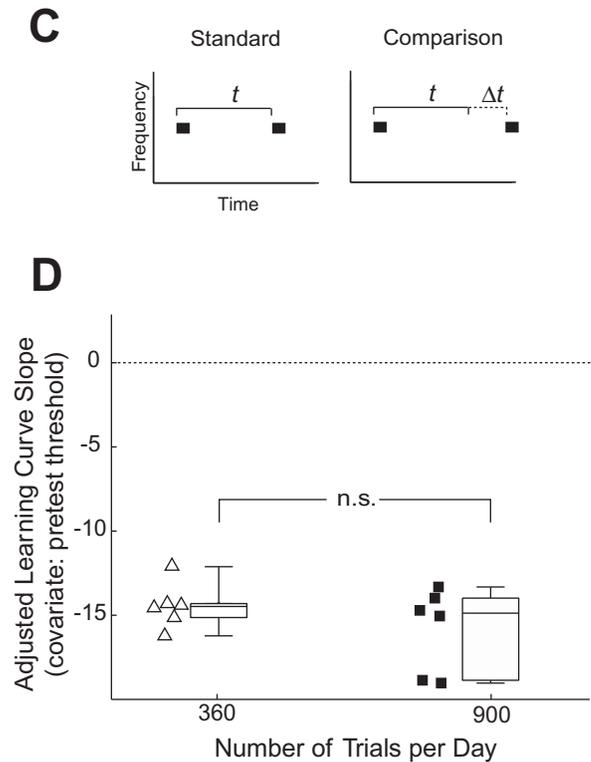

FIGURE 24.3 Different amounts of daily training required for learning across multiple sessions on frequency (*A, B*) and temporal-interval (*C, D*) discrimination. (*A*) Schematic diagram of the frequency discrimination task. Listeners discriminated between standard (left) and comparison (right) stimuli that differed from each other only in frequency. (*B*) Rate of across-session improvement on frequency discrimination indicated by the slopes of regression lines fitted, for each listener (symbols), to the daily thresholds versus the log of the training session number. Individual differences were taken into account by adjusting the slopes based on pretraining thresholds (ANCOVA). The box plots indicate the median and quartile values. The slopes did not differ significantly

different trained tasks is that training on one task rarely leads to performance improvements on other tasks (Wright & Zhang, 2009). The specific assumption here is that learning generalizes from a trained to an untrained task if and only if the practice on the trained task modifies neural processes that also govern performance on the untrained one. Therefore a failure to generalize across tasks suggests that different neural processes are modified through training on those tasks.

There are a number of examples of a lack of across-task generalization on basic auditory skills. Following multiple-session training, learning did not generalize in either direction between frequency and amplitude-modulation rate discrimination (figure 24.4) (Fitzgerald & Wright, 2005; Grimault, Micheyl, Carlyon, Bacon, & Collet, 2003), asynchrony detection and order discrimination at sound onset

Temporal-Interval Discrimination

from zero for listeners who practiced 360 trials per day for six days (open triangles; $n = 7$), indicating no improvement across training sessions. In contrast, the slopes of listeners who practiced 900 trials per day (solid squares; $n = 8$) differed significantly from zero and were negative ($p < 0.01$), indicating across-session improvement. (*C, D*) Same as *A* and *B* but for the temporal-interval discrimination task. For this task, the slopes were significantly different from zero and were negative, regardless of whether the listeners practiced 360 (open triangles; $n = 6$, $p < 0.001$) or 900 (solid squares; $n = 6$, $p < 0.0001$) trials per day for six days, indicating improvement across training sessions in both cases. (Figure adapted from Wright & Sabin, 2007.)

(Mossbridge, Fitzgerald, O'Connor, & Wright, 2006), or frequency and temporal-interval discrimination (unpublished data). It also did not generalize, in the one direction that was tested, from interaural-level-difference to interaural-time-difference discrimination (Wright & Fitzgerald, 2001), from amplitude-modulation rate to rippled-noise (figure 24.4) (Fitzgerald & Wright, 2005) or temporal-interval (van Wassenhove & Nagarajan, 2007) discrimination, or from amplitude-modulation rate discrimination to amplitude-modulation detection (figure 24.4) (Fitzgerald & Wright, 2005). The lack of across-task generalization has also been observed following a single session of training. For example, a brief period of training on sound-intensity or visual-contrast discrimination did not lead to better performance on frequency discrimination, though the same period of training on frequency discrimination did (Hawkey, Amitay,

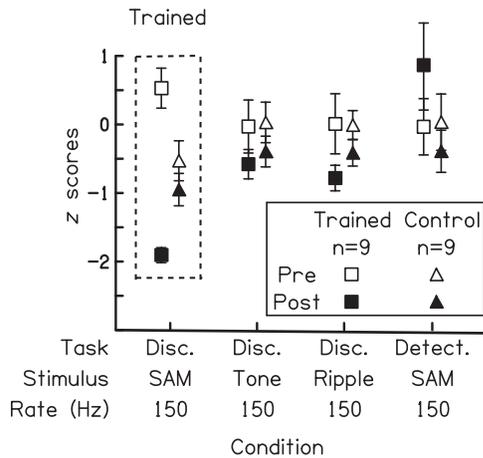

FIGURE 24.4 Lack of across-task generalization following learning on amplitude-modulation rate discrimination. The mean threshold values on a set of conditions tested before and after nine 720-trial daily training sessions on a single amplitude modulation rate discrimination condition. Trained listeners ($n = 9$; squares) improved significantly more than controls did (triangles) between the pre-training ($n = 9$; open symbols) and posttraining (solid symbols) tests on the trained condition (left column) but not on pure-tone frequency discrimination, rippled-noise discrimination, or amplitude modulation detection. The parameters for each condition are marked on the abscissas. The box indicates significantly more improvement in the trained listeners than in controls ($p < 0.05$). (Figure adapted from Fitzgerald & Wright, 2005.)

& Moore, 2004). Further, though listeners who received a single session of practice on temporal-interval or interaural-level-difference discrimination showed better performance on interaural-time-difference discrimination on the following day than naïve listeners did, this improvement was significantly smaller than that shown by listeners who were trained on interaural-time-difference discrimination itself (Ortiz & Wright, 2009). The need for practice on the target task to obtain learning on that task has been taken as evidence that the particular neural processes that are to be modified by training are selected via top-down influences, for example, through attention to the particular sound attribute that is key to performing the target task (Hochstein & Ahissar, 2002).

It should be noted that learning occasionally does generalize across tasks, but so far, the across-task generalization has been observed only in one direction. To date, the clearest instance of such unidirectional generalization is that learning generalized from asynchrony detection to order discrimination at sound offset but not vice versa (Mossbridge, Scissors, & Wright, 2008) (see the section “Relative-Timing Tasks” below). Similarly, a comparison between two other investigations suggests that learning on pure-tone frequency discrimination generalized to fundamental-frequency discrimination (Grimault et al., 2002) but not the reverse (Demany & Semal, 2002). In these cases, training on the different tasks might have engaged different but related neural processes.

ACROSS-STIMULUS GENERALIZATION A third line of evidence that practice on different auditory tasks influences different neural processes is that the pattern of generalization to the trained task with untrained stimuli differs across tasks. Similar to the assumption about across-task generalization, the assumption here is that learning on a trained task generalizes from a trained stimulus to an untrained one if and only if training modifies neural processes that govern performance with both stimuli. Therefore different patterns of across-stimulus generalization for different trained tasks indicate that the training affected neural processes with different tuning characteristics for each task.

Differences in the across-stimulus generalization patterns are apparent in two forms of comparison across tasks. First, the generalization results for a given sound attribute differ across tasks. Across-stimulus generalization to three different stimulus attributes has been examined on multiple tasks. These attributes are frequency, timing, and modality. For each of these attributes, learning generalized to stimuli with untrained values of that attribute for some tasks but not for others. Generalization across frequencies has been reported for pure-tone frequency (Amitay, Hawkey, & Moore, 2005; Delhommeau, Michey, & Jouvent, 2005; Demany & Semal, 2002; Irvine, Martin, Klimkeit, & Smith, 2000) and temporal-interval (Karmarkar & Buonomano, 2003; Wright et al., 1997) discrimination. However, learning was specific to the trained frequency for interaural-level-difference discrimination with pure tones (Wright & Fitzgerald, 2001) and tone detection in quiet (Zwislocki, Maire, Feldman, & Rubin, 1958) and to the trained tone pair for asynchrony detection and order discrimination (Mossbridge et al., 2006; Mossbridge, Scissors, & Wright, 2008). In terms of timing, learning generalized at least partially to stimuli with untrained durations (Delhommeau et al., 2005) or temporal intervals (Wright & Fitzgerald, 2005) for frequency discrimination but was specific to the trained interval for temporal-interval discrimination (Karmarkar & Buonomano, 2003; Wright et al., 1997) and for the detection of short tones in same-duration gated noise (Tucker, Williams, & Jeffress, 1968). Finally, for modality, learning on temporal-interval discrimination generalized from the auditory system to motor performance (Meegan, Aslin, & Jacobs, 2000) and from the somatosensory to the auditory system (Nagarajan, Blake, Wright, Byl, & Merzenich, 1998), but there is some indication that learning on asynchrony detection does not generalize across modalities (Virsu, Oksanen-Hennah, Vedenpaa, Jaatinen, & Lahti-Nuutila, 2008). Second, the across-stimulus generalization pattern differs across tasks when the comparison is made relative to the respective trained sound attribute of those tasks. Learning generalized across different values of the *trained* attribute for some tasks but not others. For example, learning generalized to untrained frequencies for frequency discrimination (Amitay

et al., 2005; Delhommeau et al., 2005; Demany & Semal, 2002; Irvine et al., 2000) and to an untrained standard interaural-level-difference value for interaural-level-difference discrimination (Wright & Fitzgerald, 2001) but not to untrained temporal intervals for temporal-interval discrimination (Karmarkar & Buonomano, 2003; Wright et al., 1997). The differences in across-stimulus generalization pattern for different trained tasks have been used to make inferences about the tuning characteristics of the neural circuitry that was modified by training (see below).

Characteristics of auditory processing revealed by perceptual-learning patterns

Here, we provide a systematic examination of the effect of perceptual training on each of two selected aspects of auditory perception, and the characteristics of the neural processing that can be inferred from those results. These inferences are made based on the assumptions described in the preceding sections. Note that these inferences apply only to the subset of neural processes that was affected by the training, though many may be potentially engaged while performing the trained condition.

TEMPORAL TASKS A critical role of the auditory system is to encode the duration of and the temporal relationship between events. Here, we present two sets of experiments in which we used perceptual learning patterns to gain insights into the neural processes underlying these auditory-timing abilities.

Temporal-interval discrimination In one set of experiments, we examined learning on a temporal-interval discrimination task. In the first experiment (Wright et al., 1997), we trained listeners to discriminate deviations from a standard temporal interval of 100 ms, marked by two brief 1-kHz tone pips, during multiple daily sessions. Nearly all of these listeners showed significant learning during the training phase. This learning generalized to an untrained condition that differed from the trained one only in the frequency of the stimulus (4 kHz versus 1 kHz) but did not generalize to untrained conditions that differed from the trained one only in the duration of the temporal interval (50, 200, or 500 ms versus 100 ms) (figure 24.5). After the original experiment, we administered to a control group the pretraining and post-training tests but not the multiple-day training. The controls did not show any improvement, and a between-group comparison of the trained listeners and controls yielded the same conclusions as were reached for the trained listeners alone (Wright & Fitzgerald, 2005). Thus the learning on auditory temporal-interval discrimination was specific to the trained interval but generalized across stimulus frequency. Karmarkar and Buonomano (2003) replicated this general-

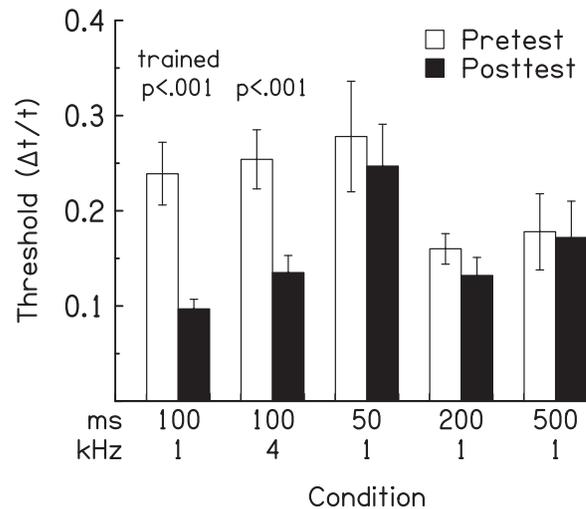

FIGURE 24.5 Learning and generalization on auditory temporal-interval discrimination. The mean threshold values on five temporal-interval discrimination conditions tested before (open bars) and after (solid bars) ten 900-trial daily training sessions on a single temporal-interval discrimination condition. The conditions are marked on the abscissa by the temporal interval (in milliseconds) and the tone frequency (in kilohertz) of the standard stimulus. Thresholds differed significantly between the pretraining and post-training tests for the trained condition (100 ms at 1 kHz), indicating that training led to learning. For the remaining conditions, the thresholds differed significantly between the pretraining and post-training tests only for the untrained frequency (100 ms at 4 kHz) but not for the untrained temporal intervals (50, 200, or 500 ms at 1 kHz). Thus the learning generalized across frequency but was specific to the trained temporal interval. Results are shown only for listeners who improved significantly across the training sessions ($n = 11$ out of 14 tested for three conditions: 100 and 200 ms at 1 kHz and 100 ms at 4 kHz; $n = 5$ out of 6 tested for the remaining two conditions: 50 and 500 ms at 1 kHz). (Figure from Wright, Buonomano, Mahncke, & Merzenich, 1997.)

ization pattern and also reported generalization to an untrained marker type (a continuous tone versus tone pips) at the trained interval.

We subsequently trained another group of observers on temporal-interval discrimination in the somatosensory system (Nagarajan et al., 1998). Parallel to the pattern observed in the auditory system, trained observers improved their performance on the trained condition, and this learning generalized to untrained positions on the trained hand and to the untrained hand but was largely specific to the trained temporal interval. Most interestingly, training in the somatosensory system generalized to the auditory system but only for the trained interval. Interval-specific generalization of interval-discrimination learning across systems has also been observed from auditory to motor performance (a motor tapping task) (Meegan et al., 2000).

Taken together, these results indicate that the neural modifications induced by the training paradigms that were used in these experiments influence auditory and somato-

sensory as well as motor performance on temporal-interval discrimination with a variety of marker conditions but only for a specific interval. These characteristics reveal a neural process that encodes temporal intervals in interval-specific channels and that is possibly located beyond the primary sensory or motor cortices.

Relative-timing tasks In another set of experiments, we examined learning on two relative-timing tasks: asynchrony detection and order discrimination. In an asynchrony-detection task, the object is to determine whether different components of a complex sound start or end at the same time (synchronously) or at different times (asynchronously). This ability helps listeners to separate multiple auditory events. For order-discrimination, the task is to determine the order in which different components of a complex sound start or end. This ability helps listeners to distinguish, for example, words (e.g., “pat” and “tap”) and musical melodies (e.g., ascending versus descending scales) perception.

In the first experiment (Mossbridge et al., 2006), we trained one group of listeners on asynchrony detection and another group on order discrimination using standard stimuli composed of 0.25- and 4-kHz tones, with the crucial information presented at sound onset (figure 24.6A–C). We used the same multiple-hour training paradigm for both groups. Controls, who did not receive the training, improved between the pretraining and posttraining tests on the trained conditions as well as on a variety of related untrained conditions, indicating that exposure to the pretraining test itself led to learning. However, both trained groups improved more than controls did on their respective trained conditions, demonstrating that the multiple-hour training induced additional learning beyond that resulting from exposure to the pretraining test. This training-induced learning did not generalize to untrained tone pairs (e.g., 0.5 and 1.5, 0.75 and 1.25 versus 0.25 and 4 kHz), to an untrained temporal position (sound offset versus onset), or to the other, untrained, task (asynchrony versus order or vice versa).

We later trained two new groups of listeners on the same tasks at sound offset (Mossbridge et al., 2008), using the same standard stimuli as in the original investigation (figures 24.6A, 24.6D, and 24.6E). Unlike at sound onset, at sound offset the control listeners in large part showed no improvement between the pretraining and posttraining tests. Also different from sound onset, and more important in the present context, the generalization patterns differed between the asynchrony and order tasks. Both groups who were trained at sound offset improved more than controls did on their respective trained conditions, demonstrating training-induced learning. For order discrimination at sound offset (figure 24.6E), as for both tasks at sound onset (figures 24.6B and 24.6C), the training-induced learning did not generalize to untrained tone pairs (0.5 and 1.5, 0.75 and 1.25 versus

0.25 and 4 kHz), to an untrained temporal position (sound onset versus offset), or to the untrained task (asynchrony versus order). However, for asynchrony detection at sound offset (figure 24.6D), while the training-induced learning was still specific to the trained tone pair, it did generalize both to the untrained temporal position (sound onset) and to the untrained task (order).

These patterns of learning and generalization provide insights into the neural processing of relative-timing tasks (Mossbridge et al., 2006, 2008). That performance improved with training for both asynchrony detection and order discrimination at both sound onset and offset indicates that the neural processes underlying relative-timing judgments are malleable. More interestingly, the lack of mutual generalization across tasks and across temporal positions suggests that the training on the four conditions affected different neural processes. However, these neural processes appear to be related, as is suggested by the unidirectional generalization of learning from asynchrony detection at sound offset to the remaining three cases. One possible form of this relationship is that performance on each task, at each temporal position, is governed by a specified neural process and that there is a unidirectional dependency among these processes. Another possibility is that while performance on asynchrony detection at sound offset is governed by a general relative-timing mechanism, performance on the other three conditions can be affected by both the global mechanism and the condition-specific mechanisms and that the training on those three conditions modified the specific ones. Regardless of the relationship, the neural processes underlying learning in all four training groups appear to be tuned to specific frequency pairs.

SPATIAL TASKS Another key role of the auditory system is to encode the spatial location of sound sources. The two primary cues to sound-source position on the horizontal plane are interaural level differences (ILDs) and interaural time differences (ITDs). These cues arise because the sound from a given source can reach the two ears at different times or with different levels, depending on the frequency content and position of the source. We have examined the effect of training on the ability of listeners to detect small variations in ILDs and ITDs in a series of experiments. We use the results to make inferences about the neural processing of these two sound localization cues.

In our first investigation of this issue (Wright & Fitzgerald, 2001), we trained two groups of listeners for multiple sessions: one on ILD discrimination with a high-frequency (4 kHz) tone and the other on ITD discrimination with a low-frequency (0.5 kHz) tone. We used different stimulus frequencies for the two cues because ILDs are known to be most effective at high frequencies and ITDs are known to be most effective at low frequencies. To manipulate the two

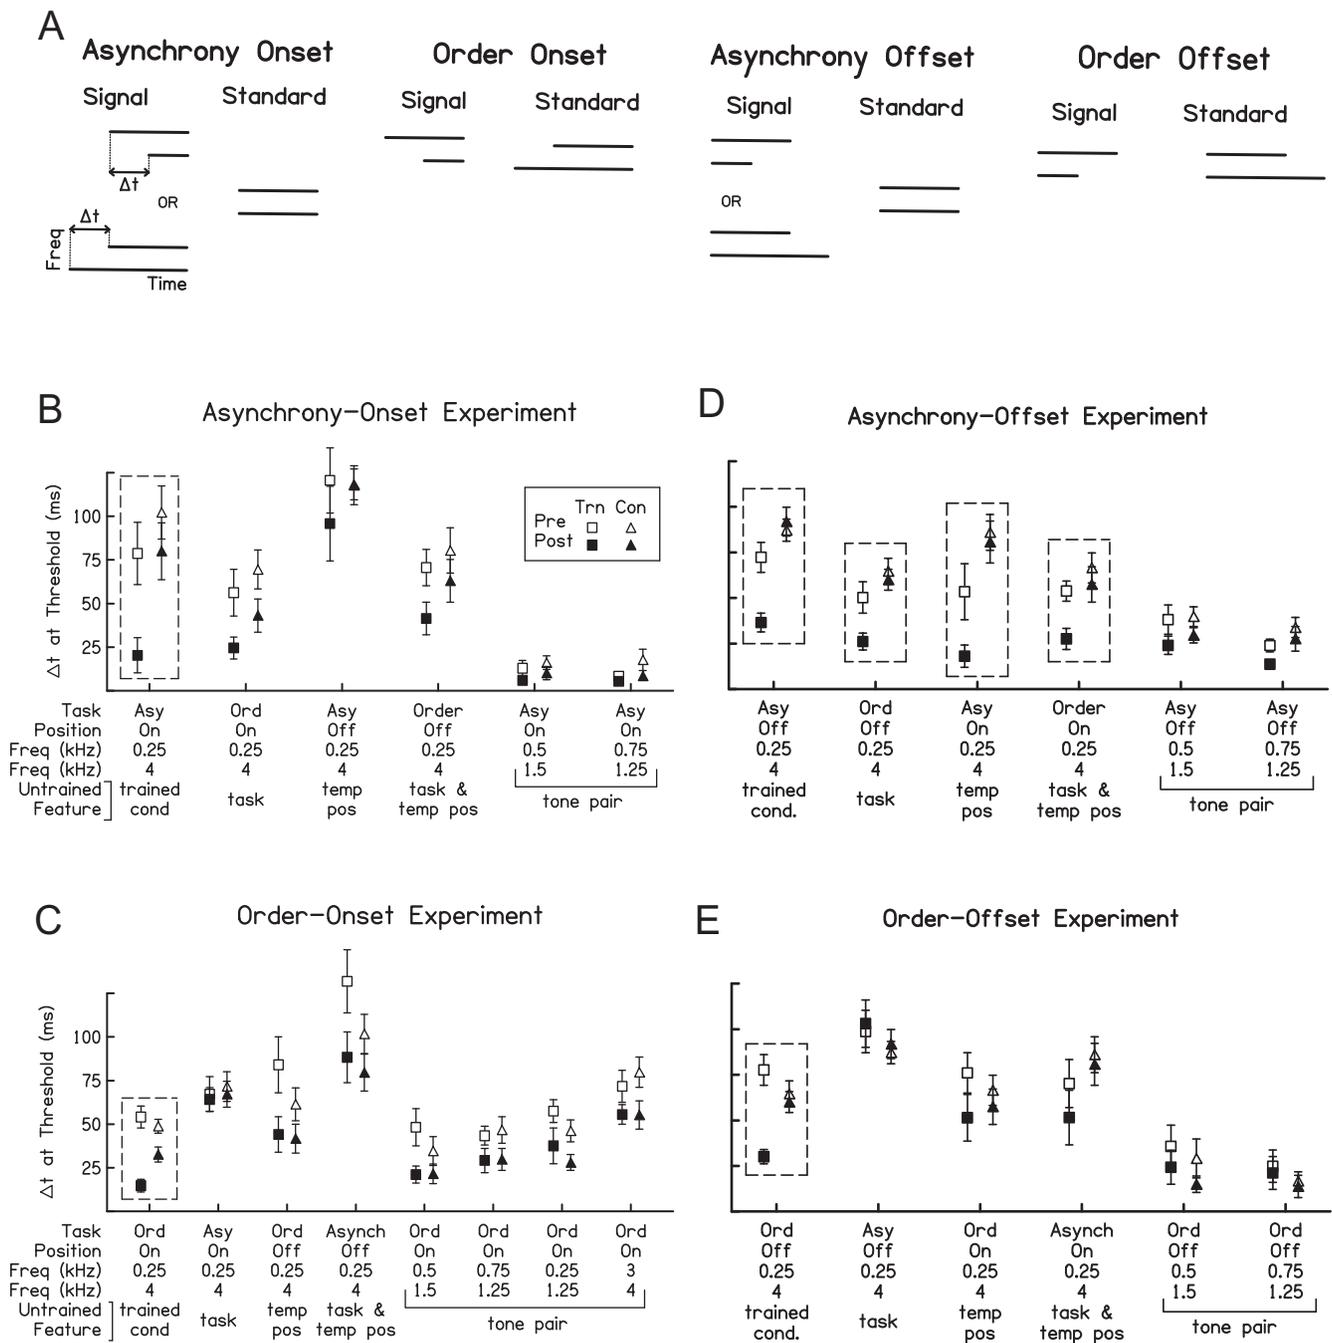

FIGURE 24.6 Learning and generalization on auditory asynchrony detection (*B, D*) and temporal-order discrimination (*C, E*). (*A*) Schematic diagrams of the signal and standard stimuli used in the four relative-timing conditions. Each stimulus consisted of two tones. The duration of the higher-frequency tone was fixed at 500 ms. The frequencies of the tones depended on the condition parameters. (*B–E*) The mean threshold values on a set of relative-timing conditions tested before and after six to eight 720-trial daily training sessions on a single condition: asynchrony-detection (*B*) or temporal-order-discrimination (*C*) at sound onset or asynchrony-detection (*D*) or temporal-order-discrimination (*E*) at sound offset. In all four cases, trained listeners (squares) improved significantly more than controls (triangles) between the pretraining (open symbols) and

posttraining (filled symbols) tests on the trained condition (left column). However, the generalization pattern differed across the trained conditions. In three cases (*B, C, E*), the learning attributable to the multiple-hour training was specific to the trained condition. In the fourth case (*D*), the learning generalized to all conditions tested with the trained frequency pair and therefore spread more broadly than learning for the other trained conditions. The parameters for each condition are marked on the abscissas ($n = 6–18$ for each group in each condition). Boxes indicate conditions on which trained listeners learned significantly more than controls did ($p < 0.05$). (Figure adapted from Mossbridge, Fitzgerald, O'Connor, & Wright, 2006; Mossbridge, Scissors, & Wright, 2008.)

cues separately, we presented the sounds over headphones. The listener's task was to discriminate changes in the lateral position of the sound image that were caused by changes in one of the two cues; therefore the task is referred to as ILD or ITD discrimination depending on the cue manipulated. The multiple-hour training had markedly different effects on ILD and ITD discrimination (figure 24.7) (Wright & Fitzgerald, 2001). Control listeners, who participated only in approximately 2-hour pretraining and posttraining tests, improved on both cues, indicating that exposure to the pretraining test itself contributed to improvements on these tasks. However, while the listeners who received multiple-hour training on ILD discrimination improved more than the controls did, the listeners who were trained on ITD discrimination did not. Thus under this training regimen, performance on ILD but not ITD discrimination continued to improve during the multiple hours of training following the pretest. In addition, the training-induced learning on ILD discrimination did not affect ITD discrimination. The different time frames of learning on ILD and ITD discrimination and the lack of influence of ILD training on ITD performance suggest differential neural processing of high-frequency ILDs and low-frequency ITDs. Further, the training-induced learning on ILD discrimination generalized to ILD discrimination with an untrained standard location (off-center versus midline) but not to untrained sound frequencies (6 and 0.5 kHz versus 4 kHz). This pattern of across-stimulus generalization suggests that the multihour training on ILD discrimination modified neural circuitry that encodes sounds of a specific frequency but from a variety of locations.

In a follow-up experiment, we tested whether the observed difference between the learning patterns on ILD and ITD discrimination resulted from the difference between the two cues (ILD versus ITD) or from the difference in stimulus frequency (4 kHz versus 0.5 kHz) (Zhang & Wright, 2007). To do so, we trained another group of listeners on ITD discrimination at the same high frequency as the one we had previously used for ILD-discrimination training (4 kHz). However, because at high sound frequencies (>1.5 kHz) humans are not sensitive to ITDs in pure tones, we amplitude-modulated the 4-kHz tone with a sinusoid of 0.3 kHz (a SAM tone), a stimulus that had been reported to yield ITD sensitivity (Henning & Ashton, 1981). In this investigation, the controls improved between the pretraining and posttraining tests, and the trained listeners did not improve more than the controls did. This learning pattern is similar to what we had observed for ITD discrimination at 0.5 kHz but different from that for ILD discrimination at 4 kHz, thereby ruling out the contribution of stimulus frequency to the observed difference in learning of ILD and ITD discrimination.

Most recently, we tested the possibility that the difference in the training results for ILD and ITD discrimination

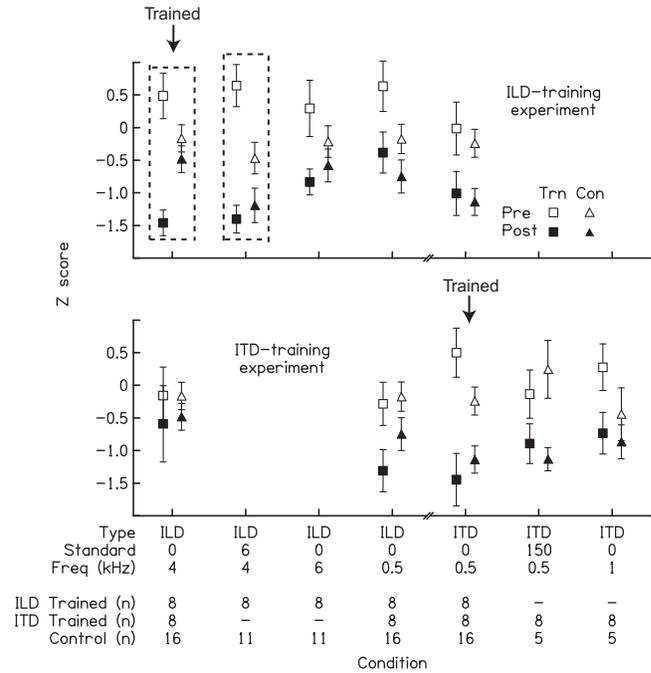

FIGURE 24.7 Learning and generalization on auditory interaural-level-difference (ILD) or interaural-time-difference (ITD) discrimination with pure tones. The mean threshold values, expressed as z-scores, on a set of conditions tested before and after nine 720-trial daily sessions on a single condition, either interaural-level-difference (top) or interaural-time-difference (bottom) discrimination. The parameters and number of listeners for each condition are marked on the abscissa. Trained listeners (squares) who practiced ILD discrimination improved significantly more than controls (triangles) between the pretraining (open symbols) and posttraining (solid symbols) tests on the trained condition (top, left column). This learning generalized to an untrained condition with a different standard ILD value (6 dB) but not to any other untrained condition. In contrast, for the ITD-training experiment, both the trained listeners and controls improved, and there was no between-group difference in any condition tested, either trained (bottom, fifth column) or untrained. Boxes indicate significant differences in improvement between trained listeners and controls ($p < 0.05$). (Figure adapted from Wright & Fitzgerald, 2001.)

at 4 kHz was due to the different stimulus types (pure versus SAM tones) rather than the different cues (ILD versus ITD) (Zhang & Wright, in review). In this experiment, we trained a new group of listeners on ILD discrimination with the same SAM tone that we had used to train high-frequency ITD discrimination. Once again, controls improved between the pretraining and posttraining tests. However, the majority of the trained listeners improved more than controls. Thus multihour training induced additional learning in ILD, but not ITD, discrimination, even for the same stimulus. These results suggest differential plasticity in the processing of the two cues regardless of stimulus frequency or type.

Notably, the detailed pattern of the training results for ILD discrimination also differed between the pure tone and

the SAM tone (Zhang & Wright, in review). There were three such differences. First, the training-induced learning on ILD discrimination with the SAM tone generalized to untrained SAM tones with different carrier frequencies and modulation rates but not to pure tones, even when those tones had the same frequency as the trained carrier or modulation rate. Thus within the trained stimulus type, learning for the SAM tone generalized across frequency, while that for the pure tone did not. Second, the amount of learning could be predicted on the basis of the starting thresholds for ILD learning with the pure tone but not with the SAM tone. Third, the learning curve was more linear for the SAM tone than for the pure tone. These differences suggest that training affects differentially the processing of ILDs in amplitude-modulated stimuli and pure tones, even at the same frequency.

Finally, we investigated the extent to which the rapid improvement that we observed on ITD discrimination results from learning of the trained stimulus, the lateralization task, or other factors that are collectively classified as the procedure (Ortiz & Wright, 2009). Toward this end, we trained three groups of listeners for a single session, each on a different condition, and tested all of them the next day on a target ITD-discrimination condition. The three trained conditions shared different elements with the target ITD condition, forming a hierarchy of similarity. One group of listeners was trained on a temporal-interval discrimination condition that shared with the target condition only the general, procedural aspects. These listeners had lower thresholds on the target ITD condition than naïve listeners did, suggesting procedure learning. Another group of listeners was trained on an ILD-discrimination condition that shared with the target condition both the procedure and the lateralization task but not the stimulus. The ITD-discrimination thresholds of the ILD-trained listeners were similar to those of the interval-trained listeners, implying that there was little additional improvement that was attributable to task learning. The third group was trained on the target ITD condition itself. These listeners had lower ITD thresholds than the ILD-trained listeners did, suggesting that the additional improvement resulted from stimulus learning. Thus rapid improvements on ITD discrimination appear to result primarily from learning of the procedure and the stimulus, implying that a single session of training can affect at least two types of neural processes.

Neural underpinnings of perceptual learning

Up to this point, we have documented the large variation in learning patterns across auditory tasks, argued that this variation suggests that different neural processes are involved in learning on these tasks, and illustrated how these learning patterns can be used to make inferences about the affected

processes. Here we speculate about the actual neural underpinnings of auditory learning on the basis of behavioral and physiological data from the auditory as well as other sensory systems.

We propose that in most cases, for auditory learning to occur on a given condition, a neural process that limits the performance on that condition has to be selected and placed in a modification-prone state (sensitized). Sufficient stimulation of the sensitized process results in modifications that lead to behavioral improvement. We further suggest that the selection and sensitization of the targeted process occurs through top-down influences such as attention or reward. These influences are typically and optimally provided by performance of the target condition rather than simply through the bottom-up stimulation received from stimulus exposures. A role for top-down influences in perceptual learning has been proposed previously for visual learning (Ahissar & Hochstein, 2004; Gilbert & Sigman, 2007; Seitz & Watanabe, 2005). The primary behavioral evidence for this involvement, both here and in other sensory systems, comes from the observations that learning on one task rarely generalizes to other tasks, even when the same stimuli are employed, and from the different learning and generalization patterns for different tasks performed with the same stimuli. The idea that sufficient stimulation of the sensitized process is required to achieve learning comes in part from the demonstration that improvement across days on an auditory task requires a sufficient amount of training per day (Wright & Sabin, 2007). It also echoes a recent proposal, arising from a literature review, that a “learning threshold” must be surpassed, through any of a variety of means, for improvement to occur (Seitz & Dinse, 2007). Note that this proposed requirement for learning provides one means for preserving the necessary balance between stability and plasticity in the nervous system.

We also suggest that the processes that are selected and sensitized during auditory training differ across tasks and can shift over the course of training. These ideas are supported by evidence from neurophysiology and imaging that the neural changes that accompany perceptual learning occur at multiple stages of the nervous system, including primary sensory cortices (Clapp, Kirk, Hamm, Shepherd, & Teyler, 2005; Furmanski, Schluppeck, & Engel, 2004; Li, Piech, & Gilbert, 2008; Pourtois, Rauss, Vuilleumier, & Schwartz, 2008) as well as associative (Law & Gold, 2008) and frontal (Krigolson, Pierce, Holroyd, & Tanaka, 2008) cortices, particularly those involved in attention (Mukai et al., 2007). There are also reports of global reorganization spanning multiple stages of processing (Schiltz, Bodart, Michel, & Crommelinck, 2001; Sigman et al., 2005; Vaina, Belliveau, des Rozières, & Zeffiro, 1998; van Wassenhove & Nagarajan, 2007). These ideas receive further support from evidence that different sites are affected at different time

points in training (Atienza, Cantero, & Dominguez-Marin, 2002; Gottselig, Brandeis, Hofer-Tinguely, Borbely, & Achermann, 2004; Karni et al., 1998; Petersen, van Mier, Fiez, & Raichle, 1998) and that changes in primary cortex that occur during learning can reverse after learning is complete, leaving the cortex in its original state (Yotsumoto, Watanabe, & Sasaki, 2008). Behavioral data have also been used to argue that a variety of different sites are affected by perceptual training. These arguments are based on the practice of matching generalization patterns to the tuning functions at different processing levels. For example, in the visual system, the specificity of learning to basic stimulus attributes has been taken as evidence for modifications in early stages of the visual system, because the neurons at those stages are tuned to those attributes (Ahissar & Hochstein, 2004; Fahle, 2004; Karni & Sagi, 1991; Poggio, Fahle, & Edelman, 1992). Similarly, broader generalization has been attributed to modifications in later visual-processing stages in which neural tuning is also less selective (Ahissar & Hochstein, 2004). However, it has been noted that both generalization patterns also could result from modifications in a common central site that interprets the sensory information obtained from earlier processing stages, with the degree of specificity reflecting the reweighting of sensory information based on different task demands (Mollon & Danilova, 1996). As to which site will be modified, one proposal is that training affects the most central level of representation that provides an adequate signal-to-noise ratio for task performance (Ahissar & Hochstein, 2004). Thus the site of modification is determined by task difficulty, with difficult tasks affecting more peripheral sites. This idea is based primarily on the observation that learning on an easy visual task generalized more broadly than that on a more difficult task (Ahissar & Hochstein, 2004).

Finally, we think that auditory learning could be mediated by different types of neural changes for different tasks. In support of this view, perceptual learning has been associated with a variety of physiological changes, including possibly interrelated changes such as the remapping of stimulus representations (Feldman & Brecht, 2005; Recanzone, Merzenich, Jenkins, Grajski, & Dinse, 1992), increased (Furmanski et al., 2004; van Wassenhove & Nagarajan, 2007) or decreased (Sigman et al., 2005; Vaina et al., 1998) neural activity, inhibition of irrelevant channels (Casco, Campana, Grieco, & Fuggetta, 2004), sharper (Schoups, Vogels, Qian, & Orban, 2001) or broader (Crist, Li, & Gilbert, 2001) neural tuning, improved neural response reliability (Yao, Shi, Han, Gao, & Dan, 2007), and alteration in synaptic (Yao & Dan, 2005) and cellular (Barkai, 2005) properties of neurons (for a review, see Buonomano & Merzenich, 1998). These changes differ in both their time course and their range of influence. Additional evidence for the involvement of different mechanisms comes from mathematical models, which,

when fitted to behavioral data, suggest that in some cases, perceptual learning results from an enhancement of the signal representation, while in others, it results from a reduction in noise (Doshier & Lu, 1998; Gold, Bennett, & Sekuler, 1999; Lu, Chu, Doshier, & Lee, 2005).

Conclusion

Training induces improvements in a variety of basic auditory skills in humans but does so with different dynamics and generalization patterns. These differences support the idea that perceptual training on different skills affects different neural processes. Detailed examinations of the patterns of learning and generalization provide information about the characteristics of the neural processes that are affected by the training. Thus perceptual training can be used as a noninvasive tool to probe into the neural substrates of sound perception. A greater understanding of the rules and mechanisms of auditory learning can also guide the development of training regimens to improve auditory skills.

25 Auditory Object Analysis

TIMOTHY D. GRIFFITHS, SUKHBINDER KUMAR, KATHARINA VON KRIEGSTEIN,
TOBIAS OVERATH, KLAAS E. STEPHAN, AND KARL J. FRISTON

ABSTRACT The question addressed in this chapter is how the auditory system allows us to represent the elements of the acoustic world? The term *auditory object* is widely used in the literature but in a number of different ways. We consider different aspects of object analysis and the ways in which these can be approached by using experimental techniques such as functional imaging. Functional imaging allows us to map networks for the abstraction of perceived objects and generalization across objects. This fundamental aspect of auditory perception involves high-level cortical mechanisms in the lateral temporal lobe. Systems identification techniques based on Bayesian model selection in individual subjects allow the testing of specific models that explain the activity of the networks that are mapped.

The concept of auditory object

In the acoustic world, we experience a number of different things that form the natural sound scene. The problem considered here is how the brain abstracts representations of these things, or objects, as a basis for perception. The computation required for this process is formidable, given the richness of our sound experience that is entirely based on two pressure waveforms arriving at the ears. The problem is a key issue for what has become known as auditory scene analysis (Bregman, 1990).

In contrast to the concept of visual objects, the concept of auditory object is controversial for a number of reasons (Griffiths & Warren, 2004). At the level of the stimulus, it is more difficult to examine the sound pressure waveform that enters the cochlea and “see” different objects in the same way that we “see” objects in the visual input to the retina. However, in the auditory system and in the visual system, objects can be understood in terms of the images they produce during the processing of sense data. The idea that objects are mental events that result from the creation of images from sense data goes back to Kant and Berkeley (Russell, 1945). In the visual system, there is good evidence

for the creation of images (brain representations corresponding to an object) with two or more spatial dimensions in the form of arrays of neural activity that preserve spatial relationships from the retina to the cortex. In the auditory system, the concept of an image is most often used to refer to a brain representation with dimensions of frequency and time or derivations of these such as spectral ripple density related to frequency (Chi, Ru, & Shamma, 2005) and amplitude modulation (Chi et al., 2005) or forms of autocorrelation (Patterson, 2000) related to time. If we accept the existence of images with a temporal dimension, then the concepts of auditory objects and auditory images can be considered in a way comparable to how the visual system is considered. The idea was first proposed by Kubovy and Van Valkenburg (2001), who suggested that auditory objects can be considered as existence regions within frequency-time space that have borders with the rest of the sound scene.

A second issue about the concept of auditory object analysis (which is also relevant to visual object analysis) is the cognitive level to which it should be extended. Consider the situation in which you hear someone making the vowel sound /a/ at a pitch of 110 Hz and intensity of 75 dB on the left side of the room. That situation requires sensory analysis of the spectrotemporal structure of the sound. It also requires categorical perception to allow the sound to be distinguished from other sounds. Sounds from which it has to be distinguished might be from another class (e.g., a telephone ringing at the same pitch, intensity, and location) or the same class (e.g., another person making the vowel sound /a/ at a different pitch, intensity, or spatial location). We can appreciate that we are listening to the same type of sound if we hear it at 80 Hz or 65 dB or on the right side of the room. We can appreciate that similarity even if we do not speak a relevant language to allow us to recognize or name the vowel. At another level of analysis, the sound must enter a form of echoic memory store (to allow comparison with sounds that might immediately follow it) and might enter an anterograde memory store that allows comparison with sounds heard over days or weeks. At a further level of analysis, we might call the sound a voice, or my voice, the vowel “a,” or (if we have absolute pitch) “A2.” The term *object analysis* might therefore be applied to (1) the perception of a coherent whole, the essence of

TIMOTHY D. GRIFFITHS and SUKHBINDER KUMAR Institute of Neuroscience, Newcastle University, Newcastle upon Tyne; Wellcome Centre for Imaging Neuroscience, University College, London, United Kingdom

KATHARINA VON KRIEGSTEIN, TOBIAS OVERATH, KLAAS E. STEPHAN, and KARL J. FRISTON Wellcome Centre for Imaging Neuroscience, University College, London, United Kingdom

which can be perceived even when cues such as pitch or intensity are changed; (2) categorical analysis; (3) encoding into working memory; (4) encoding into anterograde memory; or (5) association with a label during semantic analysis. We prefer to apply the term *object analysis* to the first stage and will emphasize it in the current chapter, but a number of workers would argue for an obligatory requirement for auditory objects, or objects in general, to have an associated label. The key point, however, is that a number of stages of analysis are required to assess the nature of an auditory object and that even the first stage above requires considerable computational work to derive a representation of particular sounds that is independent of basic cues such as pitch or intensity. Clinically, the distinction of presemantic and semantic processing stages of object analysis is relevant to the existence of apperceptive and associative forms of auditory agnosia, respectively (Griffiths, Bamiou, & Warren, in press).

A third controversial aspect of auditory object analysis is whether the concept should be applied to particular individual sounds that can be distinguished from others as argued above or to *sequences* of sounds that are grouped: auditory streams. Bregman (1990) explicitly rejects the concept of auditory object in favor of the auditory stream, a sequence of grouped sounds, as the fundamental unit of auditory perception. Others equate auditory objects with streams (Shamma, 2008). There is a problem, however, with considering streams as auditory objects corresponding to a single percept derived from analysis over longer periods of time. Streams are sequences of sounds that are grouped by perceptual properties such as pitch, timbre, or position (Moore & Gockel, 2002), where these perceptual properties all have complex relationships to the acoustic structure. This makes a description of the stream as the most fundamental unit of analysis leading to perception problematic, when the stream itself comprises elements that are perceived individually. Whether streams are regarded as objects, streams of objects, or something else, however, it is an important level of perceptual organization that will also be considered here.

In this chapter we will consider different ways in which auditory object analysis can be approached, with an emphasis on human neuroimaging. We will develop an approach that allows an understanding of how we assess objects as perceptual wholes that can be distinguished from others and generalized. We will also consider the encoding and retrieval of sequences of objects. Functional neuroimaging data demonstrate that such auditory object analysis requires distributed networks in the temporal lobe distinct from early mechanisms for the representation of spectrotemporal stimulus structure and perceived pitch in the superior temporal plane. We now have tools to tease out the detailed functional organization of the networks for object analysis.

Natural stimuli for the investigation of auditory object analysis

A reasonable starting point for the analysis of auditory objects is the use of sampled natural stimuli. These have been used in behavioral experiments that use the technique of multidimensional scaling (MDS) (Caclin, McAdams, Smith, & Winsberg, 2005; Grey, 1977). This involves pairwise judgments of the degree of difference between sounds that are then arranged in an n -dimensional space, where the degree of dissimilarity between sounds is represented by the degree of physical separation. The best fit for a given number of dimensions is determined by minimizing the normalized sum of squares error for the fits that can be expressed as a stress factor. Figure 25.1 shows musical instruments placed in a three-dimensional Euclidian space using the technique. The technique is not dependent on any assumptions about what causes them to sound different. However, the dimensions disclosed by MDS can be examined to determine whether the dimension corresponds to any systematic variation of acoustic properties. For musical sounds with the same pitch, the dimensions of timbre space have been argued to correspond to the spectrum of the sound (characterized by the spectral centroid), the temporal envelope (attack and decay), and changes in spectral centroid over time. Recent work (Caclin et al., 2005) has also emphasized the relevance of the fine-spectral structure.

Synthetic manipulation of natural stimuli to investigate auditory object analysis

An alternative and complementary approach to sampling natural sounds is to alter natural sound objects systematically using algorithms that obey natural principles. Figure 25.2 shows how this approach can be applied to sounds produced by natural resonant sources (a human voice, a French horn, and a bullfrog). Natural resonant sources usually produce a fundamental frequency and a series of harmonics at integer multiples of the harmonic frequency; the sound has a number of components when considered in the spectral domain. These components are filtered by the resonant cavities within the source, which has the effect of producing peaks or formants in the spectrum. Figure 25.2 shows modeled auditory images (Griffiths, Buchel, Frackowiak, & Patterson, 1998) for the three types of sound, where the activity within the fibers of the auditory nerve (arranged in increasing frequency order on the vertical axis), undergoes a form of autocorrelation (shown on the horizontal axis), as might be used in the auditory system to achieve time stabilisation of the auditory image. The vertical ridge at a time delay of 6.8 ms corresponds to the temporal regularity within these stimuli, which all have the same pitch (147 Hz). The formant peaks can be seen as horizontal bands of

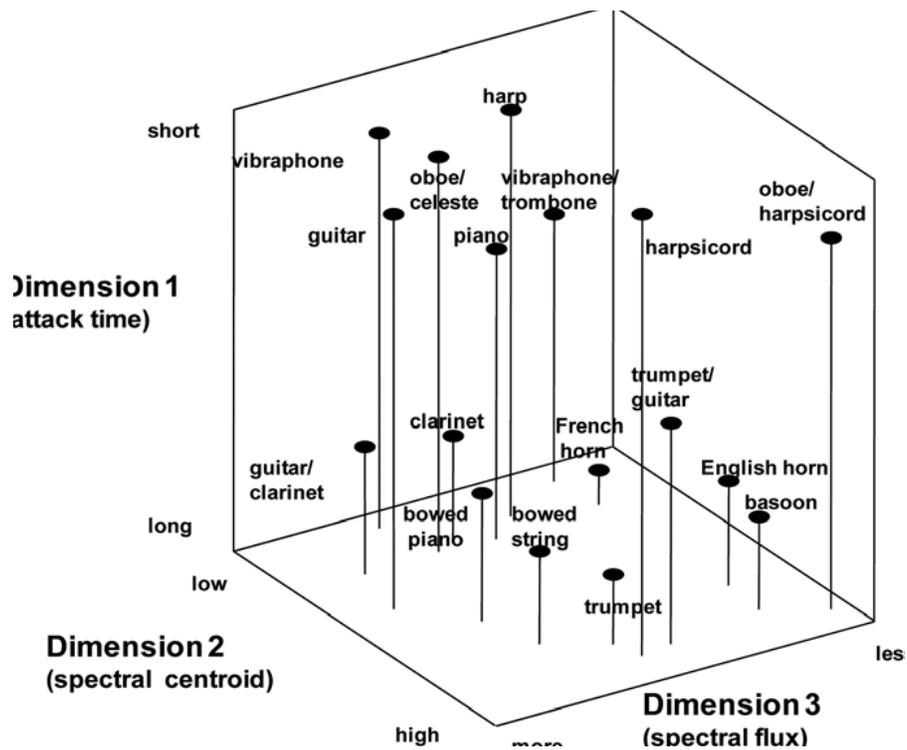

FIGURE 25.1 Multidimensional scaling to disclose the perceptual relationships between natural stimuli (Menon et al., 2002).

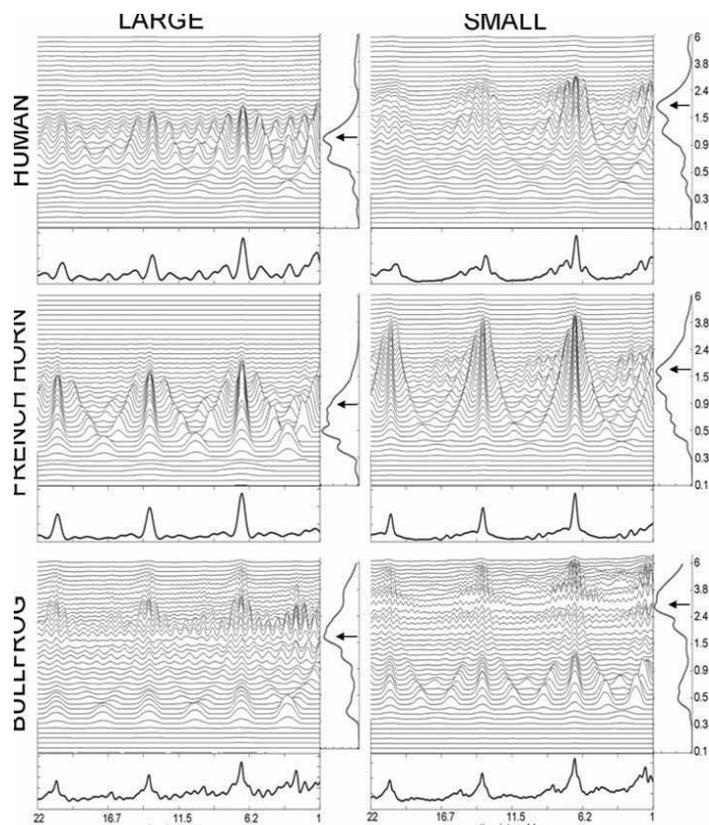

FIGURE 25.2 Resonator scale stimuli (von Kriegstein et al., 2007).

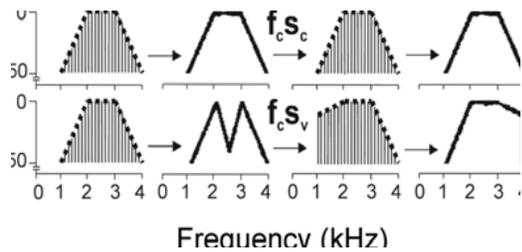

FIGURE 25.3 Spectral envelope stimuli (Warren et al., 2005).

activity at particular frequencies that are seen at the right of each figure in the form of a mean spectral activity pattern. The two columns show the auditory image for sounds emitted by large sources on the left and small sources on the right. When the sound source gets smaller, the formant peaks move to a higher frequency, as shown by the position of the black arrow, corresponding to one of the formants. Notice that this can happen without changing the pitch. Behavioral experiments (Smith, Patterson, Turner, Kawahara, & Irino, 2005) demonstrate that in the case of voices, humans judge the size of auditory objects using the acoustic effect of resonator size to a greater extent than changes in pitch.

We have used an algorithm called STRAIGHT (Kawahara & Irino, 2004) to modify the acoustic correlates of resonator size (figure 25.2). Perceptually this produces a different type of object change from the instrument changes in figure 25.1, where the perceived object remains in the same class. Unlike pitch change, change of resonator size does not generally occur within one source (with some interesting exceptions, such as stags that drop their larynges when calling during the rutting season (Fitch & Reby, 2001)). Size changes are generally perceived as object changes when they can be detected, which makes sense ethologically. Other experimental manipulations of natural objects that have been used to assess object analysis experimentally include morphing or mixing techniques similar to those used in vision (e.g., Zatorre, Bouffard, & Belin, 2004).

Synthetic stimuli for the investigation of auditory object analysis

Work based on MDS has identified a key spectral dimension that determines the differences between objects. Figure 25.3 shows synthetic stimuli that have been used in imaging experiments to reveal mechanisms for the analysis of perceived changes in objects related to the spectral envelope, regardless of changes in the fine spectral structure. The work is an example of an approach that might be called *prototimbre* based on the systematic manipulation of timbral dimensions (see Griffiths, 2008, for further examples). The work seeks mechanisms comparable to those in

vision that allow the same face to be perceived regardless of angle or illumination. The use of synthesis allows the systematic manipulation of dimensions identified by MDS in a more straightforward way than using sampled stimuli. Consider the top row of stimuli in figure 25.3. This shows the spectral representation of successive sounds in which the fine structure alternates between harmonic sounds (with an associated pitch) and noise. A common spectral envelope is applied to the sounds and listening to the stimuli establishes that there is an essential “sameness” despite the very different spectral structure. A similar mechanism allows us to perceive the same vowel sound whether it is voiced or whispered. The sounds in figure 25.3 could be vowels but not any that you might have heard, and the use of stimuli at this level allows an assessment of mechanisms relevant to generalization across different fine structure without any semantic association. The lower row of figure 25.3 shows the situation in which the spectral envelope changes from one sound to the next. This is perceived as a changing object over and above the changing fine structure. Measurements of brain activity in response to the lower stimulus compared with the upper stimulus allows inference about mechanisms for the abstraction of object identity over and above the analysis of the fine spectrotemporal structure.

Stimuli based on sequences of objects

A number of behavioral studies have examined sequential grouping based on pitch since the original demonstration of this in a paradigm introduced by van Noorden (1975). The studies demonstrate that in a sequence of the form A-B-A-A-B-A, where A and B are different pitch values, sequential grouping will occur (we hear “horse” based on sequentially grouped A-B-A triplets rather than “morse” based on segregated A and B streams) when the pitch separation between the high and the low pitch is not large and the rate of presentation of individual notes is not high (Bregman, 1990). Sequential grouping of sounds (the opposite of which, segregation, is called *streaming*) can be achieved on the basis of a number of perceptual properties, including pitch, in the majority of experiments in addition to timbre and position in space (Moore & Gockel, 2002).

In the natural world, we do not hear deterministic sequences; we hear stochastic sequences with varying degrees of predictability. Figure 25.4 shows synthetic pitch sequences based on pitch trajectories that are derived from power spectra that are related to the frequency, f , by the function f^{-n} . For any given value of n , families of pitch sequences with similar statistical properties can be constructed on the basis of power spectra with that value of n : different exemplars are created by the use of different random-phase spectra. When $n = 0$ (top part of figure 25.4), the power spectrum is flat, and the pitch trajectory created corresponds to fixed-

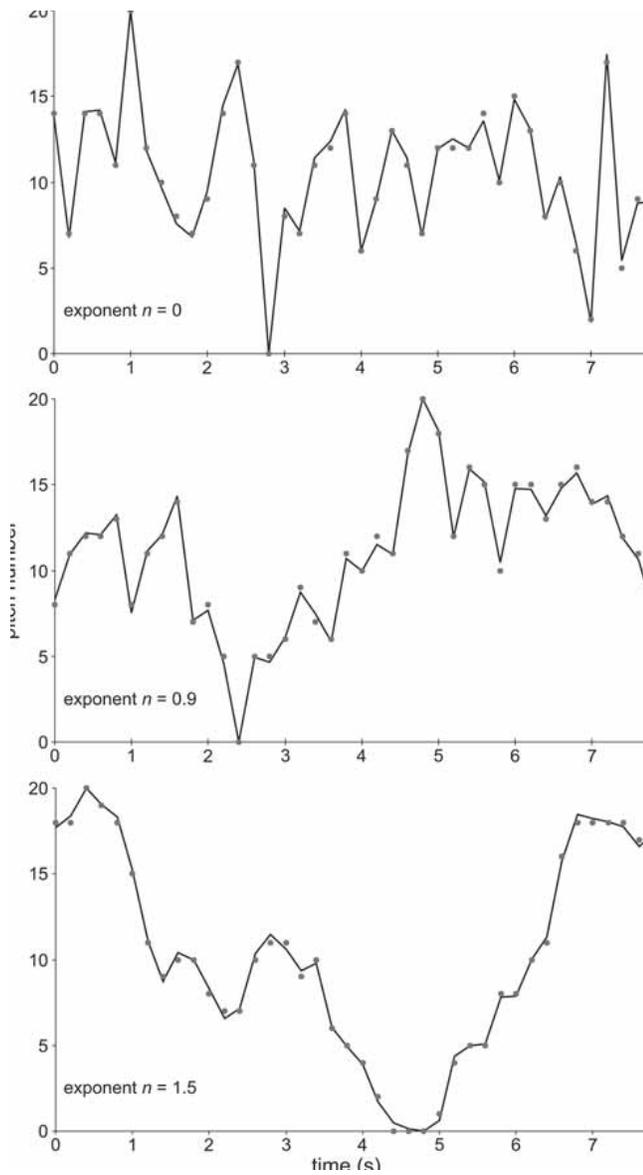

FIGURE 25.4 Fractal pitch stimuli with varying information content used to probe for sequence encoding mechanisms (see text). The pitch trajectories were derived from power spectra with the form f^{-n} , where the value of the exponent n is given with each figure. Pitch number refers to a pitch scale spanning two octaves, where each octave is divided into 10 equal log divisions. Low exponents (top) produce unpredictable pitch sequences with a large amount of information, while high exponents produce redundant sequences containing less information.

amplitude random-phase noise. In such a waveform, successive pitch values cannot be predicted by the preceding pitch, so each pitch value contains a lot of information. In contrast, as n tends to a large value, the pitch waveform tends to a sine wave in which successive pitch values can be accurately predicted by the preceding pitch, and individual pitch values (or sequences of a given length) do not contain a large amount of information. These stimuli are called *fractal pitch sequences* because of their scaling properties (Schmuckler & Gilden,

1993), but the important property used in our experiments is the relationship between n and the information contained in a sequence. Specifically, we hypothesized that computationally efficient mechanisms for the encoding of sequences of sound would use less computational resource as the amount of information in sequence decreased. These sounds are ethological in that they contain a global contour, on which smaller excursions are imposed as occurs in a variety of natural stimuli. Sampling of natural acoustic patterns demonstrates a similar balance: Music and speech have trajectories for pitch and other perceptual properties corresponding to f^{-n} power spectra, where $n = 1$ (Voss & Clarke, 1975).

Strategies for the brain measurement of auditory object analysis

A number of techniques can be used to assess brain processes related to auditory object analysis, from single-unit approaches to measurements reflecting ensemble electrical activity in MEG and EEG experiments and approaches based on the BOLD response in fMRI (considered in the next section), which reflects blood flow changes in response to neuronal ensemble activity as indexed by local field potentials (Logothetis, Pauls, Augath, Trinath, & Oeltermann, 2001). Similar principles might be applied to all of the techniques to allow inference about object analysis. At the level of single units, a helpful approach has been to characterise the selectivity of units to particular types of natural objects by establishing a profile of responses to different exemplars (Tian, Reser, Durham, Kustov, & Rauschecker, 2001; Kikuchi, Horwitz, & Mishkin, 2007). The approach has suggested a gradient of object selectivity within the superior temporal lobe with more selective responses toward the anterior temporal pole. At the level of ensemble activity, responses to natural classes of stimuli might also be sought as in the case of imaging studies of voices considered in the next section, and there are now also fMRI techniques available to establish the mapping of different exemplars within the same human cortical areas (see below). In the case of both single-unit and ensemble activity, a critical issue for natural stimuli is whether the responses are true object responses that reflect abstraction of object properties rather than a simple representation of particular spectrotemporal features. Another critical issue for natural stimuli is whether the representation is at the level of the “coherent whole” that is perceived or at the level of the associated semantic label. Definition of responses that are specific to object analysis could be achieved with any technique by defining responses that occur for between-object acoustic change (such as /a/ to /e/) but not for within-object acoustic change (such as /a/ at a different level or pitch). That approach utilizes the phenomenon of object constancy to define object-specific mechanisms.

Univariate analysis of fMRI data: Single objects

Functional imaging that assesses the BOLD response during object analysis using mass-voxel-wise univariate statistics has used a number of different stimuli, including natural sounds, synthetically manipulated natural sounds, and synthetic sounds. Figure 25.5 shows an example of an experiment in which a response to a category of natural sound was sought (Belin, Zatorre, Lafaille, Ahad, & Pike, 2000). In this experiment, the BOLD response during the perception of voices (both speech and nonspeech sounds) was contrasted with responses to nonvocal environmental sounds and demon-

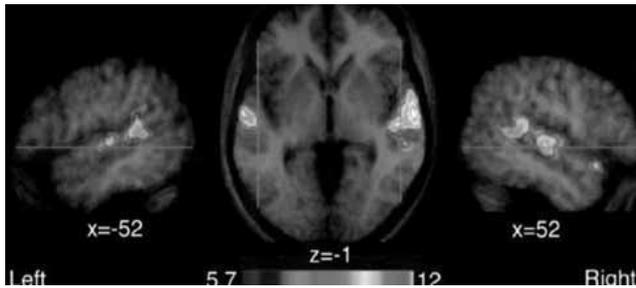

FIGURE 25.5 Activation during passive listening to voices (Belin et al., 2000). The numbers refer to planes defined in millimeters in Talairach space (Talairach & Tournoux, 1988). (See color plate 28.)

strated bilateral responses in the superior part of the superior temporal sulcus (STS). Figure 25.6 shows a mapping of changes in the BOLD response when subjects listen to variation in the size and type of resonator using stimuli shown in figure 25.2. During this experiment, subjects perceived successions of different-sized voices, French horns, or bullfrogs (von Kriegstein, Smith, Patterson, Ives, & Griffiths, 2007). Perception of object change within categories produced in this way was associated with bilateral increases in the BOLD signal in the superior temporal gyrus: this experiment also provided evidence for more specific change in the left posterior superior temporal gyrus for changes in the size of voices. The experiment demonstrated that very similar regions respond to changes in category as to changes in resonator size. The data can be interpreted in terms of generic mechanisms for the analysis of object change, whether this corresponds to a change in resonator size or a change in the class of sound.

In the resonator-size changes or category changes (von Kriegstein et al., 2007), there are associated changes in the spectral and temporal structure of the stimulus. Figure 25.7 shows an experiment in which the basis for the analysis of spectral envelope in generic acoustic objects (without associated meaning) is assessed (Warren, Jennings, & Griffiths, 2005). The figure shows mapping within the superior tem-

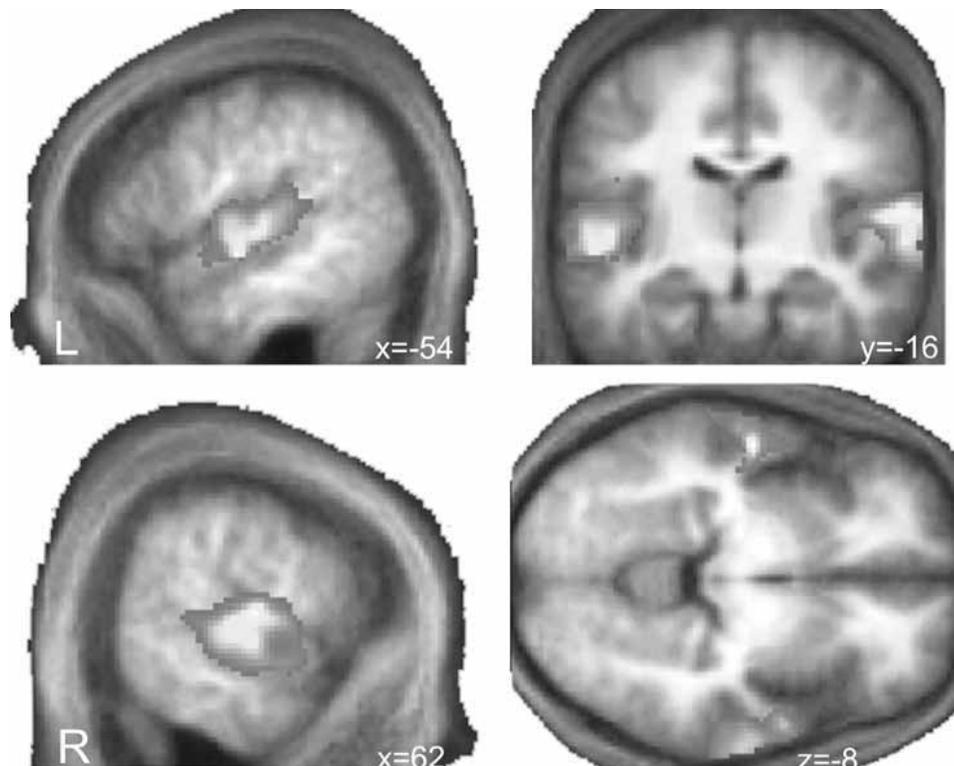

FIGURE 25.6 Activation due to passive listening to changing resonator scale and sound class in the three types of harmonic sounds shown in figure 25.2 (von Kriegstein et al., 2007). (See color plate 29.)

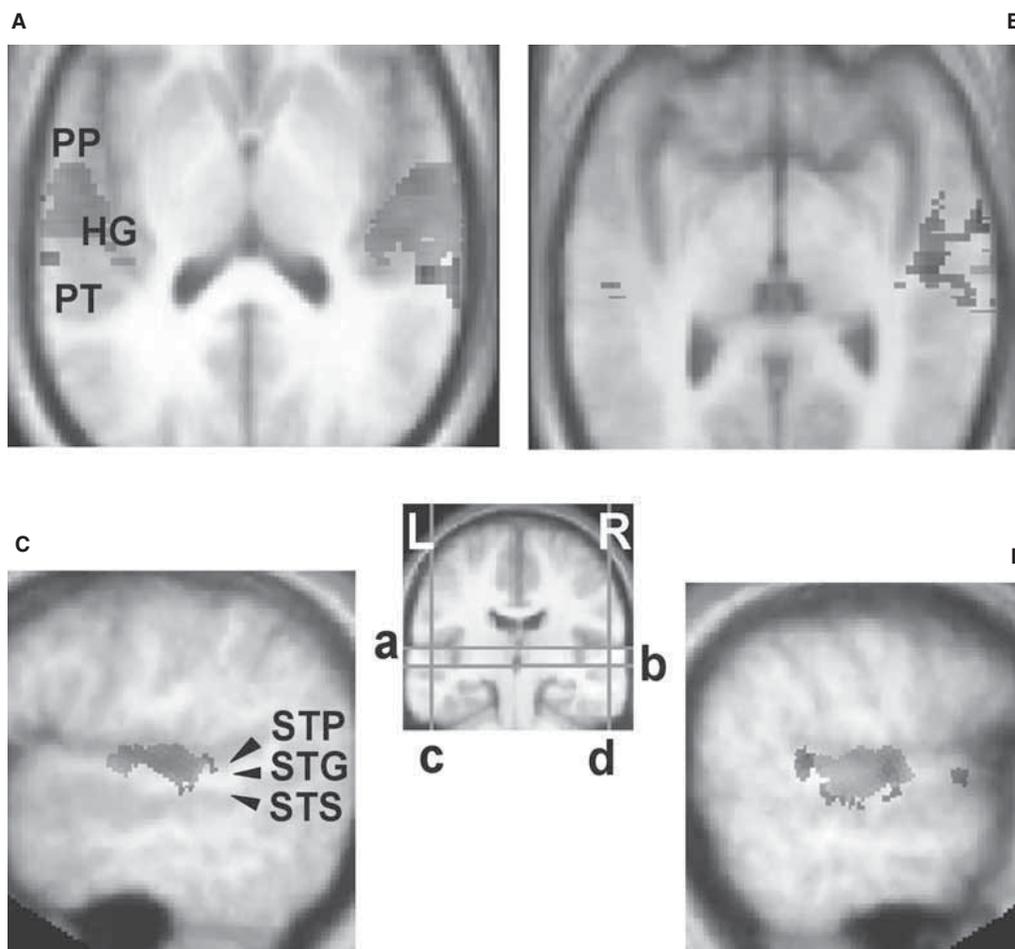

FIGURE 25.7 Activation due to passive listening to changing spectral envelope (Warren et al., 2005). HG, Heschl's gyrus; PT, planum temporale; PP, planum polare; STS, superior temporal sulcus. (See color plate 30.)

poral plane (in red) corresponding to whether or not the sounds were associated with pitch. That mapping occurs in lateral Heschl's gyrus (HG) in a region previously demonstrated to increase activity as a function of pitch salience (Patterson, Uppenkamp, Johnsrude, & Griffiths, 2002; Penagos, Melcher, & Oxenham, 2004). The key contrast in figure 25.7 (in blue) is between changing spectral envelope and fixed spectral envelope in series of objects with continuously varying fine-spectral structure (shown in figure 25.3): an argument can be made that this contrast identifies areas involved in the "abstraction" of spectral envelope relevant to object analysis over and above the analysis of the fine-spectral structure. The contrast shows bilateral activation in the superior temporal plane in the planum temporale (PT), posterior to the pitch mechanisms, and predominantly right-lateralised activation in the STS.

These studies all highlight a critical role in object analysis for temporal lobe areas beyond the primary and secondary cortices in HG in the superior temporal plane. The areas are likely to be involved in the abstraction of object pro-

perties beyond the representation of spectrotemporal structure. We consider later how the responsible system for spectral envelope analysis might be determined explicitly by using dynamic causal models of functional auditory architectures.

Univariate analysis of fMRI data: Sequences of objects

Figure 25.8 shows an experiment in which the encoding of sequences of objects was assessed: specifically, the encoding of the fractal-pitch sequences similar to the examples in figure 25.4. The information content of a pitch series was systematically varied by changing the exponent, n , determining a power spectrum with the form f^{-n} from which the pitch series was derived. The experiment was carried out as an explicit search for mechanisms for the encoding of auditory sequences. It was predicted that computationally efficient encoding mechanisms should use less computational resource (measured indirectly by using the BOLD response) for more

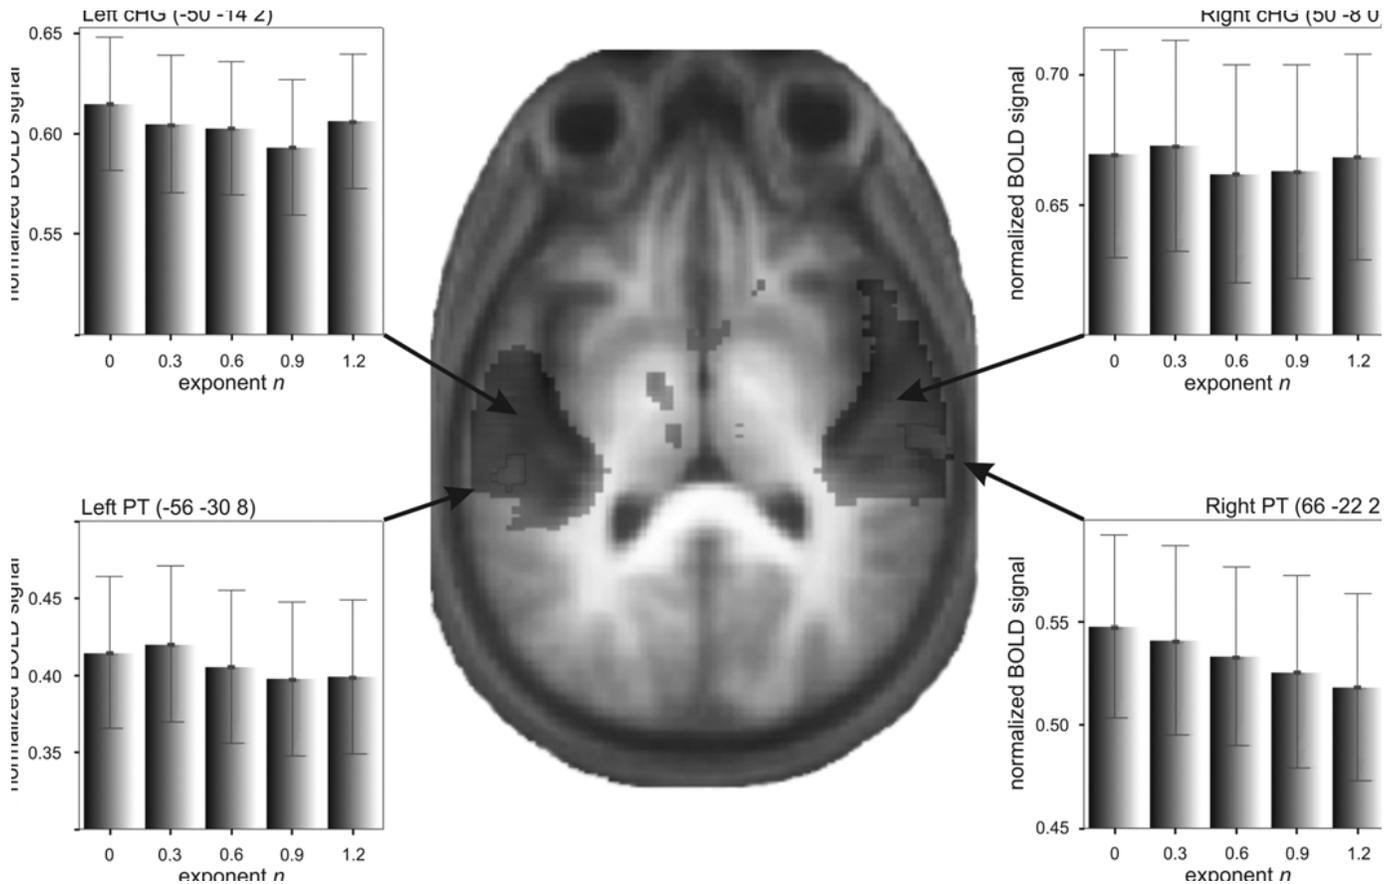

FIGURE 25.8 Activation as a function of information content of pitch sequences during the encoding of pitch sequences. A significant effect of pitch-sequence information content (which decreases as n increases) is shown in the planum temporale (PT) but not

redundant sequences containing less information. Such a relationship was demonstrated in two experiments in the PT, bilaterally, but not in the primary and secondary auditory cortices in HG. The work is consistent with the suggestion (Griffiths & Warren, 2002) that the PT represents a “computational hub” responsible for the encoding of acoustic stimuli, and suggests overlapping substrates for the abstraction of object features as in figure 25.7 and the encoding of sequences of objects. In contradistinction, figure 25.9 shows a contrast to demonstrate areas involved in the retrieval of auditory sequences in the second experiment during a one-back task where subjects were required to compare successive pitch sequences. The contrast demonstrates bilateral frontal activity including activity in the frontal operculum which in the right hemisphere is similar to that occurring during working memory tasks for melodic pitch sequences (Zatorre, Evans, & Meyer, 1994). Unlike encoding, the activity associated with retrieval was not affected by the information content of the stimulus. This can be interpreted in terms of the retrieval process requiring a symbolic level of processing that is not yoked to the complexity of the acoustic stimulus in the same way as encoding.

in Heschl’s gyrus (HG). Numbers in parentheses are Talairach coordinates in millimeters where the BOLD values were measured. (See color plate 31.)

Multivariate analysis of fMRI data

There has been considerable interest in techniques to demonstrate different spatial distributions of BOLD activity in response to sensory stimulation, which can be achieved by the use of multivariate statistical methods. For a description of this approach to visual data, see Haynes and Rees (2006). The technique has the potential resolution to allow fMRI characterization of different responses within the same cortical areas that correspond to the perception of different individual auditory objects. The interpretation of such mappings would be subject to the same issues discussed above in terms of whether spectrotemporal structure or a correlate of the perceived object is represented.

Analysis of categorical processing using fMRI

Categorical response to changes in objects can be assessed by using the technique of repetition suppression that has been developed for the analysis of visual fMRI data (Grill-Spector, Henson, & Martin, 2006). Previous work suggested categorical mechanisms for visual representation based on

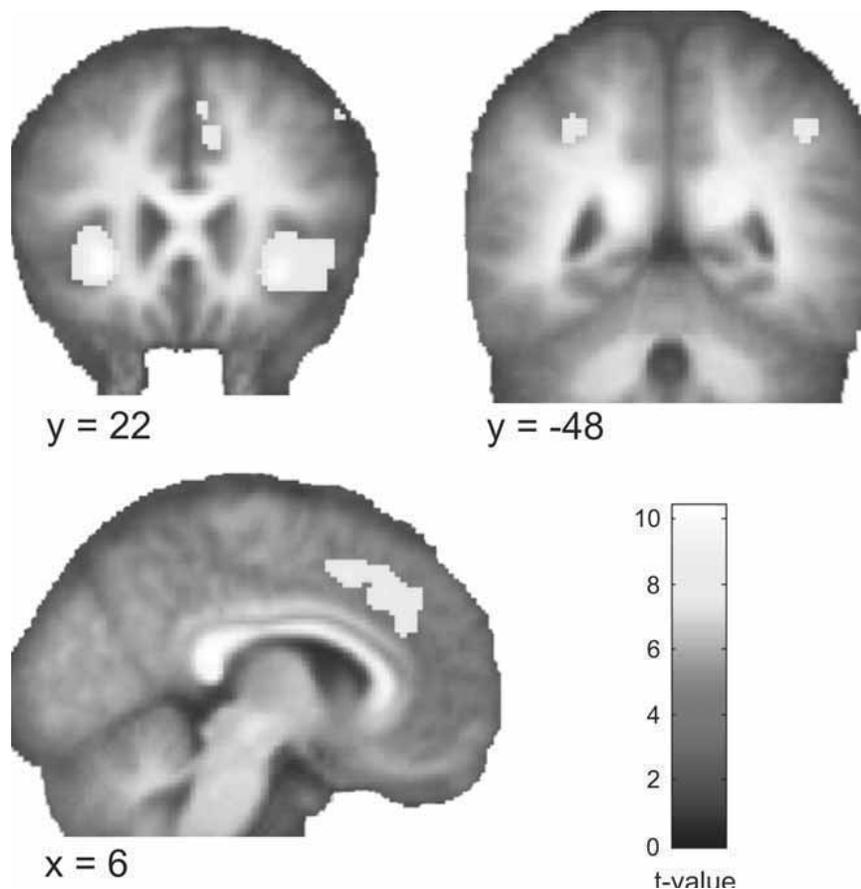

FIGURE 25.9 Contrast to demonstrate activation associated with pitch-sequence retrieval in an active listening task. (See color plate 32.)

BOLD responses to exemplars from the same category that decrease with repeated presentation, regardless of other (category-independent) stimulus changes. The technique allows categorical mechanisms to be sought even when different neuronal ensembles tuned to different categories are located in the same region. Recent visual neurophysiological work (Sawamura, Orban, & Vogels, 2006) demonstrates correlates of the phenomenon at the single-unit level. Models that might explain the phenomenon at the neuronal ensemble level are developed in Grill-Spector et al., (2006). A recent study applied a related approach to mapping of an auditory continuum between two phonemes (Raizada & Poldrack, 2007). That study demonstrated responses that changed across phoneme boundaries in areas beyond the temporal lobe, but the technique could also be applied to shifts between objects at a presemantic level that might be analyzed in temporal lobe areas.

Effective connectivity analysis of fMRI data

The conventional analyses considered in figures 25.5 to 25.9 demonstrate considerable overlap in the networks of activity that are involved in the analysis of objects assessed using different types of stimulus manipulation and in the analysis

of sequences of objects. In particular, a key role for the PT is demonstrated in these studies consistent with the idea that this is an important “computational hub” concerned with auditory encoding. The term *hub* implies connection to other nodes of analysis and a flow of information: There is a need for the identification of specific systems for object analysis that might use similar nodes in different ways. Specifically, different aspects of object analysis might be subserved by different patterns of connectivity between nodes. In this section, we consider the application of this approach to one aspect of object analysis, spectral envelope analysis, addressing the question of how PT and the other nodes within the right-hemisphere network for spectral envelope analysis are effectively connected.

We use an approach called dynamic causal modeling (DCM) (Friston, Harrison, & Penny, 2003), together with Bayesian model selection (Penny, Stephan, Mechelli, & Friston, 2004), to test different models for auditory object analysis. The approach identifies effective connectivity between areas (the causal influence of activity in one area on the activity in another) and the modulatory effect of task (or any other experimentally controlled manipulation) on effective connectivity. DCM belongs to a family of models of effective connectivity such as structural equation

modeling (SEM) (McIntosh & Gonzalez-Lima, 1994), multivariate autoregression (Harrison, Penny, & Friston, 2003), or Granger causality (Goebel, Roebroeck, Kim, & Formisano, 2003). DCM has a number of advantages (discussed in Friston et al., 2003; Stephan, 2004). A major advantage is the way in which DCM can be used to carry out a systematic comparison of competing models that might explain a regional pattern of BOLD activity.

The basic idea behind dynamic causal modeling can be summarized as follows. A cognitive or motor task in the brain is accomplished by interaction between a number of nodes. This interaction is at the level of neural activity and therefore takes place at the millisecond time scale. DCM models these neuronal interactions. However, except for invasive recording studies (e.g., Moran et al., 2008), we cannot directly observe neuronal activity, but only some consequence of it, such as a hemodynamic BOLD signal or an EEG signal measured at scalp sensors. For this reason, DCM combines a model of neuronal dynamics with a biophysical forward model that explains how the hidden neuronal activity translates into a measured signal (Kiebel, David, & Friston, 2006; Friston, Mechelli, Turner, & Price, 2000; Stephan, Weiskopf, Drysdale, Robinson, & Friston, 2007). The incorporation of the biophysical model allows inferences to be made from coarsely sampled BOLD time series about neuronal events occurring at a much finer time scale. With respect to auditory functional MRI, many experiments, including our experiment on spectral envelope analysis above, are based on “sparse” designs to avoid the effect of simultaneous scanner noise on the effects of interest. Despite the sampling rate for “sparse” BOLD time series approaching 0.1 Hz, plausible models of dynamic neural interactions at the millisecond level can still be disambiguated, given the fMRI data. This is because the forward model predicts, given the known experimental inputs, what the BOLD signal should look like at any future time point, including the times when BOLD measurements were taken; the sampling frequency (repetition time) is irrelevant.

Like any model, DCM comprises variables (that may or may not be measurable) and parameters that are estimated from the measurements. The model that is used in DCM has three types of variables: input variables (the same as those used in conventional analyses based on the general linear model, or GLM), encoding the experimental manipulation; output variables that are the regional hemodynamic responses from each of the regions considered in the model; and state variables. State variables describe the “hidden” (unobserved) states of the system and represent the neural activity and biophysical variables (e.g., blood flow) that transform neural activity into a hemodynamic response. DCM uses three different sets of parameters: endogenous parameters that model the baseline connection strengths between the regions in the absence of any external excitation

of the system, modulatory parameters that model the change in endogenous connection strength induced by the external experimental input, and a third set of parameters that model the direct influence of an exogenous stimulus on a given region. The conventional GLM analysis is based on the assumption that any exogenous stimulus has a direct influence on a region and therefore it is the third set of parameters that form the primary focus of traditional GLM analyses. DCM, therefore, can also be regarded as a generalization of the GLM in which coupling parameters between regions are allowed to be nonzero.

Once the model has been specified, it has to be estimated from the measurements. There are, however, some natural constraints on the model; for example, the neural activity of a region cannot diverge to infinity. One framework for estimating the parameters with prior constraints is Bayesian statistics, in which a parameter is treated as a random variable that is completely characterized by its probability density (distribution) function. The prior constraints about the parameters are specified in terms of a (prior) density function. Bayesian estimation procedures estimate the parameters in terms of their posterior density function.

For fMRI, DCM is based on a bilinear model of neural population dynamics that is combined with a hemodynamic model (Buxton, Wong, & Frank, 1998; Friston et al., 2000), describing the transformation of neural activity into predicted BOLD responses. The neural dynamics are modeled by the following bilinear differential equation

$$\frac{dz}{dt} = Az + \sum_{j=1}^m u_j B^{(j)} z + Cu \quad (1)$$

where z is the state vector (with one state variable per region), t is continuous time, and u_j is the j th input (i.e., some experimentally controlled manipulation). This state equation represents the strength of connections between the modeled regions (the endogenous A matrix), the modulation of these connections as a function of experimental manipulations (e.g., changes in task; the modulatory or bilinear $B^{(1)} \dots B^{(m)}$ matrices), and the strengths of direct inputs (e.g., sensory stimuli, the exogenous C matrix). These parameters correspond to the rate constants of the modeled neurophysiological processes. Combining the neural and hemodynamic model into a joint forward model, DCM uses a Bayesian estimation scheme to determine the posterior density of the parameters. Under Gaussian assumptions, this density can be characterized in terms of its maximum a posteriori estimate and its posterior covariance. The parameters of the neural and hemodynamic model are fitted such that the modeled BOLD signals are as similar as possible to the observed BOLD responses. This allows one to understand and make statistical inferences about regional BOLD responses in terms of the connectivity at the underlying neural level.

We used DCM in this way to identify the system for object analysis in the case of spectral envelope analysis shown in figure 25.7 (Kumar, Stephan, Warren, Friston, & Griffiths, 2007). In that experiment, activation during sound perception was seen in the primary and secondary areas in HG and association cortex in the PT. A contrast to show activity corresponding to the perception of object change identified bilateral activity in PT and right-lateralized activity in STS. DCM was used to identify the system that explains the pattern of activity in HG, PT, and the STS in the right

temporal lobe. A critical question is whether analysis in PT and STS occurs in a serial fashion, based on connections from HG to PT and from PT to STS, or whether the analysis is based on parallel processing due to connections from HG to both PT and STS. The analysis also addressed how connection strengths between elements of this cortical network are modulated during the spectral envelope analysis.

To test these hypotheses, two broad categories of models, serial and parallel, were specified (figure 25.10). All the models specified were based on the conventional assumption

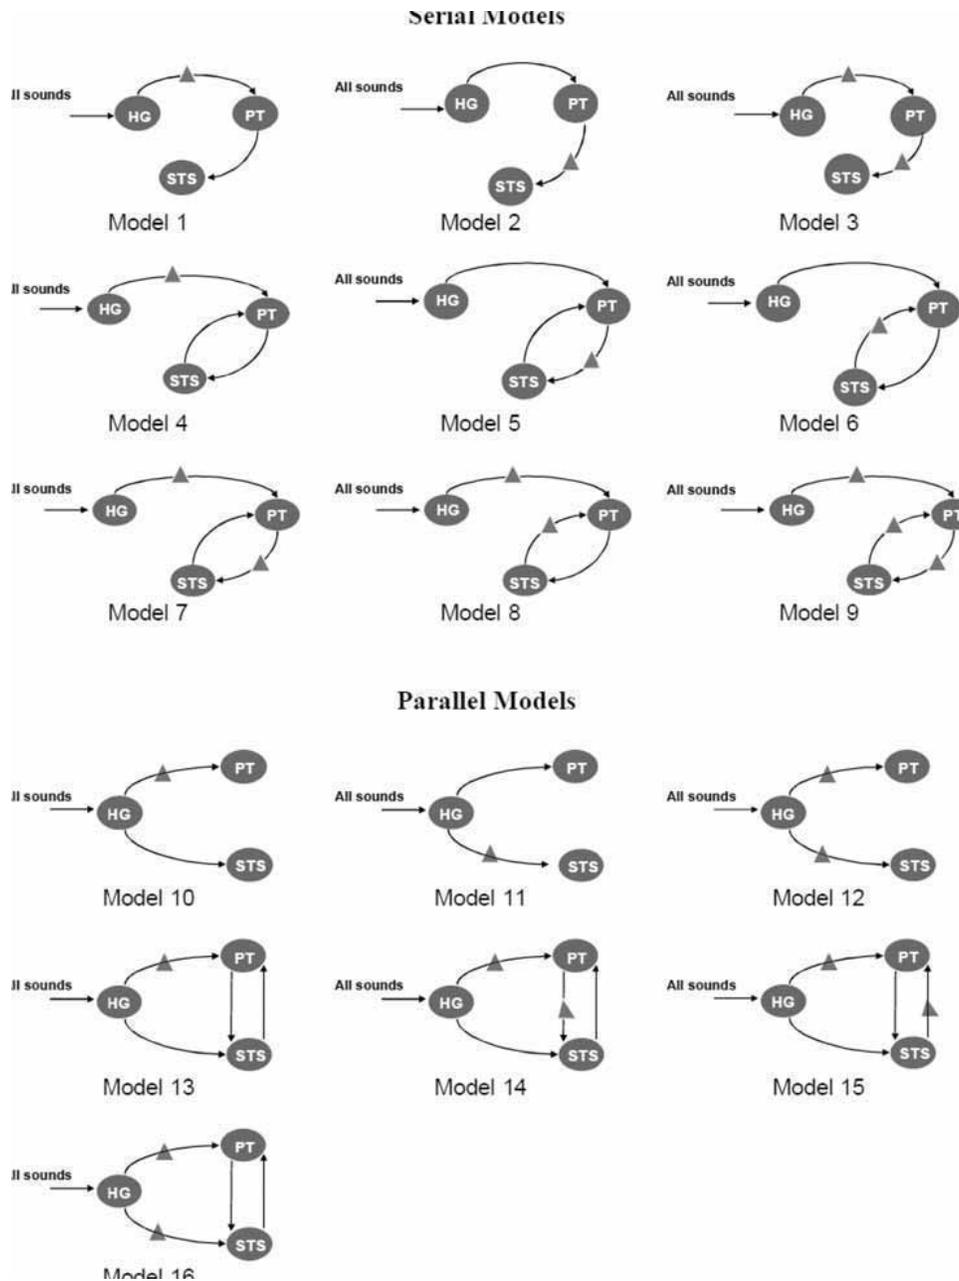

FIGURE 25.10 Serial and parallel models for spectral envelope analysis in the right hemisphere. The triangle in the pathway between two regions indicates the modulatory effect of extraction

of spectral envelope (Kumar et al., 2007). HG, Heschl's gyrus; PT, planum temporale; STS, superior temporal sulcus.

that there is a direct or exogenous effect of the sound input on the activity within the primary auditory cortex within HG. In the serial models, auditory inputs entering HG reach STS via PT and thus processing in STS depends on inputs from PT. In contrast, in the parallel models, HG connects to both PT and STS enabling parallel processing in PT and STS. In total, 70 models were fitted to the data (16 of which are shown in figure 25.10) and compared by using Bayesian model selection. It should be noted that the DCM approach developed below might yield a “best” model that is not a “true” model if the set of models tested does not include the latter. It is critical in DCM, therefore, to consider all possible models in a systematic and inclusive way. Even for a simple serial and parallel comparison for three areas, as here, there are a large number of models when all the possible forward and back projections and the possible sites of modulatory effect are taken into account.

A general problem that arises in any modeling exercise is to decide, given a measured data set, which of several competing models is the optimal. A number of criteria for selecting the optimal model have been proposed in the modelling literature (Burnham & Anderson, 2004). The optimal criterion is the model evidence, defined as the probability $p(y|m)$ of obtaining the data y given a particular model m (Raftery, 1995). Critically, the model evidence takes into account not only the relative fit of competing models but also their relative complexity, determined by the number of free parameters. This is important because there is a tradeoff between the fit of a model and how well it might generalize—in other words, how well it explains different data sets generated from the same underlying process. As the number of free parameters is increased, model fit increases, whereas beyond a certain point, the ability of the model to generalize decreases. The reason for this is overfitting: An increasingly complex model will, at some point, start to fit noise that is specific to one data set and thus become less applicable to multiple realizations of the same underlying generative process.

Because the model evidence cannot always be derived analytically, two commonly used approximations to it are Akaike information criterion (AIC) and Bayesian information criterion (BIC) (Penny et al., 2004). These approximations do not necessarily give identical results because BIC favors simpler models, whereas AIC is biased toward more complex models. A general convention is that if two models (say, m_1 and m_2) are to be compared, then a decision is made only when AIC and BIC concur. In either case, the relative evidence of one model as compared to another is determined by the Bayes factor:

$$BF_{12} = \frac{p(y|m_1)}{p(y|m_2)} \quad (2)$$

where BF_{12} is the Bayes factor of model 1 with respect to 2. Following the selection of a best model for each individual

subject, the optimal model for a group of subjects can be determined by the group Bayes factor (GBF), which is equal to the product of the Bayes factors for each individual subject.

Figure 25.11 shows the evidence for the models, determined separately by using AIC and BIC, in a group of eight subjects. Model 1 is the optimal model to explain the data. The parameters for this model specify a serial model with connectivity (HG → PT → STS) and modulation of connection from HG to PT during the analysis of spectral envelope. Table 25.1 shows the group Bayes factor (minimum of the two values computed using AIC and BIC) for model 1 with respect to the other 15 models. All the values are greater than 150, corresponding to strong evidence in favor of model 1 (Raftery, 1995). Estimates were derived for the endogenous and modulatory connection strengths (tables 25.2 and 25.3) of the optimal model and the posterior probabilities that the parameter estimates were greater than zero.

In anatomical terms, effective connectivity could be direct or could occur via a relay, but there must be a structural mediation. Data about anatomical connections between human auditory areas are lacking; there are data showing connections between HG and PT (Tardif & Clarke, 2001), but we are not aware of any data on connections from PT to STS predicted by the model. The basis for the modulatory connection deserves comment. This suggests a change in the connection strength between HG and PT during spectral envelope analysis. This model predicts a selective sensitization of PT to HG afferents that occurs specifically during spectral envelope analysis. In this way, HG acts like a “hidden node” in the system that is not demonstrated in univariate tests for increased activity during spectral envelope abstraction but does have a causal influence on activity in PT during that process.

The model has limitations and should not be regarded as a general synthesis of all aspects of object analysis. Broadly, the existence of a serial model is in accord with the concept of a single pathway for auditory object analysis and supports the concept of PT as a critical “computational hub” (Griffiths & Warren, 2002) at the interface between the abstraction of auditory object properties and further analysis in distinct higher centers for object analysis that also carry out semantic level processing. It should be emphasized that the approach taken here addresses the simplest level of perceptual analysis when the subject is required to attend to the sounds but does not carry out any object-relevant task or semantic level analysis. It will be of considerable interest to examine the effects of task and semantic analysis on connectivity patterns. A number of questions arise, including whether these levels of processing are associated with modulation at later stages of the system (the connection between PT and STS) or additional back connections.

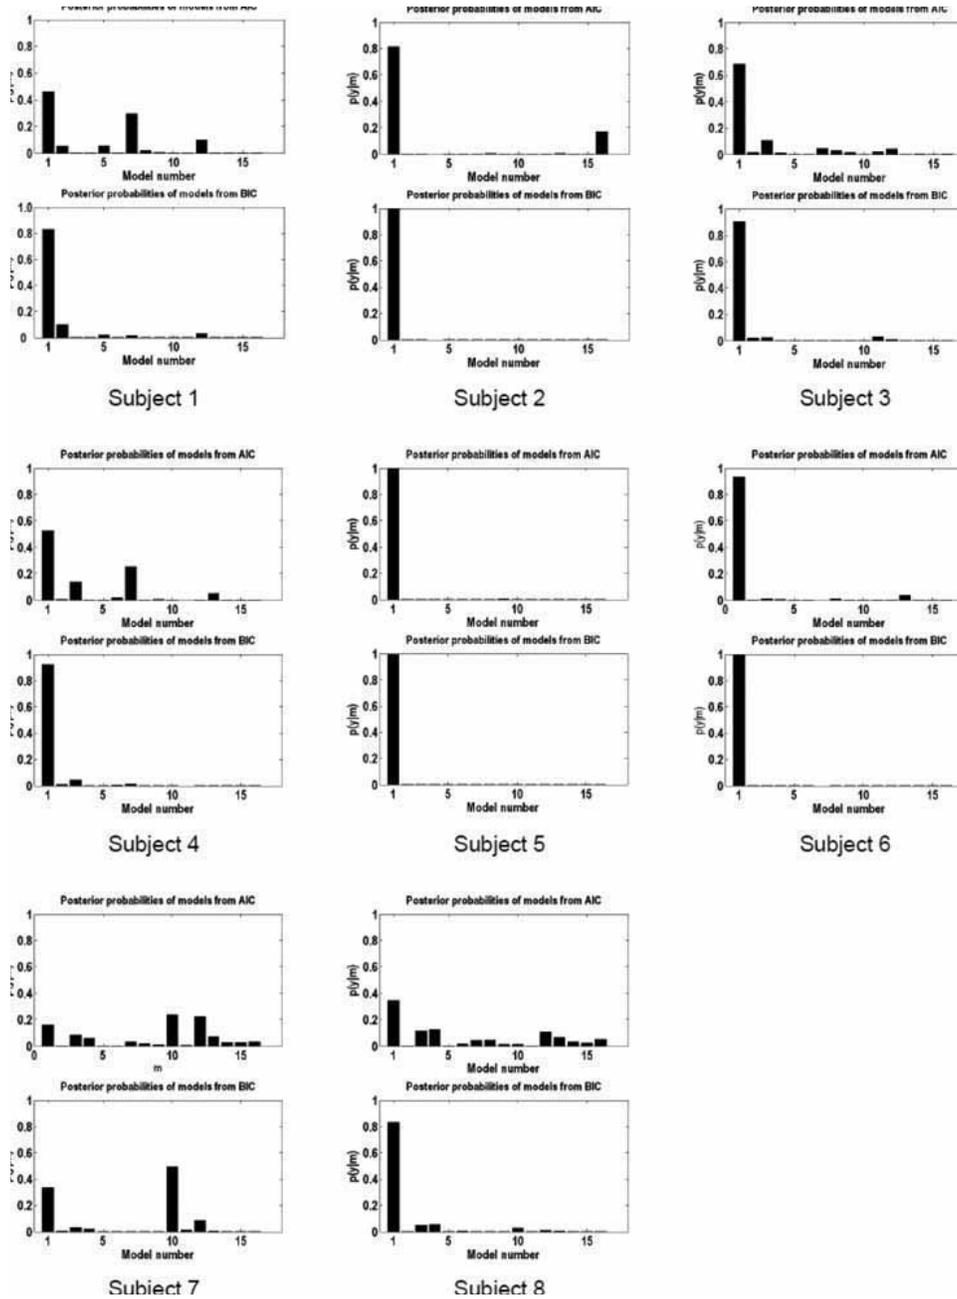

FIGURE 25.11 Evidence for different models. Plots of probabilities $p(y|m)$ for 16 of the models assessed using dynamic causal modeling. The probabilities have been normalized so that they sum to 1. The probabilities represent the probability of the model, given the

data, assuming that each model is, a priori, equally likely (Kumar et al., 2007). AIC, Akaike information criterion; BIC, Bayes' information criterion.

Conclusions

The analysis of auditory objects involves a number of different cognitive stages and the term is often used without precision. This synthesis has emphasized functional MRI, but similar approaches can allow inference about stages of object analysis using a number of other techniques, including single-unit recording, EEG, and MEG. The work described

here demonstrates that the fundamental level of abstraction of the salient features that define objects, and generalization between them requires specific mechanisms in the superior lateral temporal lobe. Systems identification techniques allow the analysis of specific networks for object perception and have the potential to disambiguate different aspects of auditory object analysis that might use the same computational nodes in different ways.

TABLE 25.1
Group Bayes' factor for the optimal model (serial model 1)

Model 1 Versus	Group Bayes Factor
2	8.65×10^3
3	4.40×10^2
4	1.06×10^7

TABLE 25.2
Endogenous connection strengths (Hz) for the optimal model (serial model 1)

Subject Number	HG to PT	PT to STS
1	0.54 (0.99)	0.71 (1.0)
2	0.41 (1.0)	0.26 (1.0)
3	0.35 (0.99)	0.41 (1.0)
4	0.49 (1.0)	0.82 (1.0)
5	0.48 (1.0)	0.07 (0.91)
6	0.49 (1.0)	0.52 (1.0)
7	0.10 (1.0)	0.44 (1.0)
8	0.16 (1.0)	0.60 (1.0)

Numbers in parentheses indicate the posterior probability that connection strength is greater than zero.

TABLE 25.3
Strength of the modulation of the HG → PT connection during spectral envelope analysis

Subject Number	HG to PT	Percent Change
1	0.16 (0.91)	29.4
2	0.54 (1.0)	130
3	0.37 (0.99)	105
4	0.55 (0.99)	113
5	0.26 (1.0)	53.4
6	0.62 (1.0)	125
7	0.13 (0.98)	130
8	0.29 (0.99)	187

Numbers in parentheses indicate the posterior probability that the modulatory strength is greater than zero. The third column is the percent increase in coupling during spectral envelope analysis (the change in the intrinsic connection strength in Table 25.2).

ACKNOWLEDGMENTS T.D.G., S.K., T.O., K.E.S., and K.J.F. are supported by the Wellcome Trust (U.K.) and KvK was supported by the VW Foundation (Germany) and is supported by the Wellcome Trust (U.K.). The ideas developed here were informed by argument with the contributors to a Novartis Foundation discussion meeting on auditory objects in London in 2007. The acoustic size experiments were acquired in collaboration with R. D. Patterson. J. D. Warren (Dementia Research Centre, University College London) acquired the imaging data related to spectral envelope analysis and was involved in the development of a number of the ideas described here.

26 The Cone Photoreceptor Mosaic in Normal and Defective Color Vision

JOSEPH CARROLL, GEUNYOUNG YOON, AND DAVID R. WILLIAMS

ABSTRACT Visual experience is initiated by photons captured in the photoreceptors. The arrangement of these photoreceptors—their topography—limits how we see and sets the stage for how the circuitry in the retina and brain operates. Four different classes of cells are interleaved in the photoreceptor layer of the retina: the rods and three spectral subtypes of cone that form the basis for trichromatic color vision, the long-, middle-, and short-wavelength-sensitive cones (L, M, and S, respectively). A great deal is understood about how the presence of three spectral cone types limits color perception; however, until recently, considerably less had been known about the spatial arrangement of these cone types and how their topography influenced visual experience. Recently, new methods have been developed that enable us to measure the spatial arrangement of cone photoreceptors in the living human eye. These new measurements have produced surprising results that answer some questions about color appearance but raise many others. In this chapter, we review the current understanding of the cone mosaic in normal and defective color vision, emphasizing recent results derived from adaptive optics retinal imaging.

Photoreceptor mosaic in normal color vision

A wealth of histological data are available describing the overall topography of the human photoreceptor mosaic. The most comprehensive data come from Curcio, Sloan, Kalina, and Hendrickson (1990), who showed that while there are gross topographical features of the mosaic that are common across different retinas, there is also considerable variability. For example, as is shown in figure 26.1, the relative rod:cone density varies dramatically across the retina, and this general feature is well preserved in all human retina that have been studied to date. However, Curcio and colleagues (1990) found that the peak foveal cone density varied by at least a factor of 3, though since the data were obtained on postmortem tissue, it was not possible to determine whether such differences had any practical impact on visual

function. As we move outward from the center of the fovea (where peak cone density occurs), cone density falls off precipitously until the ora serrata, where there is a significant elevation in cone density (R. W. Williams, 1991).

Using adaptive optics to image the foveal cone mosaic, Putnam and colleagues (2005) observed that the location of peak cone density does not correspond to the preferred retinal locus of fixation; thus there remains ambiguity about the difference between the anatomical fovea and the “functional” fovea. Shown in figure 26.2 are data from three subjects, showing the location of peak cone density with respect to the retinal locus of fixation on individual psychophysical trials. While fixation is in general very accurate, as is shown by the tight cluster of fixation points, there is a systematic deviation from the location of peak cone density. If visual acuity is reciprocally related to cone spacing near the fovea (cf. Green, 1970; Marcos & Navarro, 1997), acuity would have declined by an average of 8% for the subjects in figure 26.2 at the center of fixation compared with the anatomic center of the fovea. This is a relatively small loss in acuity that would be difficult to measure, owing to blurring by the eye’s optics, which reduces foveal visual acuity below the cone Nyquist frequency (Marcos & Navarro, 1997). Recent work using adaptive optics to image the cone mosaic of individuals with red-green color vision defects reveals severely disrupted mosaics but normal visual acuity measured with a letter target (Carroll, Neitz, Hofer, Neitz, & Williams, 2004). This further illustrates the insensitivity of standard acuity measures and advocates using interference fringe stimuli that are immune to optical blur to probe the absolute relationship between the cone mosaic and visual acuity.

The human foveal cone mosaic is an efficiently packed mosaic, with the locations of cone centers forming a triangular array. Interleaved within the overall cone mosaic are the three spectral cone submosaics (short-, middle-, and long-wavelength-sensitive; S, M, and L). Since only one spectral type of cone occupies any given location within the cone mosaic, there is an apparent confound as to how the

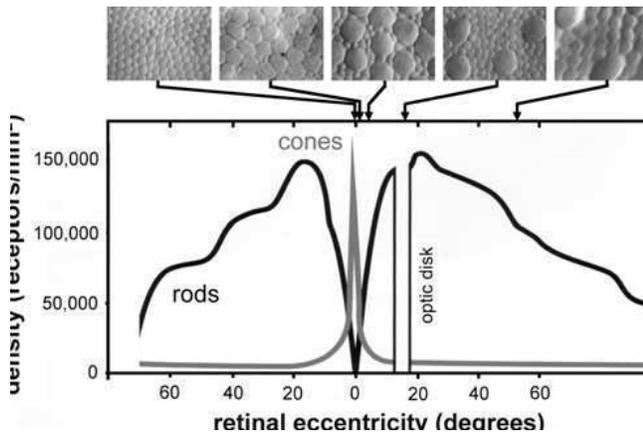

FIGURE 26.1 Nonuniform distribution of rods and cones in the human retina. Plot of photoreceptor density as a function of retinal eccentricity. The top panels show ex vivo images of the photoreceptor mosaic from Curcio, Sloan, Kalina, and Hendrickson (1990). The leftmost image is from the all-cone fovea; the remaining panels contain both rods (smaller cells) and cones (larger cells). While rod density increases dramatically in the peripheral retina, rod diameter remains relatively constant (about 2 μm). Conversely, the cone photoreceptors increase from about 2 μm in diameter at the fovea to about 8 μm at about 10 degrees eccentricity, after which point they remain relatively constant (Samy & Hirsch, 1989). (Modified from Webvision (<http://webvision.med.utah.edu>), with permission.) (See color plate 33.)

visual system is able to reliably extract color information at all spatial locations within an image. As such, the precise arrangement of these spectral subtypes has been of great interest, and we discuss the S, M, and L cone mosaics below.

S CONE MOSAIC: STRUCTURAL ORGANIZATION The S cones can easily be distinguished from L and M cones by morphological and histochemical features (Ahnelt & Kolb, 2000; Cornish, Hendrickson, & Provis, 2004; de Monasterio, Schein, & McCrane, 1981; Szel, Diamanstein, & Rohlich, 1988). They are more cylindrical in shape (Curcio et al., 1991), have distinct neural circuitry (Mariani, 1984) and synaptic structure (Ahnelt & Kolb, 2000), and contain a photopigment that is distinct from that found in the L/M cones (Bowmaker & Dartnall, 1980; Nathans, Thomas, & Hogness, 1986). The S cones are relatively sparse throughout the human retina (averaging about 6–8% of the total cone population), with peak density (usually about 10% of the local cone number) occurring near 1-degree eccentricity (Curcio et al., 1991). An interesting feature of the S cone submosaic is that the very central fovea is lacking S cones (König, 1894; Willmer & Wright, 1945; D. R. Williams, MacLeod, & Hayhoe, 1981a, 1981b). The extent of this S cone free zone is about 20 degrees of arc in diameter, though the size and even existence of this area are variable across individuals. In humans, the S cone mosaic is randomly

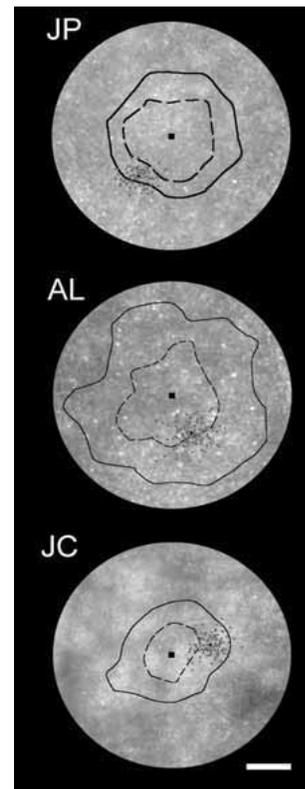

FIGURE 26.2 The area of highest cone density is not always used for fixation. Shown are retinal montages of the foveal cone mosaic for three subjects. The black square represents the foveal center of each subject, as defined by the location of peak cone density. The dashed black line is the isodensity contour line representing a 5% increase in cone spacing, and the solid black line is the isodensity contour line representing a 15% increase in cone spacing. Red dots are individual fixation locations. Scale bar is 50 μm . (Reproduced from Putnam et al., 2005, with permission.) (See color plate 34.)

interleaved among the L/M mosaic near the fovea but becomes regularly arranged at more peripheral locations. A number of questions surrounding the S cone mosaic remain, such as why the arrangement of the mosaic is different in nonhuman primates, what the variability is across subjects, and what molecular mechanisms govern the nonuniform placement of S cones within the human retina.

S CONE MOSAIC: FUNCTIONAL CONSEQUENCES It has long been believed that the S cone mosaic is sparser than the other L and M cones because the retinal image quality that is available to the S cones is reduced by the eye's chromatic aberration (Packer & Williams, 2003; D. R. Williams et al., 1981a, 1981b; Yellott, Wandell, & Cornsweet, 1984), although this interpretation is controversial. McLellan, Marcos, Prieto, and Burns (2002) concluded that when monochromatic aberrations are taken into account, chromatic aberration does not, in the average eye, degrade the retinal image quality of the S cones. However, there is theoretical and experimental evidence that the role of

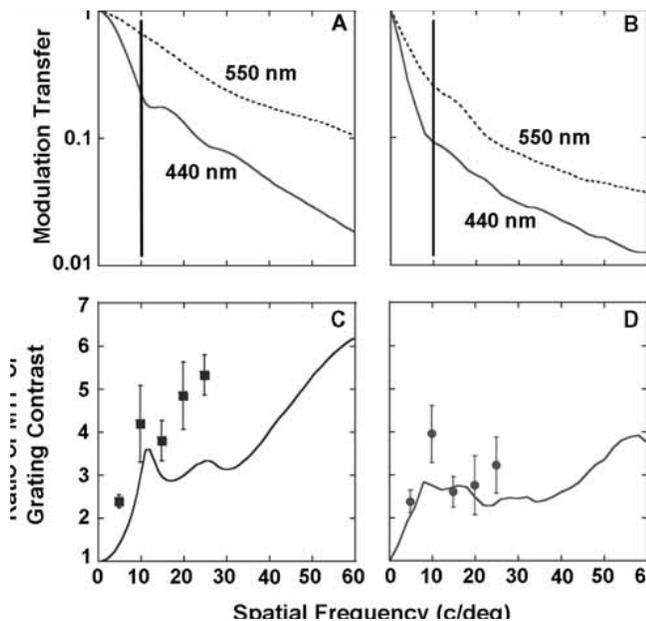

FIGURE 26.3 Chromatic aberration degrades the retinal image quality of the S cone submosaic. (A, B) Modulation transfer functions at 440 nm (solid line) and 550 nm (dashed line) computed with the measured aberrations for a 3-mm (A) and 6-mm (B) pupil. Nine wavefront measurements were made on each eye, and the average modulation transfer function (MTF) was calculated. The average root mean square wavefront errors (from second to fifth order without defocus) for the 3- and 6-mm pupil size were $0.2 \pm 0.11 \mu\text{m}$ and $0.82 \pm 0.23 \mu\text{m}$ (mean \pm standard deviation), respectively. The amount of defocus was adjusted for each subject to maximize the modulation transfer of a 550-nm grating with a 15 cycle/degree spatial frequency. To compute the MTF of a 440-nm grating, we added 1.0 diopter of defocus induced by longitudinal chromatic aberration when the eye was focused at 550 nm. The Nyquist limit for the S cones is shown as a vertical line at 10 cycles/degree. (C, D) Solid lines show the ratio of the MTF at 550 nm to that at 440 nm for 3- and 6-mm pupils, respectively. The symbols show matching data from the psychophysical experiment. They represent the ratio of the fixed contrast (50%) of the 440-nm grating to the contrast of the 550-nm grating that matched it in subjective contrast. The error bars in the experimental data represent ± 1 standard error.

chromatic aberration does, in fact, substantially degrade the retinal image quality available to S cones.

We calculated modulation transfer functions (MTFs) from the wavefront aberrations of five normal subjects measured with a conventional Shack-Hartmann wavefront sensor. Figures 26.3A and 26.3B show the average of the horizontal and vertical MTFs. For both pupil sizes, retinal image quality at 550 nm is significantly better than that at 440-nm grating across all spatial frequencies. The difference between the MTFs for 440 nm and 550 nm is smaller for a larger pupil, indicating that the impact of chromatic aberration becomes less dominant when the magnitude of the monochromatic aberrations increases with an increase in pupil size. However, the MTF at 440 nm remains approximately three times on

average lower than the 550-nm MTF up to 60 cycles per degree (cpd). Similar conclusions follow from calculations of the overall contrast of the retinal image in white light for each of the three cone classes (Packer & Williams, 2003).

We performed a psychophysical experiment to verify the MTFs. The same subjects matched the perceived contrast of two gratings of equal luminance. In each half of a 1.5-degree visual field, a sinusoidal grating with the same spatial frequency was simultaneously viewed in a split field with 440-nm and 550-nm light with paralyzed accommodation. The subject maximized contrast of a 15 cpd sinusoidal grating in the 550-nm half of the field. Contrast matching of the 550-nm grating to the 440-nm grating with 50% contrast was subjectively performed at each of five different spatial frequencies presented in random order. At each experimental condition, four trials were conducted for both horizontal and vertical gratings and were averaged.

Figures 26.3C and 26.3D show the ratios of the MTF at 550 nm to those at 440 nm and the contrast of the 440-nm grating to the matched contrast of the 550-nm grating. If the contrast of the 440-nm grating were decreased by chromatic aberration, this ratio would be larger than 1 because subjects would need to reduce the contrast of the 550-nm grating to match that of the 440-nm grating blurred by chromatic aberration. In agreement with the ratios computed from the MTFs, the subjective contrast of the 440-nm grating was decreased by a factor of approximately 3 (6-mm pupil) and 4 (3-mm pupil) on average compared to the 550-nm grating. All five subjects reported a reduction in subjective contrast of the 440-nm grating at all spatial frequencies. Because 440-nm and 550-nm gratings differ in color, it was conceivable that neural factors, rather than chromatic aberration, were responsible for the selective subjective blur of short-wavelength gratings. Therefore the experiment was repeated in two subjects with 540-nm and 420-nm gratings chosen to minimize differential activation of L and M cones. Moreover, differential S cone contribution was greatly reduced by superimposing the gratings on a steady violet background. With this method, both sides of the field appeared blue, with almost no discernable color difference. Nonetheless, a large reduction in contrast of the 420-nm grating relative to the 540-nm grating persisted, consistent with a largely optical rather than a neural effect. Our experimental and theoretical results both confirm that the eye's chromatic aberration causes a substantial decrease in retinal image quality even when the eye's wavefront aberration contains large amounts of higher-order aberrations. Contrary to the conclusions of McLellan and colleagues (2002), the blur produced by chromatic aberration is substantial despite the diluting effect of the monochromatic aberrations, consistent with the widely accepted explanation for the sparseness of the S cone submosaic. At 1-degree eccentricity, the S cone mosaic has a Nyquist limit that is approximately 4.1 times less than that

of the M/L cones (Curcio et al., 1991; Hofer, Carroll, Neitz, Neitz, & Williams, 2005; Roorda & Williams, 1999). For a 3-mm pupil, the spatial bandwidth of the 550-nm MTF is about 3.2 times greater than that for the 440-nm MTF, showing that the relationship between optical quality and sampling is not very different for the S cones and the M and L cones.

LAND M CONE MOSAIC: STRUCTURAL ORGANIZATION There is no antibody that can distinguish L cones from M cones; this is because the photopigments they contain are 96% identical (Nathans, Thomas, & Hogness, 1986). As such, much of what we know about the L/M submosaic has come from indirect measurements of the retina. Recent direct work using adaptive optics and molecular analyses has for the most part confirmed previous results, though it has uncovered surprising levels of variation within this mosaic.

Given that they make up about 95% of the total cone population and thus drive the majority of our visual activity, there has been considerable interest in the L and M cones, both in their relative numbers (Carroll, Neitz, & Neitz, 2002; DeVries, 1946; Dobkins, Thiele, & Albright, 2000; Jacobs & Neitz, 1993; Kremers et al., 2000; Pokorny, Smith, & Wesner, 1991; Roorda & Williams, 1999; Rushton & Baker, 1964) and in their topographical arrangement throughout the mosaic (Balding, Sjöberg, Neitz, & Neitz, 1998; Bowmaker, Parry, & Mollon, 2003; Deeb, Diller, Williams, & Dacey, 2000; Hagstrom, Neitz, & Neitz, 1998; Knau, Jägle, & Sharpe, 2001; Mollon & Bowmaker, 1992; Packer, Williams, & Bensinger, 1996; Roorda, Metha, Lennie, & Williams, 2001). For many years, scientists used indirect measures to assess the homogeneity of these ratios across the retina and across observers. With the advent of adaptive optics, it has become possible to examine the L/M mosaic noninvasively and directly. What is now clear is that in humans with normal color vision, there are on average two L cones for every M cone, there is variability in the relative numbers of L and M cones between people, and the ratio of L to M cones is not completely uniform across an individual retina.

While most studies suggest that the ratio of L to M cones is probably constant across the central retina, the evidence for this is somewhat inferential. In fact, direct evidence from adaptive optics and retinal densitometry has shown that in at least one individual, the relative numerosity of L and M cones is not homogenous across the central retina (Hofer et al., 2005). However, there are other, larger-scale inhomogeneities in the primate L/M mosaic. There is a nasal-temporal asymmetry in the local L-to-M cone ratio in macaque retina, though whether this asymmetry is a prominent feature of human retinae is not clear. Data from mRNA analysis and cone isolating mfERG of human retina reveal that the relative L-to-M cone ratio increases significantly in

the peripheral retina, reaching nearly an all L cone mosaic at the edge of the retina (M. Neitz, Balding, McMahon, Sjöberg, & Neitz, 2006). Shown in figure 26.4 is a topographical map of L-to-M mRNA, revealing the dramatic and systematic variation across the retina.

As was mentioned above, numerous indirect studies have suggested that there are on average about twice as many L cones as M in the human retina, with large intersubject variability. Direct information on the numbers and locations of L, M, and S cones obtained with spatially localized retinal densitometry in 10 living human subjects reveals the extent of this variability in L-to-M cone ratio across individuals with normal color vision to be over a 40-fold range (Hofer et al., 2005). Shown in figure 26.5 are pseudo-colored images of the human cone mosaic, showing the remarkable variation in L-to-M cone ratio. Also evident from these images is the fact that the L and M cone submosaics are randomly interleaved.

LAND M CONE MOSAIC: FUNCTIONAL CONSEQUENCES In the face of the dramatic intersubject and intrasubject variation in the L-to-M cone mosaic, questions arise regarding the behavioral consequence of such variability. The fundamental experiment in color vision, color matching with spatially uniform fields, is very sensitive to the spectral absorbance of the cone photopigments but invariant with respect to the local ratio of cone types. Thus both across observers and across visual field position for a single observer, color matches will be preserved despite variations in the ratios of cone types. There are pronounced deficits in L/M color vision in the periphery compared to the central retina (Gordon & Abramov, 1977; Mullen, 1991); however, this has more to do with postreceptoral sampling than with L/M numerosity. Even the variation in L-to-M ratio between subjects has been shown to have little consequence for color vision, despite previous hypotheses (cf. Cicerone, 1987). For example, Miyahara, Pokorny, Smith, Baron, and Baron (1998) showed that in two female carriers of a red/green color vision defect, despite a dramatic skew in their L-to-M cone ratio, their red/green color vision was completely normal. J. Neitz, Carroll, Yamauchi, Neitz, and Williams (2002) used the flicker photometric ERG to probe L-to-M ratio in over 60 individuals and showed that that wavelength of unique yellow (the presumed null point of the red-green system) did not change across subjects, suggesting a postreceptoral normalization mechanism that compensates for any biases in L-to-M cone ratio. The reality is that the human visual system is quite resilient to variation at the retinal level, though this is obviously dependent on the sensitivity of the test used to probe color vision.

The fact that the three cone submosaics each sample the retinal image at a lower rate than the overall mosaic makes the retina susceptible to aliasing at lower spatial frequencies

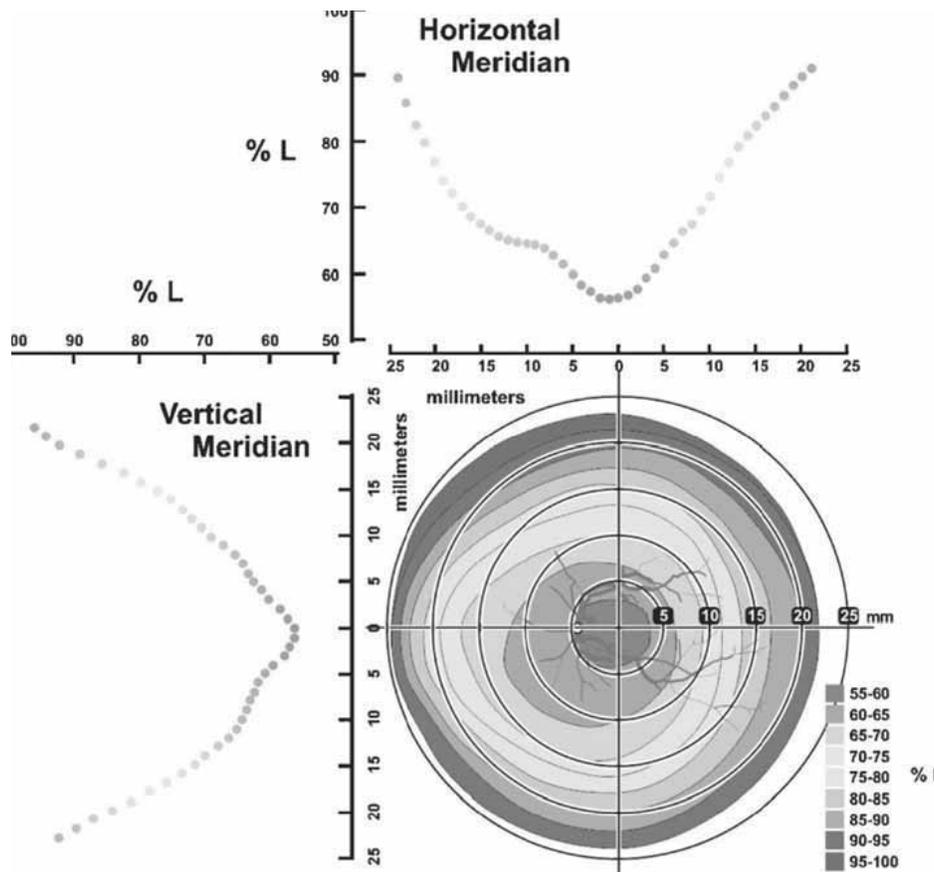

FIGURE 26.4 The L-to-M cone ratio is not constant across the retina. The lower right panel shows a topographical map of the percent of L-opsin mRNA in a human donor retina. The proportion of L-opsin to M-opsin mRNA is directly related to the relative numbers of L and M cones at a locus, assuming that L and M cones

produce the same absolute amounts of mRNA. Horizontal and vertical meridian slices show the dramatic increase in percent of L as a function of eccentricity. (Reproduced from Neitz et al., 2006, with permission.) (See color plate 35.)

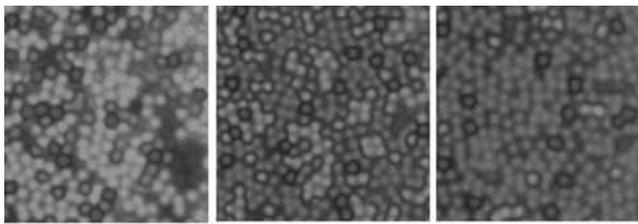

FIGURE 26.5 Intersubject variation in L-to-M cone ratio. False color images showing the arrangement of L (red), M (green), and S (blue) cones in the retinas for three human subjects. The identity of each cone as L, M, or S was inferred from retinal densitometry measurements obtained with an adaptive optics fundus camera. The proportion of S cones does not vary significantly between subjects; however, the L-to-M cone ratio can vary by a factor of 40 across individuals with normal color vision. Scale bar is 5 arcmin. (See color plate 36.)

than would be expected from a monochrome mosaic with the same total number of cones. The aliases that are produced by the cone submosaics exposed to luminance patterns would be expected to be strongly chromatic. It is possible to observe submosaic aliasing with high-frequency

achromatic gratings seen through the S cones (D. R. Williams & Collier, 1983) and the L and M cones (D. R. Williams, Sekiguchi, Haake, Brainard, & Packer, 1991). However, submosaic aliasing is fleeting and subtle in visual experience, contrary to the predictions of simple sampling and interpolation models. This suggests that the visual system must have a more sophisticated mechanism to expunge submosaic aliasing from visual experience. Brainard, Williams, and Hofer (2008) have suggested that well-known features of human color and spatial vision may play a role in reducing submosaic aliasing. Specifically, the spatial bandwidth of postreceptoral chromatic mechanisms is lower than that of the achromatic mechanism (Mullen, 1985; Poirson & Wandell, 1993), and this difference persists even when optical blurring and chromatic aberration are eliminated with laser interferometry (Sekiguchi, Williams, & Brainard, 1993a, 1993b). This difference reduces submosaic aliasing by suppressing chromatic interpretations of high spatial frequencies in the retinal image. There is additional evidence for spatial averaging of color information with suprathreshold stimuli (Cao & Shevell, 2005), collectively referred to as

assimilation, that is qualitatively similar to the reduced spatial bandwidth for chromatic mechanisms assessed at detection threshold. It is possible that assimilation effects occur because of the need to protect against submosaic aliasing, though a quantitative model of the benefits assimilation could provide has yet to be made.

Cone topography in inherited color vision deficiencies

There are a number of instances in which normal color discrimination is impaired, and there is now a detailed understanding of the molecular mechanisms underlying these defects. Nearly all inherited color vision defects have their origin in a disruption of normal cone photopigment expression; either a cone pigment is absent or a mutant pigment is expressed. Until recently, little attention had been given to the residual photoreceptor mosaic of these individuals. Results using adaptive optics retinal imaging have stimulated a reevaluation of the ideas about what the appearance of these mosaics might be. Here, we review the four major types of inherited color deficiencies and discuss what has been revealed about the accompanying cone photoreceptor mosaic.

TRITANOPIA Tritan color vision deficiency is an inherited autosomal dominant abnormality of S cone function (Wright, 1952). The disorder is reported to exhibit incomplete penetrance, meaning that individuals with the same underlying mutation manifest different degrees of color vision impairment (Cole, Henry, & Nathan, 1966; Kalmus, 1955; Miyake, Yagasaki, & Ichikawa, 1985; Pokorny, Smith, & Went, 1981; Went & Pronk, 1985). Four different amino acid substitutions in the S cone photopigment have been associated with tritanopia, which is only slightly more rare than autosomal dominant retinitis pigmentosa (adRP) (Gunther, Neitz, & Neitz, 2006; Weitz et al., 1992; Weitz, Went, & Nathans, 1992). Each substitution occurs at an amino acid position that lies in one of the transmembrane alpha helices of the protein and is therefore expected to interfere with folding, processing, or stability of the encoded opsin.

In adRP, rod photopigment mutations are associated with degeneration of the associated photoreceptors. This is due in part to the fact that the photopigment plays such an important structural role in maintaining the integrity of the outer segment, comprising nearly 90% of the protein in the outer segment. To investigate whether there is S cone degeneration in autosomal dominant tritan defects, Baraas and colleagues (2007) examined two related tritan subjects (a 57-year-old male and his 34-year-old daughter) both heterozygous for a novel mutation in their S-opsin gene. The mutation resulted in a substitution of glutamine for arginine at position 283 (R283Q). Given the sensitive microenviron-

ment of the photopigment, the substitution of a polar, neutral amino acid for a positively charged one would be expected to compromise the function of the photopigment. The father manifests as tritanopic on all color vision tests, whereas the daughter made mild tritan errors on only a small subset of color vision tests. Interestingly, the father reports that it has only been in recent years that he has noticed difficulties with discriminating between some colors such as orange-yellow and pink, while the daughter reports never having any color discrimination problems. We used adaptive optics ophthalmoscopy to obtain high-resolution images of the cone mosaic of both individuals combined with retinal densitometry to identify S cones in the mosaic. Surprisingly, while normal S cone density was reported for the daughter (4.9%, or 2224 cones/mm²), no evidence for S cones was observed in the father, though the overall cone density was within normal limits for both individuals. Since S cones normally occupy a small minority of the total cone population and since cone density is so variable across normal individuals (Curcio et al., 1990; Gao & Hollyfield, 1992), it is not surprising that the cone density of the father appeared normal despite the apparent absence of S cones.

One feature of the cone mosaic that *can* be exploited to study subtle disruptions in the packing geometry of the cone mosaic is the spatial regularity. The spatial regularity of the mosaic can be assessed by using a number of metrics (Cook, 1996; Rodieck, 1991); one of the more intuitive ones is the Voronoi analysis (Curcio & Sloan, 1992; Pum, Ahnelt, & Grasl, 1990). With this analysis, individual cones are represented as points in a two-dimensional plane. For each cell, a Voronoi domain is constructed by defining points in the plane that are closer to that cell than any other cell in the mosaic. The number of sides of the resultant polygon reflects the packing geometry of the local mosaic. In a perfectly regular mosaic with triangular packing, each cell would have a hexagonal Voronoi domain. Shown in figure 26.6A is the Voronoi analysis of a normal human cone mosaic and that of the tritan father mosaic. The polygons are color coded according to the number of sides they have, with green indicating six sides. While the majorities are green (indicating a largely triangular mosaic), there are many fractures in the regularity of the mosaic. These disruptions have been hypothesized to correlate with the location of S cones in the mosaic (Pum et al., 1990); however, compelling evidence for this is lacking. Nevertheless, the father's mosaic was significantly more irregular than normal (figure 26.6C), while the daughter's mosaic was indistinguishable from normal (figure 26.6B). The disparate S cone mosaics in these two subjects are consistent with their distinct behavioral phenotypes, the increased irregularity in the father's mosaic likely being a remnant of the degeneration of the S cones in his mosaic.

The work reported by Baraas and colleagues (2007) provides the first anatomical evidence that tritan phenotypes

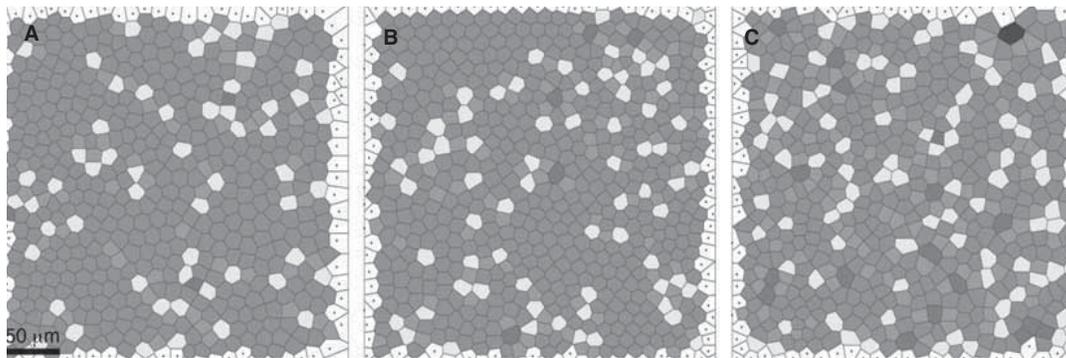

FIGURE 26.6 Regularity of the human cone mosaic. Voronoi domain associated with each cone photoreceptor in a patch of retina from (A) a normal trichromat, (B) a 34-year-old female with a mild tritan defect, and (C) a 57-year-old male with a severe tritan defect. The color code indicates the number of sides on each Voronoi polygon (magenta = 4, cyan = 5, green = 6, yellow = 7, red = 8, purple = 9). Large regions of six-sided polygons indicate a regular triangular lattice, whereas other colors mark points of

associated with S-opsin mutations can be associated with the loss of S cones. This suggests a mechanism in which the mutations produce their effects by reducing the viability of the S cones (similar to the mechanism in adRP), and heterozygotes that express both the normal and mutant S opsins will exhibit trichromatic color vision that can be indistinguishable from normal until the S cones succumb to the toxicity of the mutant opsin.

RED/GREEN COLOR VISION DEFICIENCY The most common form of inherited color vision deficiency is one that affects the red-green (L-M cone) system. Among individuals of Western European ancestry, about 7–10% of males have a red-green color vision defect. The incidence in females is much lower (approximately 0.4%) because the defects are inherited as X-linked recessive traits, though approximately 15% of females are carriers of a red-green defect. The general genetic causes of red-green color vision deficiency involve a disruption of the L/M gene array on the X-chromosome. The most common cause is rearrangement of the L/M genes resulting either in the deletion of all but one visual pigment gene or in the production of a gene array in which the first two genes both encode a pigment of the same spectral class (Deeb et al., 1992; Jagla, Jäggle, Hayashi, Sharpe, & Deeb, 2002; Nathans, Piantanida, Eddy, Shows, & Hogness, 1986; M. Neitz et al., 2004; Ueyama et al., 2003). The second general cause is the introduction of an inactivating mutation in either the first or second gene in the array. The most prevalent inactivating mutation results in the substitution of arginine for cysteine at position 203 (C203R) in the L/M pigment (Bollinger, Bialozynski, Neitz, & Neitz, 2001; M. Neitz et al., 2004; Winderickx et al., 1992). Cysteine 203 forms an essential disulfide bond being highly conserved among G-protein-coupled receptors

disruptions in the hexagonal packing of the foveal mosaic. Despite the fact that the father and the daughter carried the same heterozygous mutation in their S-opsin genes (predicting a tritan phenotype), the regularity of the father's mosaic was significantly disrupted, while the daughter's was indistinguishable from normal. Scale bar is 50 μm . (Reproduced from Baraas et al., 2007, with permission.) (See color plate 37.)

(Sakmar, 2002). This mutation was first observed in blue cone monochromacy (Nathans et al., 1989) where it was shown to directly disrupt photopigment function (Kazmi, Sakmar, & Ostrer, 1997). Mutating the corresponding cysteine residue in human rhodopsin (position 187) causes autosomal dominant retinitis pigmentosa (Richards, Scott, & Sieving, 1995).

The two different causes of red/green color vision defects might be expected to have different retinal phenotypes. It is thought that all photoreceptors that are destined to become L or M cones will express either the first or second gene in the X-chromosome array (Hayashi, Motulsky, & Deeb, 1999). In the case of gene rearrangements, all photoreceptors are expected to express a gene that encodes a functional pigment, though these would all be of the same spectral type. However, in the case of inactivating mutations, a fraction of the photoreceptors will express a pigment that is not functional and, in fact, may be deleterious to the viability of the cell. Recently, it was discovered that there are different retinal phenotypes among red-green color-blind individuals. Carroll, Porter, Neitz, Williams, and Neitz (2005) found that in individuals having either a single-gene array or an array in which the first two genes both encode a pigment of the same spectral class, the cone mosaic is normal in appearance. In contrast, in individuals in whom one of the genes in the array encodes a pigment with an inactivating mutation, dramatic loss of healthy cones is observed, consistent with the hypothesis that cells expressing the mutant pigment degenerated (Carroll et al., 2004). Shown in figure 26.7 are adaptive optics images from individuals with color vision defects caused by photopigment mutations.

Besides a reduction in color discrimination, the disrupted mosaics (sometimes having 60% fewer cones than normal) might also be expected to confer a reduction in spatial vision.

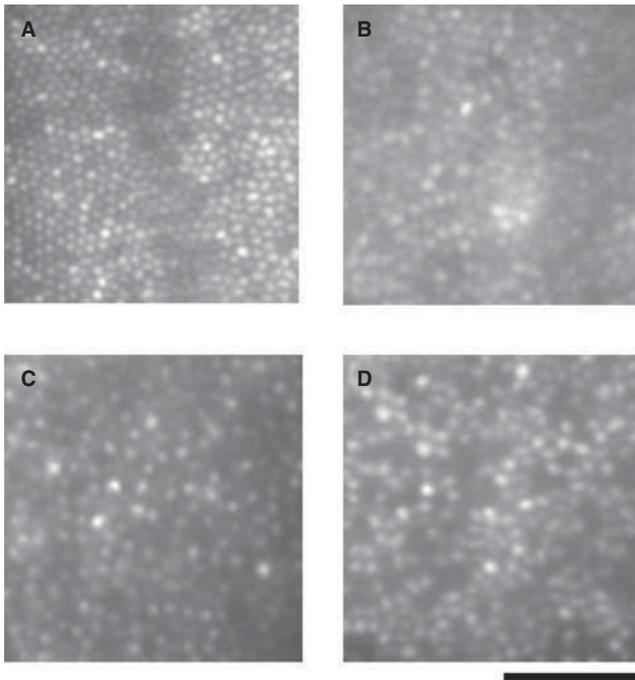

FIGURE 26.7 Images of the cone mosaic from individuals with different cone opsin mutations. Images are from 1-degree temporal retina from (A) a normal trichromat, (B) a blue-cone monochromat carrier (Carroll, Porter, Neitz, Williams, & Neitz, 2005), (C) a protanope male (Carroll et al., 2007), and (D) a deuteranope male (Carroll, Neitz, Hofer, Neitz, & Williams, 2004). The density of cones in the BCM carrier (B) is reduced significantly (21,684 cones/mm² for the BCM carrier retina, compared with an average normal density at this retinal eccentricity of 55,184 cones/mm²), though the mosaic appears continuously packed (the cells are slightly larger in diameter). The density of the cones in the males with red/green defects is also reduced, though the appearance of the mosaic is quite different, with numerous punctate gaps in the cone mosaic. Sale bar is 50 μ m.

However, clinical tests of visual acuity and visual field sensitivity are completely normal in these individuals. To demonstrate that the dark areas in the retinal images indeed correspond to nonfunctional cones, Makous and colleagues (2006) used adaptive optics to deliver small stimuli to the retina. By using adaptive optics to correct for the eye's aberrations, it is possible to confine a majority of the energy of the spot to an area of retina about the size of a single cone aperture. They found a marked reduction in sensitivity that was almost exactly proportional to the amount of retinal mosaic occupied by dark spaces. Thus the absence of a clinical deficit likely reflects redundancy in the stimuli used in the diagnostic tests, which causes correlated responses even in neurons whose sensitivities do not overlap. For example, the smallest spots used in clinical perimetry subtend 0.11 degrees. Even without optical spread, the image of such a spot covers some 150 cones at the center of the fovea of an average retina. Nevertheless, the fact that a visual deficit is apparent only when bypassing the eye's optical aberrations

further highlights the limiting effect these aberrations can have on our normal visual activity.

BLUE CONE MONOCHROMACY Blue cone monochromacy (BCM) is a condition in which L and M cone function is absent (Pokorny, Smith, & Verriest, 1979). This is caused by either a deletion of essential DNA elements needed for normal transcription of the pigment genes or a deletion of all but one of the X-chromosome visual pigment genes with the one remaining gene containing a missense mutation (Ayyagari et al., 2000; Nathans et al., 1989, 1993). Affected individuals have very poor acuity, myopia, nystagmus, poor color discrimination, and minimally detectable ERG responses.

Owing to the X-linked nature of the condition, female carriers are spared from a full manifestation of the associated defects but can show abnormal cone ERG amplitudes (Berson, Sandberg, Maguire, Bromley, & Roderick, 1986). Using adaptive optics, Carroll and colleagues (2005) imaged the photoreceptor mosaic of a BCM carrier and found a mosaic that had 60% fewer cones than normal, with foveal cones that were larger in diameter than normal (see figure 26.7). As a result of X-inactivation, on average half of the L/M cones will express a gene from a normal L/M array, while the other half will attempt to express a gene from the array harboring the BCM mutation. The loss of cones is believed to reflect the fact that those cones that were unable to express a photopigment gene degenerated early in development. The preliminary observations in the BCM carrier predict that an affected male would have a completely disrupted cone mosaic, with only about 5–10% of the normal cone complement. No adaptive optics data on BCM males are available; however, indirect data from optical coherence tomography suggests that there is an alteration of the outer segment of the photoreceptors and an alteration in the area of the somata of the photoreceptors in males with BCM (Barthelmes et al., 2006). Future work to compare these complementary imaging modalities should yield valuable information about the origin of the disrupted OCT signal in these BCM males.

ROD MONOCHROMACY Rod monochromacy is a rare disorder (approximately 1 in 30,000) typically characterized by a lack of color discrimination, photophobia, reduced acuity, visual nystagmus, and nondetectable cone electroretinograms (see Hess, Sharpe, & Nordby, 1990, for thorough reviews). Complete achromatopsia has been linked to numerous mutations in CNGA3 and CNGB3 (which encode the α - and β -subunits, respectively of the cone cyclic-nucleotide gated channel), as well as GNAT2, which encodes the α -subunit of the cone G-protein transducin. To account for the apparent absence of cone function, Galezowski (1868) first proposed a rod-only theory in which the cones of the

retina are malformed or completely absent and visual function takes place entirely in the rod photoreceptors. Subsequent histological studies partially discounted this theory, but the result is an inconsistent picture of the photoreceptor mosaic of the achromat. Larsen (1921) reported scarce, malformed retinal cones in the fovea and normal peripheral cones in the retina of a 29-year-old female. Harrison, Hoefnagel, and Hayward (1960) found imperfectly shaped and reduced numbers of cones throughout the retina of a 19-year-old male. In the retina of a 69-year-old female, Falls, Wolter, and Alpern (1965) observed normal numbers of odd-shaped foveal cones and scarce numbers in the periphery. Most recently, Glickstein and Heath (1975) found no evidence of cones in the fovea and reduced numbers of cones elsewhere in the retina of an 85-year-old male.

Nishiguchi, Sandberg, Gorji, Berson, and Dryja (2005) found significant phenotypic variation among rod monochromats—specifically that some had small amounts of remaining cone function. It seems likely that this would be at least partly driven by the underlying genetic variation. As

a first step toward developing a genotype-phenotype map in rod monochromacy, Carroll, Choi, and Williams (2008) obtained the first images of the photoreceptor mosaic from a living rod monochromat for whom the genetic cause of the disease was known. As is shown in figure 26.8, clear images of the photoreceptor mosaic were obtained; however, they were not normal in appearance. The rod monochromat had a disrupted photoreceptor mosaic, and the cells in the mosaic were comparable to rod diameters, not cone diameters, consistent with the hypothesis that this retina is largely (if not completely) devoid of healthy cone photoreceptors. While the appearance of the photoreceptor mosaic in rod monochromacy might seem trivial, given that new gene therapies are on the horizon that promise restoration of cone function in rod monochromats (Alexander et al., 2007; Komaromy et al., 2007), it seems especially relevant to consider the photoreceptor substrate with which any such therapy would have to work. Even beyond the photoreceptors, it has been shown that the retinal circuitry remodels in response to photoreceptor degeneration (see Jones & Marc, 2005, for a

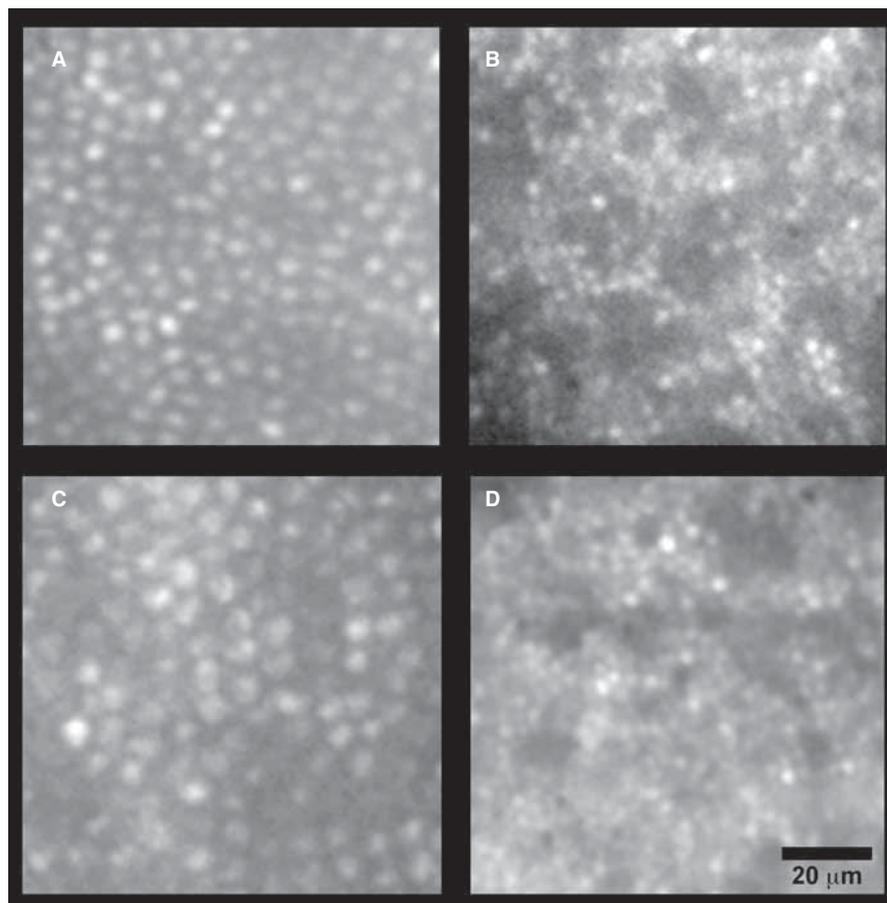

FIGURE 26.8 The retina of the rod monochromat is highly unusual. (A, C) Images from a 28-year-old normal male, who had been imaged as part of a number of unrelated studies over the course of 3 months. (B, D) Images from a 28-year-old rod mono-

chromat. Images are from 2.5 degrees (A, B) and 4 degrees (C, D) temporal retina. The size and density of the visible cells were typical for rod, not cone, photoreceptors. Scale bar is 20 μm . (Reproduced from Carroll, Choi, & Williams 2008, with permission.)

review) and that cortical signals in rod monochromats are abnormal (Baseler et al., 2002). Thus gene therapies for rod monochromacy would also need to account for the developmental reorganization in the visual cortex, as well as any potential remodeling of the retinal circuitry.

27 Bayesian Approaches to Color Vision

DAVID H. BRAINARD

ABSTRACT Visual perception is difficult because image formation and sensory transduction lose information about the physical scene: Many different scenes lead to the same image data. Understanding how the brain copes with this information loss, so that our percepts provide a useful representation of the world around us, is a central problem in cognitive neuroscience. In the case of color vision, the nature of the information loss is well understood. First, the light reflected to the eye confounds illuminant properties with those of objects. Second, spectral and spatial sampling by the cone photoreceptors further reduces the available information. To provide a stable representation of object color, the brain must compensate by combining the directly available information with assumptions about which scene configurations are likely to occur. This chapter reviews how Bayesian decision theory can model how this happens and discusses two Bayesian models that have been effective in accounting for color appearance.

Visual perception is difficult. One pervasive reason for this difficulty is that image formation and sensory transduction lose information about the physical scene, so many different scenes could have caused the same image data. Color vision presents an opportunity to understand how the brain copes with this information loss, because our understanding of the information loss and the scene parameters of perceptual interest is well developed. In this sense, color provides a model system for developing and testing theories that may have more general applicability. Of course, color perception is an important aspect of our perceptual experience, and understanding how it arises is also interesting in its own right. This chapter provides an introduction to Bayesian modeling of human color vision and reviews two lines of work where the approach has been fruitful.

Fundamentals of color vision

The visual system assigns a color to essentially all viewed objects. The information available about an object's color is carried by the spectrum of the light reflected from it, as illustrated by figure 27.1A. This spectrum, which we refer to as the *color signal*, is specified by its power at each wavelength.

The color signal is given as the wavelength-by-wavelength product of the illuminant power and the object's surface reflectance function, where the latter specifies the fraction of incident light reflected from the object. Thus the color signal confounds object properties with those of the illuminant. To provide a representation of object reflectance that is stable across changes of illuminant, the visual system must process the color signal to separate the physical effects of illuminant and object surface.

The postreceptoral visual system does not have direct access to the color signal. Rather, this spectrum is encoded by the joint responses of the retinal mosaic of cone photoreceptors. There are three classes of cones, each characterized by a distinct spectral sensitivity (figure 27.1B). These are often referred to as the L, M, and S cones.

Each individual cone codes information about light as a scalar quantity, the rate at which its photopigment is isomerized. This rate confounds the overall intensity of the color signal with its relative spectrum. Thus two physically distinct color signals can produce the same isomerization rate in all three classes of cones (figure 27.1C). Moreover, there is at most one cone at each retinal location. To obtain even trichromatic information about the spectrum of the color signal, the visual system must combine information from cones at different retinal locations; sampling of the image by the retinal mosaic confounds spatial and chromatic image structure.

This brief review illustrates a series of stages in which information about object spectral properties is lost: The color signal confounds object reflectance with the spectral power distribution of the illuminant; the retina as a whole contains only three classes of univariate cones, so the color signal's full spectrum is represented by at most three numbers; and at each retinal location, there is only one cone. Each of these stages of information loss produces ambiguity about the scene being viewed.

How does the visual system resolve ambiguity to extract a perceptually useful representation of object color? Since the cone responses do not completely determine the reflectance properties of the object, some additional constraints must be imposed. Here, we apply Bayesian analysis as a framework to express these constraints and develop models of color perception.

DAVID H. BRAINARD Department of Psychology, University of Pennsylvania, Philadelphia, Pennsylvania

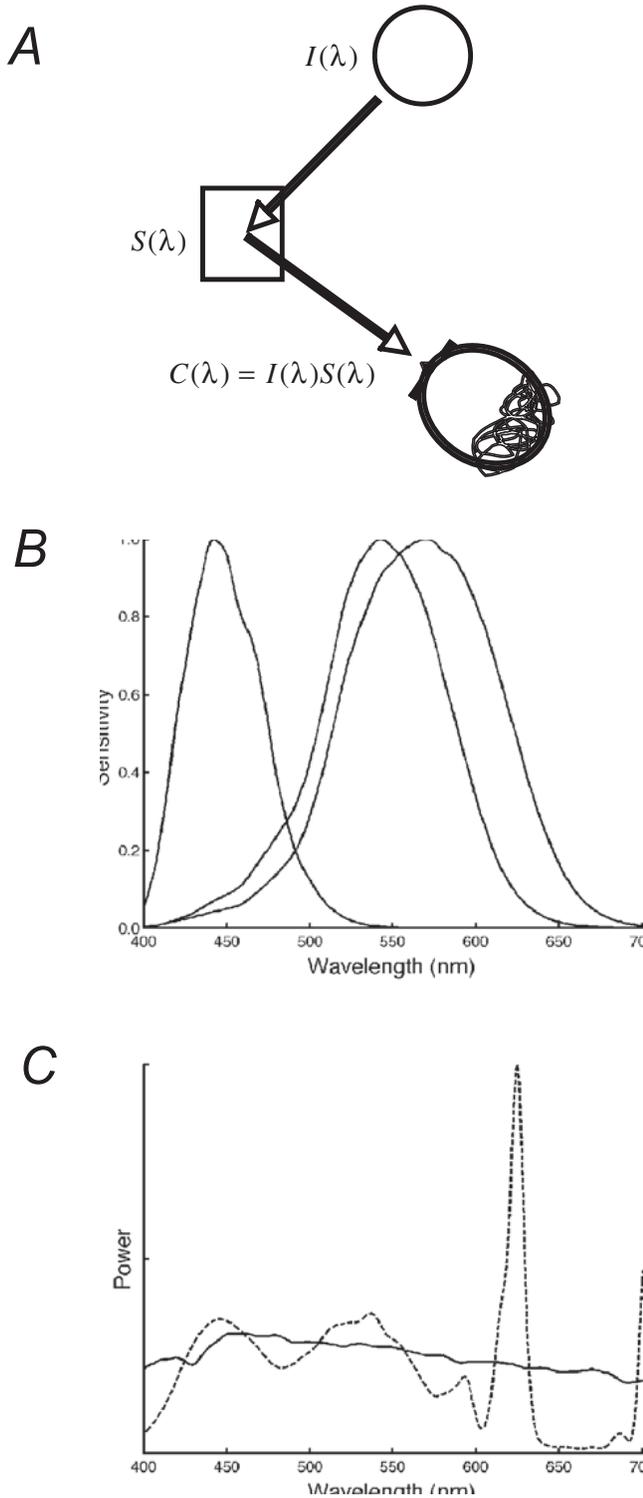

FIGURE 27.1 Information loss in color vision. (A) Color vision begins when light reflects from an object to the eye and is imaged on the retina. The color signal reaching each location of the retina is characterized by its spectrum, which is the amount of power at each wavelength. (B) The spectral sensitivities of the L, M, and S cones. The isomerization rate of photopigment is determined by multiplying the incident rate of the color signal at each wavelength by the photopigment's spectral sensitivity and summing over wavelength. (C) Two physically distinct spectra that produce the same isomerization rates in the human L, M, and S cones simultaneously.

language of probability distributions. These two types of information are then combined via Bayes' rule to produce a *posterior* distribution that expresses what is known about the scene. A specific estimate of the scene configuration can then be extracted from the posterior, for example, by taking its mean.

An example serves to illustrate the key ideas. Imagine a toy universe containing only one wavelength of light and one spatial location. An illuminant impinging on a surface is specified by an intensity i , and the object surface reflectance is specified by a single number s . We refer to these as the *scene parameters*, as fixing their values specifies the physical scene. The color signal here reduces to a single number, $c = is$. If an eye with a single photoreceptor images the scene, we can model its response r by the equation $r = c + n$, where n is additive noise. We then ask, "What do the *image data* r tell us about the values of the scene parameters?" Within the framework of Bayesian analysis, this is given by the *likelihood*, written $p(r|i, s)$. For any scene parameters, the likelihood tells us how probable any observed response r is. Figure 27.2A illustrates the likelihood for our example, for the case $r = 1$. When the image data are held fixed, the likelihood is a function of the scene parameters.

Two features of the likelihood are worth note. First, some pairs (i, s) lead to higher likelihood than others. This means that the image data provide some information about the scene parameters. Second, the likelihood function has a ridge of equal values along the hyperbola $is = 1$. The fact that the likelihood is equal along this ridge indicates that the image data provide incomplete information; there are multiple scene configurations that the image data do not distinguish.

Because the image data do not uniquely determine the scene parameters, some other principle must be invoked to resolve the ambiguity. The prescription provided by the Bayesian approach is to specify the statistical properties of the scene parameters. In our toy universe, for example, it might be that not all illuminant intensities occur with equal probability. This fact can be expressed as a *prior* probability distribution over the scene parameters (figure 27.2B). Here, the prior has a ridge parallel to the s dimension, indicating that all values of s are equally likely. But along the i dimen-

Bayesian principles

BASIC IDEAS Bayesian statistics provides a general formulation that allows image data to be combined with prior assumptions to provide a reasonable estimate of the physical scene configuration. Both the information provided by the data and the prior assumptions are expressed in the common

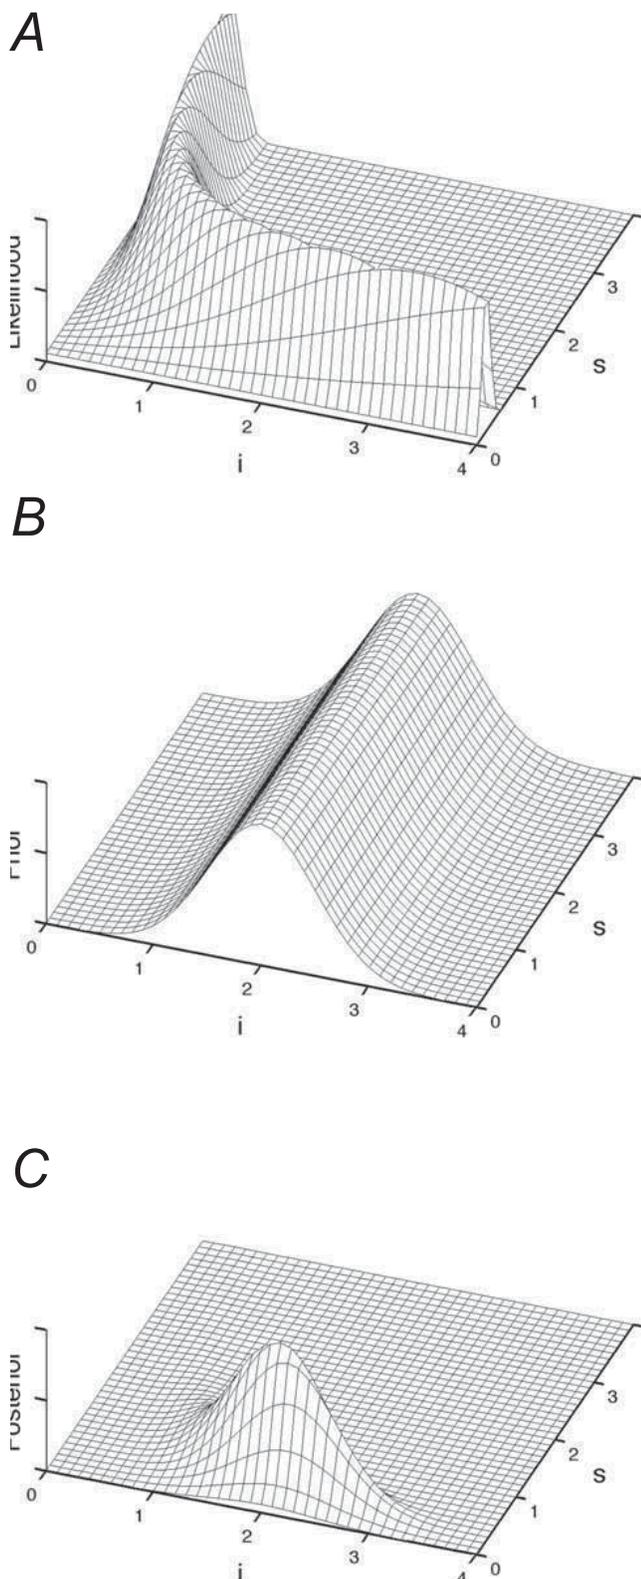

FIGURE 27.2 Simple example of Bayesian analysis. (A) Likelihood function for simple example. The likelihood function $p(r|i, s)$ is plotted as a function of (i, s) for the case in which $r = 1$. Values of i and s are assumed to be constrained between 0 and 4. (B) Prior for simple example. The prior probability distribution $p(i, s)$ is plotted, showing a prior where illuminant values are more likely near $i = 2$ but that is silent about surface reflectance s . (C) The posterior is given by the pointwise product of the likelihood and the prior and then is normalized. The resulting $p(i|s, r)$ is shown for the likelihood in panel A and the prior in panel B. For additional discussion of this example, see Brainard and Freeman (1997).

sion, there is a concentration of illuminant probability in the vicinity of $i = 2$. The prior is a function of the same scene parameters as the likelihood.

Bayes' rule says that to combine the prior and likelihood into the posterior, all that is necessary is to multiply the two functions point by point and normalize the result so that the total probability is unity (Gelman, Carlin, Stern, & Rubin, 2004). The result of this operation for our example is illustrated by figure 27.2C. The use of multiplication makes intuitive sense: the posterior has high values when both the prior and the likelihood are high and goes to zero if either the prior or the likelihood is zero. The posterior is often written in the form $p(i, s|r)$. In the case shown, the posterior has an unambiguous peak, even though both the likelihood and the prior are individually ambiguous about the scene parameters. Often, the scene parameters are estimated by the maximum or as the mean of the posterior; other methods are also available (Blackwell & Girschick, 1954; Brainard & Freeman, 1997; Maloney, 2002).

BAYESIAN MODELS Bayesian analysis provides a framework for generating models that may be applied to specific perceptual phenomena. The task of the modeler is to express the content of interest as a likelihood and prior and then to link the resulting estimate of the scene parameters to perception. The framework is useful to the extent that it consistently generates models that describe, predict, and clarify empirical data.

The first part of Bayesian modeling is to specify the likelihood, which amounts to understanding the process by which scene parameters determine image data. For vision, the likelihood is in essence a description of how light flows through a scene to produce the retinal image, how the retinal image is sampled by the photoreceptor mosaic, and how precise the photoreceptor responses are. In the case of color, these factors are well understood (Wyszecki & Stiles, 1982; Kaiser & Boynton, 1996; Wandell, 1995), which means that generating the likelihood portion of a Bayesian model is straightforward.

The second part of Bayesian modeling is to specify the prior. In cases in which the likelihood is well constrained,

the prior carries the critical content of the model. One way to obtain a prior is to examine statistical regularities in the natural environment and to choose a prior that captures these regularities. The idea is that evolution and development have optimized visual processing for the environment in which we operate and that statistical regularities in the environment are likely to be deeply embedded in visual processing (see Helmholtz, 1910; Attneave, 1954; Shepard, 1987, 1992; Adelson & Pentland, 1996; Mamassian, Landy, & Maloney, 2002; Weiss, Simoncelli, & Adelson, 2002; Geisler & Kersten, 2002; Maloney, 2002; see also Knill & Richards, 1996; Rao, Olshausen, & Lewicki, 2002).

Often, not enough is known about natural scene statistics to completely determine a prior. In this case, one strategy is to choose a parametric form for the prior that is broadly consistent with available measurements and then to use psychophysical data to constrain these parameters. We (Brainard et al., 2006; Brainard, Williams, & Hofer, 2008) and others (e.g., Mamassian & Landy, 2001; Stocker & Simoncelli, 2006) have found that this hybrid approach leads to effective models and allows good progress to be made with the Bayesian approach even as we seek improved methods for measuring and specifying priors.

We defer to the discussion a number of important issues related to the selection of priors in Bayesian models of perception. Such discussion is more cogent in the context of the specific models reviewed in this chapter.

The final step in developing a Bayesian model of perception is to link the output of the Bayesian calculation, which is typically an estimate of scene parameters extracted from the posterior, to a measurement of human performance. Often, the linking hypothesis involves the assumption that that goal of perception is to provide an explicit representation of one of the scene parameters. For example, color appearance is often taken to be a perceptual correlate of object surface reflectance. Given this idea, a natural linking hypothesis for object color appearance is that two objects, viewed in different scenes, will have the same color appearance when a Bayesian estimation algorithm returns the same estimate of surface reflectance for each (Brainard, Kraft, & Longère, 2003).

Color constancy

In daily life, it is common to refer to objects as having a color appearance: “the red apple,” “the blue house,” “the green car.” Although this is effortless, it is also remarkable. The color signal that is reflected from any object varies with the illumination, so a stable percept must involve postreceptoral processing. The stability of object color appearance is called *color constancy*. Both color constancy and its close cousin, lightness constancy, have long been the target of experimental investigation (e.g., Helson & Jeffers, 1940; Burnham,

Evans, & Newhall, 1957; McCann, McKee, & Taylor, 1976; Arend & Reeves, 1986; see Katz, 1935; Brainard, 2004; Gilchrist, 2006).

A few empirical generalizations are easy to state. First, the data confirm the introspective conclusion that human vision often exhibits excellent color constancy: Object color appearance changes less than would be predicted by the corresponding change in reflected light (Arend & Reeves, 1986; Brainard, Brunt, & Speigle, 1997; Brainard, 1998). Second, color constancy is not perfect: Object color appearance does change somewhat with the illuminant. Third, factors other than the illuminant affect object color appearance. A particularly important factor is the surface reflectances of other nearby objects in the scene (Kraft & Brainard, 1999; Gilchrist, 2006).

Given that the above general facts are well established, it seems clear that our goal should not be to generate further broad confirmations. Rather, we should seek models that accurately predict the color appearance of any object when it is viewed in an arbitrary scene. This is not an easy task, as a combinatorial explosion prevents enumeration and direct study of all possible scenes. It is therefore critical to build models that not only fit extant data but also embody principles that make it likely that they will generalize well (see Wyszecki & Stiles, 1982, pp. 584–586; see also Krantz, 1968; Brainard & Wandell, 1992).

Different approaches to developing models of color appearance may be distinguished by the nature of the core principles they embody, and how these might enable generalization. Mechanistic models are constrained by abstracted properties of neurons in the visual pathways (Stiles, 1967). Examples of such abstractions include chromatic adaptation (von Kries, 1902) and contrast coding (Wallach, 1948; Land, 1986). These models will generalize well if the mechanisms that are revealed by simple stimuli continue to operate unaltered for more complex images.

A second modeling approach tackles generalization directly and involves explicitly formulating and testing rules of combination. An example would be additive prediction of the action of the superposition of two scenes on an object’s color appearance from measurements of the effect of each scene alone (Brainard & Wandell, 1992). A complement to this approach is to identify grouping and segmentation principles that allow the decomposition of complex scenes into separate and simpler regions and then to study effects of context within such regions and to consider how they interact (Gilchrist et al., 1999; Adelson, 1999).

A third approach is *computational* (Marr, 1982; Barrow & Tenenbaum, 1978). Here, the guiding hypothesis is that perceptual representations may be understood as biological approximations to well-defined information processing tasks. The use of Bayesian algorithms to model perception is an example of this approach. It will generalize well if the under-

lying hypothesis is correct: As one moves to richer and richer stimulus configurations, what must be updated is the modeled likelihood and prior, but no new idea is required.

A Bayesian model of human color constancy

Here, we outline a Bayesian model of color appearance. The first step is to define the likelihood function. This is based on the following imaging model (Brainard & Freeman, 1997; Brainard et al., 2006). A collection of flat matte objects is lit by a single spatially uniform and diffuse illuminant. The j th object is characterized by its surface reflectance $s_j(\lambda)$, which specifies the fraction of incident light reflected at each wavelength λ . The illuminant is characterized by its spectral power distribution $i(\lambda)$, which provides light power at each wavelength. The color signal reflected from the j th object to the eye at each wavelength is simply $c_j(\lambda) = i(\lambda) s_j(\lambda)$. For this example, we assume that the spatial scale of each object is large enough that we may neglect the fine structure of the interleaved retinal mosaic, so the information obtained from the color signal reflected from each object is the isomerization rates of the L, M, and S cones. These are easily computed from $c_j(\lambda)$ and the known spectral sensitivities of each cone class.

The isomerization rates arising from a given $c_j(\lambda)$ will be perturbed by noise, which can be modeled as additive and normally distributed. Given the surface reflectances $s_j(\lambda)$ of N objects in the scene and the illuminant spectral power distribution $i(\lambda)$, the likelihood may then be computed as a multivariate normal distribution with dimension $3N$, whose mean is given by the mean isomerization of the L, M, and S cones for each object and whose covariance matrix represents the additive noise. As with the simple example of figure 27.2, this likelihood function leads to an underdetermined estimation problem.

To specify a prior distribution for color constancy, we start with separate distributions over surface reflectance functions and illuminant spectral power distributions. The same general form is used for both and is illustrated for surfaces in figure 27.3. Following a number of authors (Cohen, 1964; Buchsbaum, 1980; Maloney & Wandell, 1986; see also Maloney, 1986; Jaaskelainen, Parkkinen, & Toyooka, 1990), we first assume that each surface reflectance function $s_j(\lambda)$ may be approximated within a three-dimensional linear model. This means that we can write $s_j(\lambda) = w_j^1 s^1(\lambda) + w_j^2 s^2(\lambda) + w_j^3 s^3(\lambda)$, where the three *basis functions* $s^i(\lambda)$ are held fixed (see figures 27.3A and 27.3B). The basis functions can be determined by applying principle components analysis to a large set of measured surface reflectance functions.

Within the three-dimensional model, each surface is specified by its triplet of weights w_j^1, w_j^2, w_j^3 . To induce a prior distribution over surfaces, we measure the three-dimensional

histogram of weights corresponding to an ensemble of surfaces and fit this with a multivariate normal distribution (figure 27.3C) (Brainard & Freeman, 1997). Doing so allows us to compute the prior probability of any surface reflectance $s_j(\lambda)$. The same approach can be used to determine prior probabilities for illuminants $i(\lambda)$.

Delahunt and Brainard (2004b) conducted experiments in which observers were asked to judge the appearance of a test patch embedded in the simulated images of 17 scenes. Images of four of the scenes are shown in figure 27.4A, the location of the test patch being indicated by the black rectangle in each image. Observers adjusted the chromaticity of the test patch until it appeared achromatic. Psychophysical measurements of this sort establish the chromaticity of the *achromatic locus* at the test patch location within each image, and this provides an excellent first-order characterization of how scene context affects the color of any object (Speigle & Brainard, 1999). Across the set of scenes, both the illuminant and the surface reflectance of the background surface were varied. Figure 27.4B plots the chromaticity of the illuminant for each example scene (large open circles) along with the achromatic loci (large solid circles). For three of the scenes, the chromaticity of the achromatic locus is near to that of the illuminant. These are the scenes in which only the illuminant varied, and this pattern indicates good color constancy (see Delahunt & Brainard, 2004b; Brainard et al., 2006). For the fourth scene, in which the background reflectance was also manipulated, the achromatic locus is far from the illuminant chromaticity; constancy was poor under this manipulation.

Brainard and colleagues (2006) used the general form of likelihood and prior described above and implemented a variant of Brainard and Freeman's (1997) Bayesian algorithm that estimates the chromaticity of the scene illuminant from image data. They used a prior for surfaces that captured the structure of a large set of measured reflectances (as in figure 27.3) and explored a parametric set of illuminant priors, all based on the CIE linear model for daylight. Brainard and colleagues (2006) then used the Bayesian algorithm to estimate the illuminant chromaticities for the same 17 scenes studied by Delahunt and Brainard (2004b). To link the illuminant estimates to the measured achromatic loci, they interpreted the achromatic loci as representing the chromaticity of light reflected from a fixed achromatic surface. This allowed mapping of estimated illuminant chromaticities to predictions of the achromatic loci (Brainard et al., 2006).

Figure 27.4B shows the predictions derived in this fashion (small open circles). The prediction for the leftmost image is guaranteed to be correct because this datum was used to infer the reflectance of the achromatic surface. The predictions for the other three scenes, and indeed for the entire collection of 17 images (see Brainard et al., 2006), are good.

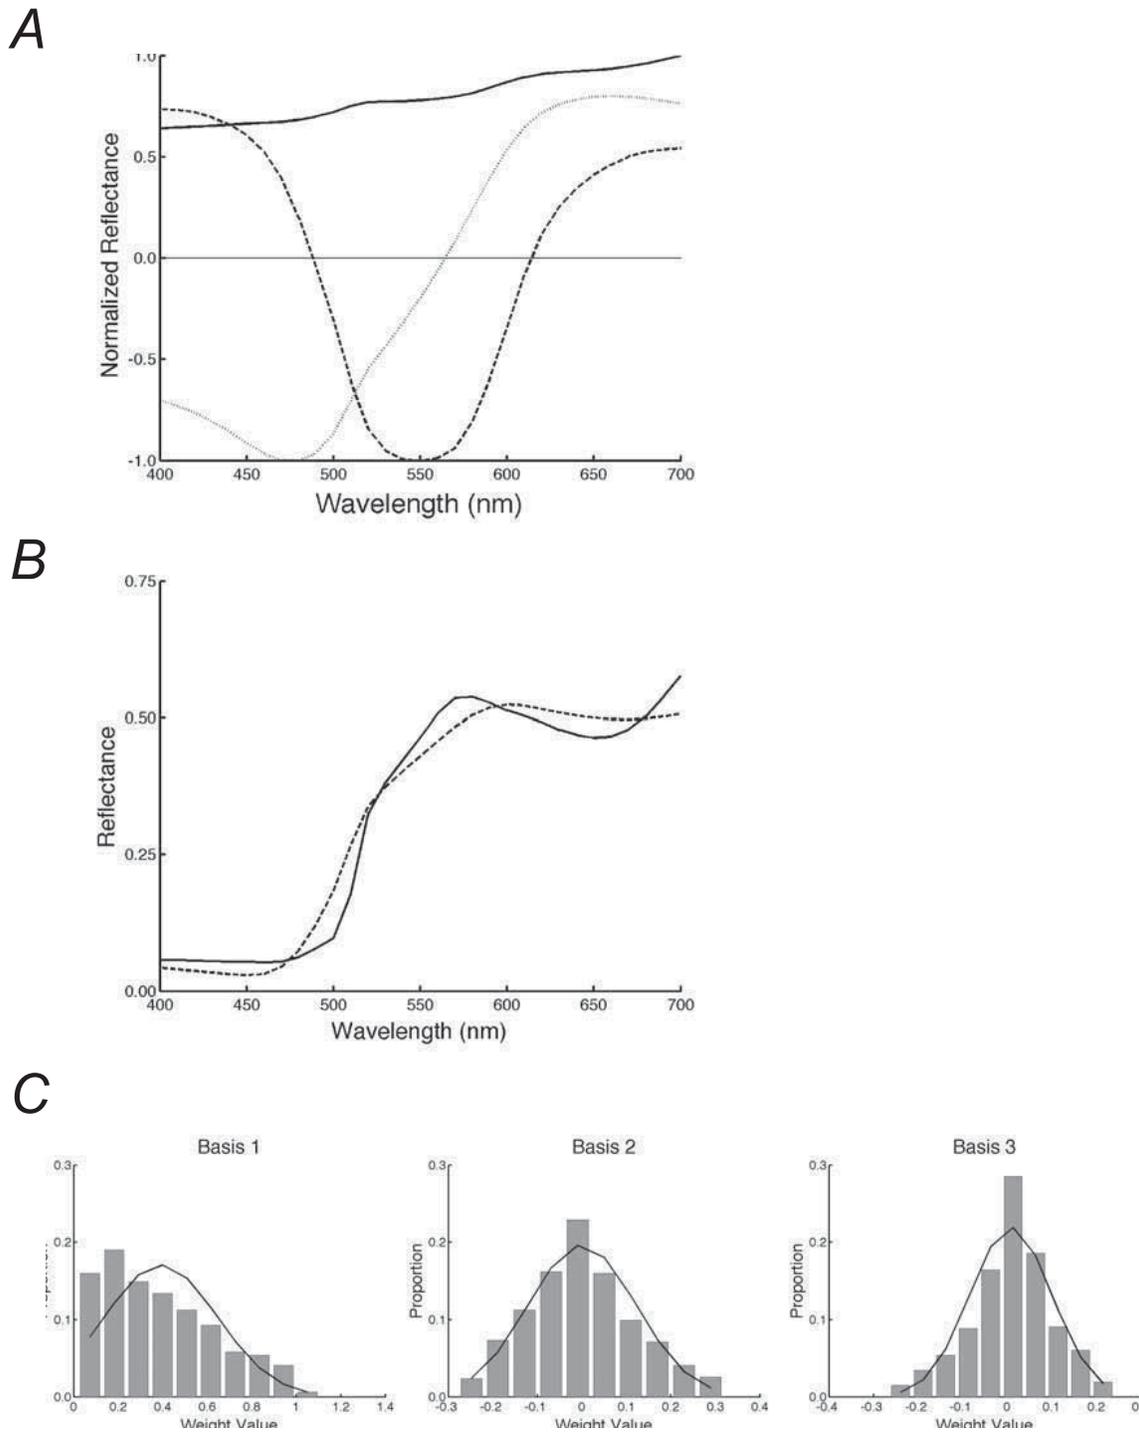

FIGURE 27.3 Prior over surface reflectance. (A) Three basis functions of a linear model for surfaces. The basis functions were obtained through analysis of the principle components of a collection of 462 measured surface reflectance functions (Newhall, Nickerson, & Judd, 1943; Nickerson, 1957). (B) A measured surface reflectance function (solid curve) from the same data set used to

generate the linear model, and its approximation (dashed curve) within the model shown in panel A. (C) Distribution of model weights for the 462 surface reflectance functions in the data set used to generate the linear model. Each panel shows the histogram for one basis function. The solid curves are a normal approximation. (After Brainard & Freeman, 1997; see their figure 4.)

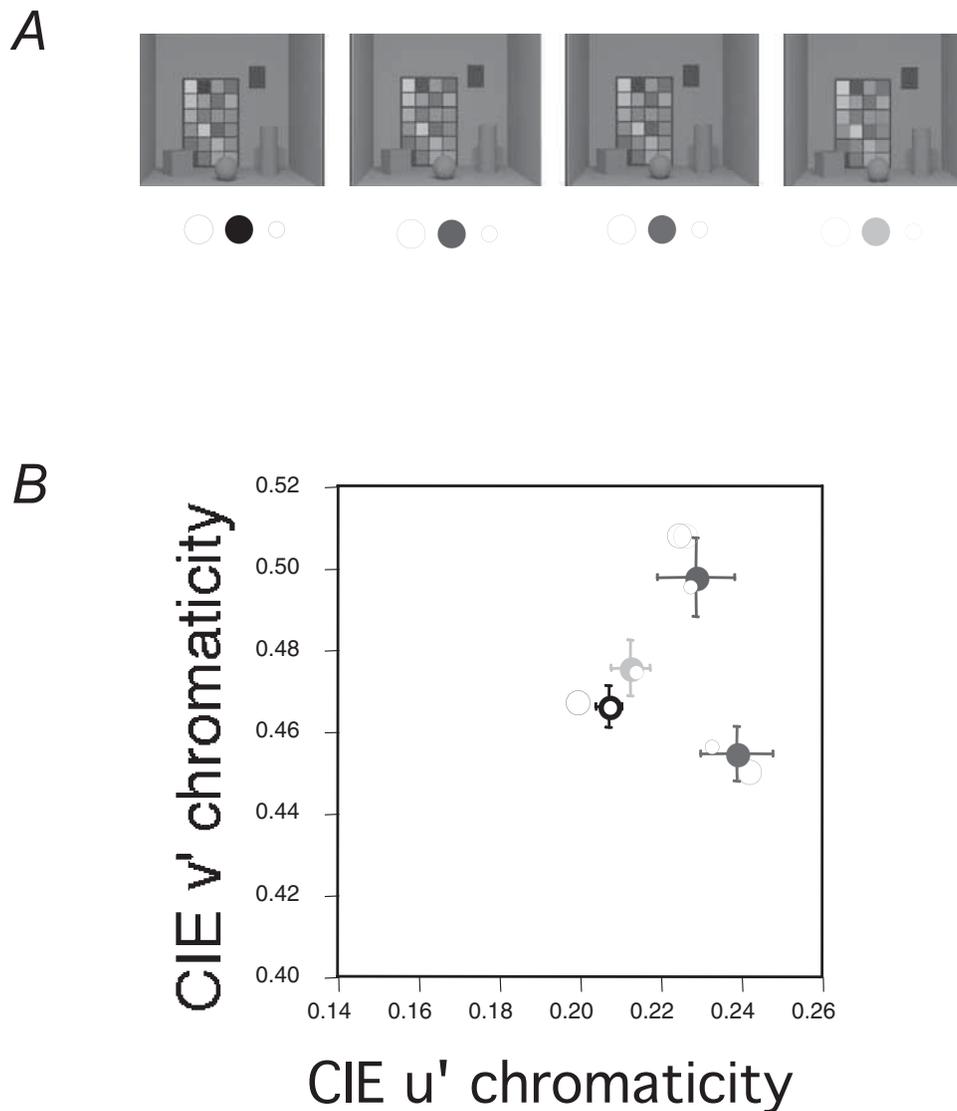

FIGURE 27.4 Color constancy performance. (A) Images of 4 of 17 simulated scenes used to compare human performance and a model derived from a Bayesian illuminant estimation algorithm. Each scene has the same spatial structure. In the first three images, from left to right, the illuminant varies. In the rightmost image, the illuminant is the same as that in the second image, but the background surface has been changed so that the light reflected from it matches that reflected from the background surface in the leftmost image. (Reproduced from Brainard et al., 2006, figure 1.) (B) Illuminants, achromatic loci, and model predictions plotted in

the CIE $u'v'$ chromaticity diagram. This is a standard color representation that preserves information about the relative responses of the L, M, and S cones but not about intensity. Large open circles show the scene illuminants, with the color key as indicated beneath the images in panel A. Large solid circles show the achromatic loci measured by observers who adjusted a test patch at the location indicated by the black rectangle in each image. The small open circles show the model's predictions of the achromatic loci. (Reproduced from figure 7 of Brainard et al., 2006.) (See color plate 38.)

Of importance is that the agreement occurs both for cases in which the observers showed good constancy and cases in which constancy was poor.

Bayes and the cone mosaic

The treatment of color constancy above addresses the information loss caused by the interaction of surfaces and illuminants in the formation of the image and the reduction from

a full spectral representation of the color signal to the trichromatic representation provided by the L, M, and S cones. It assumed, however, that the responses of all three cone classes were available at each spatial location. This is intuitively reasonable if the spatial scale of the image of various objects is large in comparison to the spacing between cones. Nonetheless, it would be more satisfying to have a theory of how information from cones is combined across space to provide a representation that is effectively trichromatic at such spatial

scales. To develop such a theory, we can again turn to a Bayesian analysis.

As with the color constancy case, developing a Bayesian model requires specifying the likelihood and prior. We begin by deciding what scene parameters need to be estimated. Here, we take these to be an *ideal image*, which we conceive of as the isomerization rates of the L, M, and S cones at each image location, before optical blur or retinal sampling. From the ideal image, we can compute the mean isomerization rate for each of the actual cones in the interleaved mosaic. The computation incorporates effects of blurring by the eye's optics as well as the location and type of each individual cone. We then use an approximation of additive normal noise to convert the mean isomerization to the likelihood function.

To develop an appropriate prior, we rely on a few well-established observations about natural images. First, within a cone class, images vary slowly over space. This is often expressed by the observation that the energy in natural images falls off as $1/f$, where f is spatial frequency (Field, 1987). Alternatively, the same fact may be described as a strong correlation between image values at nearby locations within each cone class (Pratt, 1978). Second, at any given location, there are high correlations between the isomerization rates of the L, M, and S cones (Burton & Moorehead, 1987; Ruderman, Cronin, & Chiao, 1998). This correlation occurs because typical color signals are spectrally broadband and vary slowly with wavelength, because the spectral sensitivities of cones are themselves broad, and because the spectral sensitivities of different cone classes overlap. We instantiate these strong spatial and spectral correlations in our prior by using a multivariate normal distribution whose covariance matrix is separable in space and color. This allows expression of the appropriate correlations (Brainard, 1994; Brainard et al., 2008). The use of a normal prior does not describe all of the regularities of natural images, but is strong enough to enable an effective algorithm.

Combining the likelihood and prior described above allows an estimate (Brainard, 1994; Brainard et al., 2008) of the ideal image from the isomerization rates of cones in the mosaic. Figure 27.5 illustrates estimator performance for a low spatial frequency stimulus. For such stimuli, the estimator returns near veridical estimates of the ideal image. This justifies the typical assumption that the fine structure of the interleaved mosaic may be neglected for most treatments of color vision.

It is possible to present stimuli that cause individuals with different cone mosaics to have distinguishable perceptions. Hofer, Singer, and Williams (2005) used adaptive optics to present very small flashed monochromatic spots to observers whose chromatic topography had also been mapped. Figure 27.6 summarizes the results of these experiments. The top row (A) shows mosaics for five individual observers. The

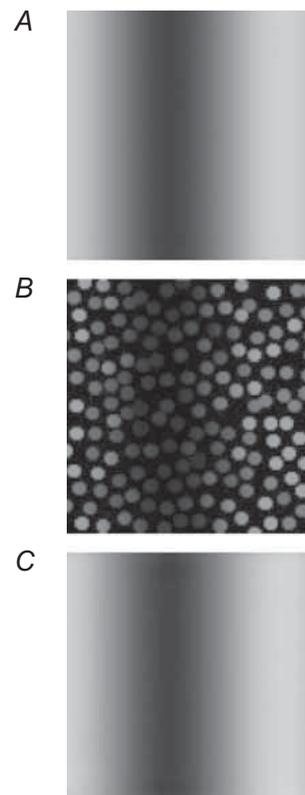

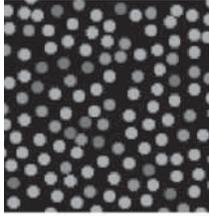

FIGURE 27.5 Trichromatic reconstruction. (A) Small patch of sinusoidal isochromatic grating. (B) The intensity of each colored cone represents the isomerization rate of a cone. The class of each cone is indicated by whether it is plotted in red (L), green (M), or blue (S). (C) The isochromatic grating as reconstructed by the Bayesian algorithm. The grating shown corresponds to a spatial frequency of 6 cycles per degree presented at about 1 degree of eccentricity for a human observer; the mosaic is of observer AP of Hofer and colleagues (2005). Brainard and colleagues (2008) provide additional reconstruction examples that show similarly veridical performance for low-spatial-frequency isoluminant gratings and for an additional mosaic. (See color plate 39.)

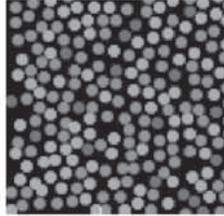

FIGURE 27.6 Small spot experiment. (A) Schematic of five individual observer cone mosaics. Red, green, and blue circles show locations of L, M, and S cones. Mosaics represent approximately 12 by 12 feet of visual angle at 1 degree of eccentricity. (Reproduced from Brainard et al., 2008, figure 2 (top panel).) (B) Data from Hofer and colleagues (2005) for 550-nm spots. Observers named each small spot that they saw and judged namable. The available names were red, orange, yellow, yellow-green, green, blue-green, purple, and white. For each observer, the histogram shows the proportion of each color named used, with the color code corresponding to the name. Note that the white region of the bars represents the proportion of white responses. Not all observers used all available names. (Reproduced from figure 11 of Brainard et al., 2008.) (C) Predictions from the Bayesian model, obtained as described in the text, for the experimental conditions corresponding to the data in B. (Reproduced from figure 11 of Brainard et al., 2008), which also shows data and predictions for 500-nm and 600-nm spots.) (See color plate 40.)

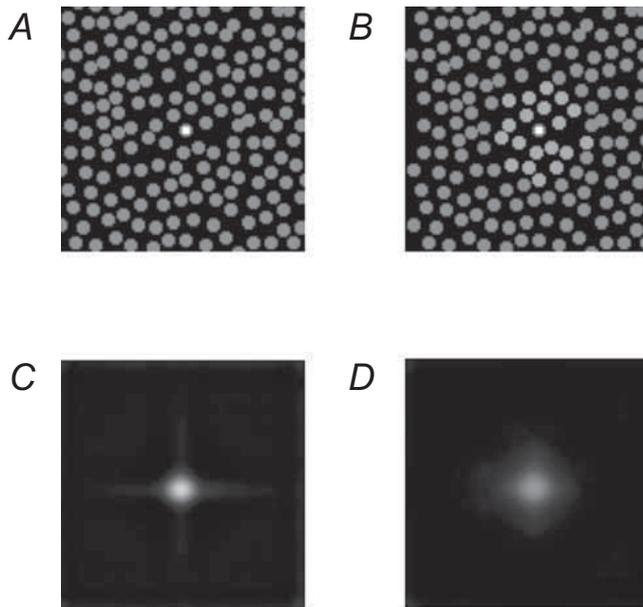

FIGURE 27.7 Small spot intuitions. (A) A mosaic consisting only of L cones. The white spot in the center indicates a single cone whose stimulation was simulated. (B) This mosaic is identical to the one shown in panel A, with the exception that the cones surrounding the central L cone have been changed to M cones. (C) Model output when the central cone in panel A is stimulated. The result is a bluish-white spot. As described by Brainard and colleagues (2008), a windowing procedure was applied to model output here and in panel D to reduce visible ringing in the reconstruction. (D) Model output when the central cone in panel B is stimulated. The result is a reddish spot. (Reproduced from figure 7 of Brainard et al., 2008.) (See color plate 41.)

second row (B) shows histograms of the aggregate naming behavior of each observer. There is large individual variation. Of particular note is that individuals with extreme L-to-M cone ratios tended to see more flashes as “white” than did individuals with more equal cone ratios.

We simulated the experiment of Hofer and colleagues (2005) and obtained reconstructed spots for each simulated flash. These were then mapped to color names through their chromaticities. Figure 27.6C shows the predicted naming histograms for each observer. The predictions capture the broad patterns of the data well. In particular, the fact that highly asymmetric mosaics lead to more flashes named “white” is a salient feature of the predictions, just as it is with the data.

Figure 27.7 provides intuition about the model’s predictions. First consider the left-hand panels (A and C). These show a mosaic consisting only of L cones and the Bayesian estimate of the ideal image when only the central L cone is stimulated. A mosaic consisting of only L cones is completely monochromatic, and its responses provide no information about the relative spectral composition of the stimulus. When the Bayesian algorithm is applied to data provided by such a

mosaic, it must rely on the prior to resolve the spectral ambiguity. The prior had a mean of CIE daylight illuminant D65, and the resulting estimate is correspondingly a bluish white.

The right-hand panels of figure 27.7 (B and D) show a second mosaic with the same spatial arrangement of cones. In this mosaic, however, the central L cone is surrounded by a set of M cones. We again simulated stimulating only the central L cone and obtained the algorithm’s estimate. Here, the resulting spot is red. This occurs because the M cones near to the central L cone add information about the spectral composition of the ideal image that was not available in the all L cone mosaic. These M cones have isomerization rates of zero, indicating that there is no middle wavelength light at their locations. Because the prior includes a specification of strong spatial correlations within each color plane, the zero M cone responses say that had an M cone been present at the central location, it too would have had a small response. Putting this together with the large observed L cone response leads to an estimate of a spot with more power in the long wavelengths than in the middle wavelengths, and the result appears red.

Although the actual individual mosaics are more complex than the examples shown in figure 27.7, the same intuitions apply. In mosaics in which there are large regions of homogeneous cone types, the reconstructed spots will have to rely more on the prior mean and will tend to be “white” rather than a more saturated color. The detailed modeling results shown in figure 27.6 play this and related intuitions out in detail.

Discussion

The work reviewed here links color appearance to the performance of Bayesian algorithms. The first model (Brainard et al., 2006) accounts for both successes and failures of human color constancy. The second model (Brainard et al., 2008) explains how the visual system integrates information from individual cones in the retinal mosaic to provide a seamless trichromatic percept under normal viewing conditions. This model successfully predicts the color appearance of spots that are small enough to stimulate single cones.

The two models have important common features. First, the modeling begins with an analysis of information loss between the scene parameters and the responses of the cones. Second, the core of each model is the specification of a prior distribution over the scene parameters of interest. The prior acts to resolve the ambiguity about the scene parameters that remains after the image data have spoken. Given that the likelihood is well constrained, it is the prior that provides the content of each model. In both cases, the general parametric form of the prior was determined through an analysis of naturally occurring scenes. The particular

priors used to model the data were then tuned by comparison of model predictions to the data (see Brainard et al., 2006, 2008).

The Bayesian approach leads to parsimonious models that account for a performance across a wide range of conditions. Consider the color constancy example. Many studies of color constancy vary only the illumination, while the surfaces in the scene are held fixed (e.g., McCann, McKee, & Taylor, 1976; Arend & Reeves, 1986; Brainard & Wandell, 1992; Hansen, Walter, & Gegenfurtner, 2007). Under these conditions, many computational models can predict the generally good constancy that is observed (Buchsbaum, 1980; Land, 1986; Brainard & Freeman, 1997). When the surfaces in the scene are covaried with the illuminant, constancy is a more challenging computational problem that can differentiate between models (Maloney & Wandell, 1986; Brainard & Wandell, 1986; Brainard & Freeman, 1997; Kraft & Brainard, 1999). The model presented here accounts for performance when the illuminant is varied alone and when both illuminant and scene surfaces are covaried. This feature emerged as a consequence of the interaction of a reasonable prior with the likelihood, as implemented through Bayes rule. A similar parsimony characterizes the account of small spot colors.

The Bayesian approach provides a clear generalization path. Both models presented here have to date undergone only preliminary tests against data, and it is likely that conditions can be found that produce model failures. For example, a few classic and more numerous recent studies of color and lightness constancy have sought to generalize to stimulus conditions beyond diffusely illuminated flat matte surfaces (Hochberg & Beck, 1954; Gilchrist, 1980; Nishida & Shinya, 1998; Bloj, Kersten, & Hurlbert, 1999; Yang & Maloney, 2001; Boyaci, Maloney, & Hersh, 2003; Boyaci, Doerschner, & Maloney, 2004; Doerschner, Boyaci, & Maloney, 2004; Delahunt & Brainard, 2004a; Ripamonti et al., 2004; Motoyoshi, Nishida, Sharan, & Adelson, 2007; Xiao & Brainard, 2008; see also Fleming, Dror, & Adelson, 2003). It is not surprising that experiments of this sort reveal phenomena that cannot be accounted for by the Bayesian constancy model presented above, since that model is based on a likelihood and prior that do not allow for spatially varying illumination, objects and scenes that vary in three dimensions or for objects with geometrically complex surface reflectance functions. On the other hand, the Bayesian prescription tells us that to build more general models, it may be sufficient to generalize the likelihoods and priors. This is less daunting than developing models *de novo*. Recently, models that may be conceived as generalizing the likelihood function to account for directional illumination and variation in object pose have been reported (Boyaci et al., 2003; Bloj et al., 2004; Boyaci, Doerschner, & Maloney, 2006).

Although the Bayesian approach has the appealing features described above, it will not provide a complete account of vision when employed alone. First, the approach is silent about mechanism. The way in which the models are implemented on a digital computer need not speak to how equivalent performance is achieved by the nervous system. The value of a Bayesian model in understanding mechanism is indirect. The model tells us what input-output relationship any mechanistic model must satisfy.

One common misconception about Bayesian models is that because the likelihood and prior are clearly separated in the formulation, this separation should be expected in the physiological representation. That this is not necessary is easily grasped if one considers that there is a simple linear receptive field interpretation of the Bayesian model of trichromatic image reconstruction. For any choice of prior distribution, the appropriate transformation from cone responses to the estimated ideal image may be accomplished by weighted sums that link cone responses to each estimated L, M, or S value (Brainard et al., 2008). In a neural implementation of this sort, the properties of the likelihood and prior are jointly and implicitly encoded in the specific values of the weights; neither the likelihood nor the prior appears explicitly.

An often-asked question that arises in the context of Bayesian models is “Where did the priors come from?” If we view the role of the prior in a Bayesian model as specifying how the visual system resolves the ambiguity in the likelihood, then it becomes clear that this question is not really about the priors. Rather, the question is really “How did evolution and development shape the visual system so that it operates effectively in the natural environment?” This is an excellent question but one that applies to any model that correctly describes stable adult performance. The current absence of an answer is not a weakness that is specific to the Bayesian approach. Indeed, one appeal of the Bayesian approach is that the prior is represented explicitly. Thus the prior that is used in a successful model converts the raw experimental data to a form that can be compared to measurements of the statistics of the natural environment (see Brainard et al., 2006). When the derived prior matches the environmental statistics, the Bayesian model provides a quantitative link between behavioral performance and the statistics of the environment. When there is a mismatch between the derived prior and environmental statistics, the modeling emphasizes that our understanding remains incomplete.

Finally, we close by noting there are interesting and important factors that the Bayesian approach, as elaborated here, does not include. Because information processing consumes energy, for example, there may be tradeoffs between optimal estimation and efficient processing. A number of

analyses interpret mechanisms of early color vision as efficient solutions to information transmission and representation (Buchsbbaum & Gottschalk, 1983; Derrico & Buchsbbaum, 1990; Atick, 1992; van Hateren, 1993; Ruderman et al., 1998; Parraga, Brelstaff, Troscianko, & Moorehead, 1998; von der Twer & MacLeod, 2001; Parraga, Troscianko, & Tolhurst, 2002; Lee, Wachtler, & Sejnowski, 2002; Doi, Inui, Lee, Wachtler, & Sejnowski, 2003; Caywood, Willmore, & Tolhurst, 2004; Wachtler, Doi, Lee, & Sejnowski, 2007). Although this work shares with the Bayesian models presented here an emphasis on the statistics of the ensemble of natural scenes, it differs in its emphasis. The Bayesian models presented in this chapter focus on veridicality rather than efficiency of representation. Moreover, additional insight is likely to be obtained when both veridicality and precision of representation are considered together (see Stocker & Simoncelli, 2006; Abrams, Hillis, & Brainard, 2007; Hillis & Brainard, 2007).

28 Wiring of Receptive Fields and Functional Maps in Primary Visual Cortex

DARIO L. RINGACH

ABSTRACT This chapter deals with the question of how receptive fields and cortical maps are wired before the onset of the classical critical period. In particular, we ask how simple-cell receptive fields may arise without an intermediate phase of overlap between ON and OFF subregions and without the need for correlated spontaneous activity in the developing thalamus. We discuss one possible solution, the statistical connectivity hypothesis, which postulates that initial wiring of the cortex is highly constrained by the spatial arrangement of the retinal ganglion cell mosaic and their coverage ratios. We examine a recently confirmed prediction of the theory: that orientation bandwidth must depend on the location of neurons within the orientation map. Finally, the theory is shown to predict the existence of orientation scotomas: At any given retinal location, not all orientations can be represented equally well by neurons in primary visual cortex.

Wiring of receptive fields and functional maps in primary visual cortex

To fully understand the development and the adult organization of primary visual cortex, there are three separate questions that must be addressed. First, we need to discover the mechanisms that are responsible for wiring receptive fields and cortical maps at the earliest stages of development (Albus & Wolf, 1984; Hubel & Wiesel, 1963; Sherk & Stryker, 1976). Second, we need a description of how activity-dependent processes maintain, modify, or refine these initial structures during the critical period (Crair, Gillespie, & Stryker, 1998; Crowley & Katz, 2002; Katz & Crowley, 2002; Miller, Erwin, & Kayser, 1999; Swindale, 1996). Third, we need to understand which features of the resulting receptive fields and cortical maps are vital for normal visual processing and which may arise as an epiphenomenon of developmental processes and wiring constraints (Adams & Horton, 2003; Chklovskii & Koulakov, 2000; Horton & Adams, 2005; Koulakov & Chklovskii, 2001; Purves, Riddle,

& Lamantia, 1992; Swindale, 1991). This chapter deals primarily with the early establishment of the circuit. We want to know how receptive fields and cortical maps are wired before the onset of the critical period. The reason this question is a critical piece of the puzzle of V1 development is clarified by a summary of some experimental findings.

In their pioneering studies of visual cortex, Hubel and Wiesel (1963) demonstrated that kittens lacking normal visual experience have cells that are tuned for orientation. They also found that orientation-tuned cells cluster into populations of similar preference, suggesting the presence of an early orientation map in these young animals (Hubel & Wiesel, 1963). These early cortical responses were also found to be heavily dominated by contralateral input (Crair et al., 1998; Fregnac & Imbert, 1978; Movshon & Van Sluyters, 1981).

Recent studies using intrinsic imaging of cortical activity in combination with single-unit electrophysiology have confirmed and refined these classical findings, showing that in kittens, orientation maps and ocular dominance columns are already present by two weeks of age (Crair et al., 1998; Crair, Horton, Antonini, & Stryker, 2001). Furthermore, there are no obvious differences in the development of ocular dominance and orientation maps of normal and binocularly deprived animals up to the third postnatal week, demonstrating that normal visual stimulation is not necessary for the early wiring of receptive fields and maps (Crair et al., 1998, 2001).

An important finding is that receptive fields with segregated ON and OFF subregions, which are characteristic of simple cells, are observed in the thalamo-recipient layers 4 and 6 as soon as the cortex becomes visually responsive (Albus & Wolf, 1984; Blakemore & Van Sluyters, 1975; Braastad & Heggelund, 1985; Hubel & Wiesel, 1963; Sherk & Stryker, 1976). Furthermore, the ratio between the numbers of simple and complex cells in the first weeks of development remains approximately constant and does not differ from that in the adult (Albus & Wolf, 1984; Braastad & Heggelund, 1985).

DARIO L. RINGACH Department of Neurobiology and Psychology, Jules Stein Eye Institute, David Geffen School of Medicine, University of California, Los Angeles, California

These data are difficult to reconcile with the notion that simple-cell receptive fields develop from a set of heavily overlapping ON/OFF inputs (Linsker, 1986; Miller, 1994; Reid & Alonso, 1995). If this were the case, one would have predicted (1) an initial prevalence of receptive fields with overlapping ON/OFF receptive fields with a progressive spatial segregation of subregions during development and (2) an increase in the ratio of simple to complex cells during this developmental process. Instead, the available data indicate that salient features of the adult cortical organization, including the subregion segregation of simple cells, orientation, and ocular dominance maps, manifest themselves at the earliest stages of cortical development, well before the onset of the critical period.

We are thus faced with the challenge of explaining how receptive fields and cortical maps are wired initially. A couple of hypotheses have been considered so far. One possibility is that the presence of structured spontaneous activity in the developing thalamus could drive the initial thalamo-cortical wiring (Miller, 1994; Miller et al., 1999). Such correlation-based models predict a specific pattern of activity: Thalamic cell pairs having the same center sign (either ON/ON or OFF/OFF) should be more correlated than cells with different center signs at small distances (on the scale of a subregion width); an opposite pattern, in which same-sign cells are less correlated than opposite sign pairs, should be observed at larger separations. This pattern of spontaneous activity and a synaptic connectivity rule by which “neurons that fire together, wire together” ensure the emergence of segregated ON/OFF subregions (simple-cell receptive fields) from overlapping ON/OFF inputs. To guarantee the periodicity of orientation columns, an additional mechanism that leads nearby cells to develop similar receptive fields and cells at large separations to develop different receptive fields must be invoked.

Recent measurements of spontaneous activity in the developing thalamus, however, have failed to corroborate the predicted pattern of correlations (Ohshiro & Weliky, 2006; Weliky & Katz, 1999). Instead of the predicted Mexican hat profile, one observes a Gaussian falloff of correlation for same-sign receptive fields and zero correlation for different-sign pairs at all distances. Under these conditions, the model fails to develop segregated ON/OFF subregions. These ideas could still be rescued by invoking a more complex “split constraint” that conserves the synaptic strength of ON and OFF center cells separately during development. However, its biological implementation is hard to imagine (Ohshiro & Weliky, 2006).

A second possibility is that molecular cues, involved in axonal guidance/patterning, help to establish the initial cortical architecture (Crowley & Katz, 2000; Katz & Crowley, 2002). If thalamic afferents carrying signals from overlapping ON/OFF-center receptive fields are to be sorted,

perhaps this is done by different molecular markers specifying the locations where each input type is allowed to create synaptic contacts on the target neuron, thereby generating nonoverlapping ON/OFF subregions.

Molecular guidance has been shown to be involved in the establishment of a coarse retinotopy and in retinogeniculate laminar segregation (Cang, Kaneko, Yamada, Woods, & Stryker, 2005; Huberman, 2007), yet its role in guiding connectivity at the fine spatial scales required to shape the structure of the subregions in individual receptive fields has never been demonstrated and appears unlikely. For example, it is difficult to conceive how different simple cells, on the same orientation column, could coordinate the expression of markers so that all their receptive fields develop similar orientation preferences.

Molecular patterning has also been proposed as underlying the generation of ocular dominance columns (Crowley & Katz, 1999; Hubener & Bonhoeffer, 1999; Katz & Crowley, 2002). This may be a more appealing possibility, owing to the larger spatial scales involved, but we should consider that functional maps are related in specific ways. In the cat, for example, orientation pinwheels tend to align with the centers of ocular dominance domains (Bartfeld & Grinvald, 1992; Grinvald, Frostig, Siegel, & Bartfeld, 1991), and peaks of low/high spatial frequency domains tend to align with the pinwheel centers (Everson, 1998, Issa, Trepel, & Stryker, 2000). Envisioning how molecular guidance by itself could simultaneously explain the development of cortical maps (retinotopy, ocular dominance, orientation, spatial frequency) and their relationships appears to be a rather difficult task indeed.

Arguably, these considerations weaken the case for spontaneous activity in the developing thalamus and molecular guidance as explanations for the early establishment of the cortical architecture. While it is premature to rule out their involvement altogether, one cannot help but wonder whether there are any other wiring mechanisms that have not been considered.

The proposal that I would like to discuss here was born out of the realization that the common assumption that simple cells develop from a set of overlapping ON/OFF receptive fields is not supported by the available data. Thus asking how simple cells arise from overlapping inputs is *not* the right question to pursue. The relevant question is how the subregions of simple cells could be wired without going through a developmental phase of substantial ON/OFF overlap.

The answer to this question, I propose, is that receptive fields of LGN afferents are not expected to have a high degree of overlap in the first place (Ringach, 2004, 2007). This assertion is based on the known statistics of retinal ganglion cell mosaics, the degree of overlap of their receptive fields (coverage ratios), and the fact that LGN cells are dominated by a single ganglion cell input (thereby reflecting the

spatial statistics of the RGC mosaic and their receptive fields) (Chichilnisky & Kalmar, 2002; Cleland & Lee, 1985; Usrey, Reppas, & Reid, 1999; Wässle, Boycott, & Illing, 1981). In other words, the solution to the problem of simple-cell wiring might rest on the recognition that the problem does not actually exist.

At first, this might appear to be a trivial observation, but it turns out to be one with profound implications. In a formal development of these ideas, I have shown that they not only lead to an explanation for how simple-cell receptive fields emerge early during development, but also provide an account for statistics of monosynaptic connections between the thalamus and cortex, the relationships between various cortical maps, and the dependence of neuronal selectivity across the functional architecture of the cortex. In the remainder of this chapter, we review some of these results at the conceptual level and highlight some curious predictions of the model.

Statistical connectivity theory

The working hypothesis behind the proposal is that the *blueprint* for the formation of simple-cell receptive fields in V1, the feature maps in the cortex and several of their mutual relationships, resides in the layout of the retinal ganglion cell mosaics in the contralateral eye combined with a simple statistical connectivity scheme between the thalamus and the cortex.

The notion that the structure of the RGC mosaic could influence the development of receptive fields in the cortex was first formulated by Wässle, Boycott, & Illing, (1981, p. 192) and considered by Soodak (1987). These investigators noted that nearest neighbors on the X-cell RGC mosaic tend to be of opposite sign, thus generating ON/OFF pairs in close proximity. The spatial statistics of the RGC mosaic are reflected in the LGN, as thalamic cells are driven mostly by one input. If cortical cells were to pool in space a small number of nearby thalamic afferents representing neighboring RGC inputs, the result would be the sum of slightly displaced ON and OFF Gaussian receptive fields. This would generate a simple-cell receptive field with a preference for orientation (figure 28.14).

It should now be apparent that this idea provides a way out of the puzzle of simple-cell wiring early in development, as it explains both the reason for a lack of overlapping ON/OFF inputs and how a simple (isotropic) pooling of afferent inputs can generate orientation-tuned cells. The model also predicts that individual subregion widths should be comparable to the width of the receptive field center of LGN afferents, as has been found experimentally (Alonso, Usrey, & Reid, 2001; Hubel & Wiesel, 1959, 1962). Furthermore, the model is consistent with the notion that simple-cell receptive fields in layer 4 are initially formed by summation

of inputs from a relatively small number of spatially displaced ON- and OFF-center LGN afferents (Gilbert, 1977; Heggelund, 1986).

If, as postulated, the local distribution of RGC receptive fields is responsible for inducing orientation tuning in the cortex, then it must be the case that V1 cells with different orientation preferences must get their input from RGC with receptive fields that do not overlap significantly (otherwise, the resulting preferred orientations would be similar) (figure 28.1B). This predicts the presence of *orientations scotomas*: At any given retinal location, and when input is restricted to one type of ganglion cells, not all orientations can be represented equally well by V1 receptive fields. This is because the RGC mosaic imposes severe constraints on the receptive fields that can be constructed at each location.

Experimental evidence for the existence of orientation scotomas would be of high significance, as it would not only confirm the model's prediction but also invalidate the classic view of the cortical hypercolumn as a population of neurons with overlapping receptive fields tuned for possible orientations preferences. The finding that large orientation differences between nearby cells are accompanied by large jumps in the retinotopic location is consistent with the prediction (Das & Gilbert, 1997), but we must note that this result remains highly controversial (Bosking, Crowley, & Fitzpatrick, 2002; Buzas, Volgushev, Eysel, & Kisvarday, 2003). Future studies using *in vivo* two-photon imaging (Ohki, Chung, Ch'ng, Kara, & Reid, 2005; Ohki et al., 2006) along with precise receptive field mapping procedures could potentially settle this issue.

The existence of orientation scotomas could potentially be tested psychophysically. One such attempt was performed by Zanker and Braitenberg (1996), who measured performance in an orientation discrimination task using very small lines of different lengths at various eccentricities. They noted that when detection performance is expressed in terms of the cortical size of the line (by taking into account the average human magnification factor), all data points collapse into a single curve, as is typical of many psychophysical tasks (Rovamo & Virsu, 1979; Watson, 1987).

Notably, it was found that performance levels of 60–80% can be achieved with stimuli that cover merely 0.2–0.3 mm of cortical territory. Because these are smaller than the size of an entire orientation cycle (about 1 mm in primates), they decided to use such small stimuli to map biases in orientation discrimination performance at different retinal locations. This attempt was only partially successful; in individual sessions, they obtained orientation biases that appeared to resemble orientation maps as measured by optical means. Unfortunately, these maps could not be consistently reproduced from one experimental session to the next. An obvious difficulty with their experiment (which the authors acknowledged) was the lack of control over eye movements and the

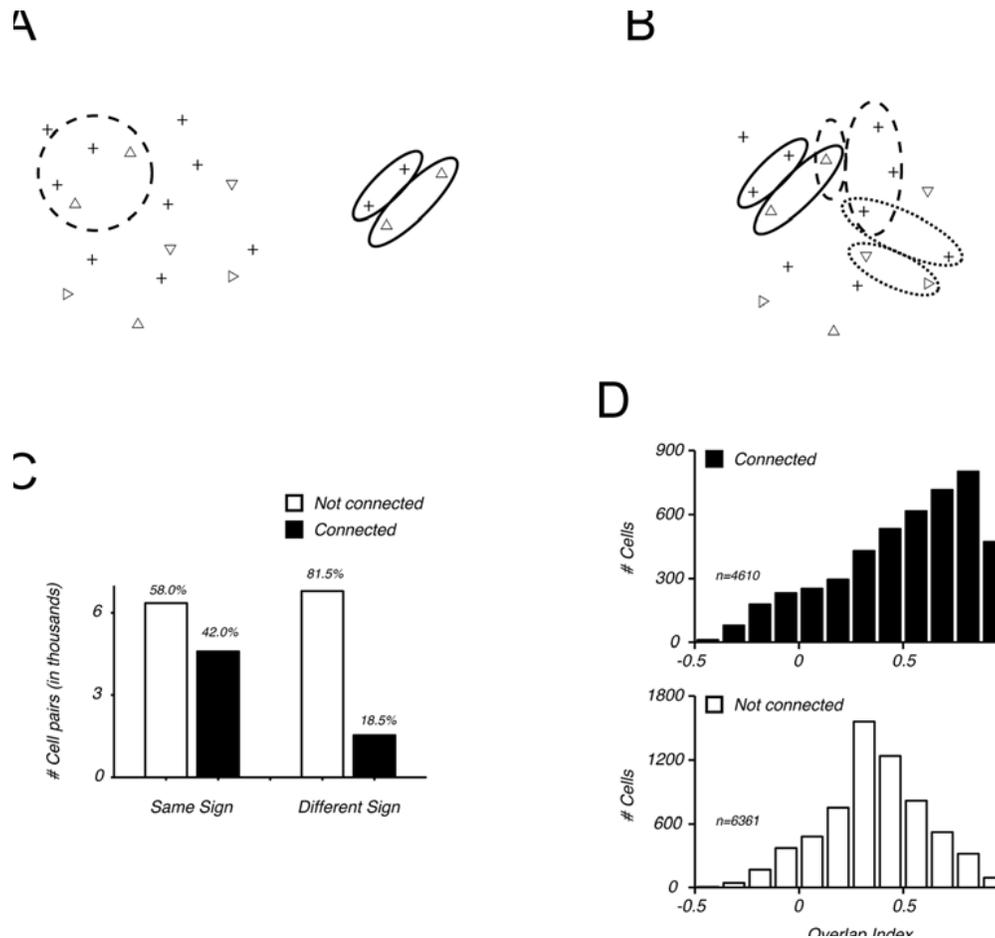

FIGURE 28.1 Conceptual description of statistical connectivity and some of its consequences. (A) The theory posits that the distribution of ON-center (plus signs) and OFF-center (triangles) retinal ganglion cells receptive fields, along with a moderate coverage ratio (the solid disks indicate 1 standard deviation of the receptive field center), and the isotropic sampling of incoming afferents (dashed circle) are responsible for the establishment of the early cortical architecture. In this example, sampling from the afferents within the indicated area would generate a receptive field with

ability to repeatedly stimulate the exact same retinal location across experimental sessions. We are currently attempting to perform similar psychophysical experiments while carefully monitoring eye movements.

Another success of statistical connectivity is in explaining the probability and strength of monosynaptic connections from thalamus to cortex. In particular, the model replicates the *sign rule* of connectivity (Alonso et al., 2001; Reid & Alonso, 1995). This refers to the finding that the probability of a monosynaptic connection is highest when the geniculate receptive field overlaps a simple-cell subregion of the same signature (either ON or OFF), while the probability of “inappropriate” connections between receptive fields of opposite signature is much lower. These data have been interpreted as supporting the existence of precise rules of synaptic connectivity in accordance with the classic wiring scheme for

adjacent ON/OFF subregions are shown to the right. (B) Two consequences of statistical connectivity can be inferred from this simple diagram. First, to obtain receptive fields with substantially different orientation, one must move to a different retinal location (orientation scotomas). Second, there should be a tendency for overlapping simple-cell receptive fields to have the same sign within the overlap area. (C, D) The theory is consistent with the statistics of thalamocortical connectivity. Both the sign rule and the distribution of receptive field overlap is explained by the model.

simple cells (Hubel & Wiesel, 1962). However, this interpretation rests on the assumption that the cortex receives afferents from a large number of overlapping ON and OFF geniculate receptive fields, which, as was discussed above, is incorrect.

Statistical connectivity offers an explanation for the apparent precision of thalamocortical wiring (figure 28.1C). In the model, an ON subregion of a simple-cell results in the event that an ON-center rather than OFF-center geniculate cell dominates that location of visual space. As a consequence, one would expect a tendency for ON subregions to avoid OFF inputs. The reason is simply that there are no OFF inputs to avoid at that location. A similar analysis is to plot the distribution of the correlation coefficient between the spatial receptive field of thalamic afferents and overlapping cortical receptive fields for cases in which cells were

connected or not. The model replicates two salient properties of these data: (1) Connected receptive fields have higher overlap indices than nonconnected pairs, and (2) the overlap index in the nonconnected case has a positive mean. The latter one is of high significance, as it indicates that one cannot experimentally find pairs with high negative correlation (whether connected or not). The only possible explanation is that such pairs are nonexistent.

Statistical connectivity also predicts orientation columns. That is, even if cells in the same column sample *independently* from the LGN afferents with some probability of connection, there is a tendency for them to have the same orientation preference (Ringach, 2004). This statistical sampling generates a diversity of the *relative* phase of the receptive fields, spanning the entire range from even symmetric to odd symmetric reception fields (DeAngelis, Ghose, Ohzawa, & Freeman, 1999). However, the model predicts that overlapping subregions of simple-cell receptive fields must agree in sign (figure 28.1B). This observation leads to another testable prediction of the model: different ON or OFF afferents from the LGN dominate the cortical input at different locations, generating a spatial-phase map on the cortex. Recent data confirmed this prediction in cat cortex (Jin et al., 2008), with similar organizations described previously in ferrets (Zahs & Stryker, 1988) and minks (McConnell & Levay, 1984).

Statistical connectivity and cortical maps

Statistical connectivity generates not only simple-cell receptive fields and orientations columns, but orientation maps as well (Ringach, 2007; Soodak, 1987). Detailed computer simulations have revealed several other important consequences of statistical connectivity (Ringach, 2007). First, the theory predicts that the local magnification factor should be directly related to local fluctuations in the density of the RGC mosaic. That is, fluctuations in the density of RGCs around its mean value, on a small spatial scale, should induce a parallel fluctuation in the local cortical magnification factor. The existence of fluctuations in the local magnification factor could potentially be tested by using *in vivo* two-photon imaging along with careful receptive field mapping. Second, statistical connectivity predicts that the orientation tuning width of individual cells should depend on their location within the orientation map. As we discuss below, we have recently obtained new data confirming this relationship. Third, it predicts the existence of spatial frequency maps and a tendency for preference for extreme spatial frequencies (high or low) to align with orientation pinwheels, as reported experimentally (Issa et al., 2000). Fourth, it predicts the existence of clustered regions of broad selectivity (identified as putative cytochrome-oxidase blobs) and a tendency for pinwheels to lie preferentially in interblob regions, which is supported by extant data

(Bartfeld & Grinvald, 1992; Hubener, Shoham, Grinvald, & Bonhoeffer, 1997).

The relationship between orientation selectivity and the location of neurons within the map has been the subject of several studies. While the subthreshold tuning of cells conforms with the prediction of the statistical connectivity model with broader tuning seen near pinwheel locations (Marino et al., 2005), the tuning of *spike* responses has been described as being invariant across the map (Maldonado, Godecke, Gray, & Bonhoeffer, 1997; Marino et al., 2005). We decided to take another look at this question using a novel technique (Nauhaus & Ringach, 2007). The method involves measuring the orientation map with optical means and then recording from multiple neurons with a micromachined electrode array. Briefly, we obtained the orientation map on a cortical patch of V1 using optical imaging (Bonhoeffer & Grinvald, 1991; Grinvald & Hildesheim, 2004) (figure 28.2A). Subsequent to the acquisition of the orientation maps, we implanted a 10×10 electrode array with grid spacing of 400 μm on the same cortical patch. Finally, we measured the orientation tuning of neuronal responses across the array using reverse correlation in the orientation domain, where the stimulus consists of a rapid sequence of gratings at random orientation (Ringach, Hawken, & Shapley, 1997). The average orientation-triggered response, at the optimal time delay, generates an orientation tuning curve (figure 28.2B). A Gaussian fit to each tuning curve provides an estimate of the preferred orientation, θ_0 , and tuning width, $\Delta\theta$.

The position of the array with respect to the orientation map is estimated by searching for the location that yields the maximum agreement between the preferred orientations measured optically and those measured from the electrode array. The outcome of this computation in one experiment is shown in the scatterplot of figure 28.2C, along with the estimated location of the array in figure 28.2A. The location of the array on the surface of the cortex is determined by just three parameters: two for its translation and one for its rotation. Because the number of parameters is small in comparison with the number of electrodes, the optimization problem is greatly overdetermined and robust to noise.

Once the array location has been estimated, we computed a measure of homogeneity in orientation preference for the neighborhood surrounding each electrode. We define a local homogeneity index at a cortical point by computing the magnitude of a vector sum. The vector angles are determined by the orientations in the map, and the magnitudes are defined by a spatial two-dimensional Gaussian window centered at the given cortical point. The local homogeneity index is bounded between 0 and 1. It is high in regions that exhibit similar preferences for orientation, such as iso-orientation domains, and low in regions where the preferences for orientation are diverse, such as near pinwheel

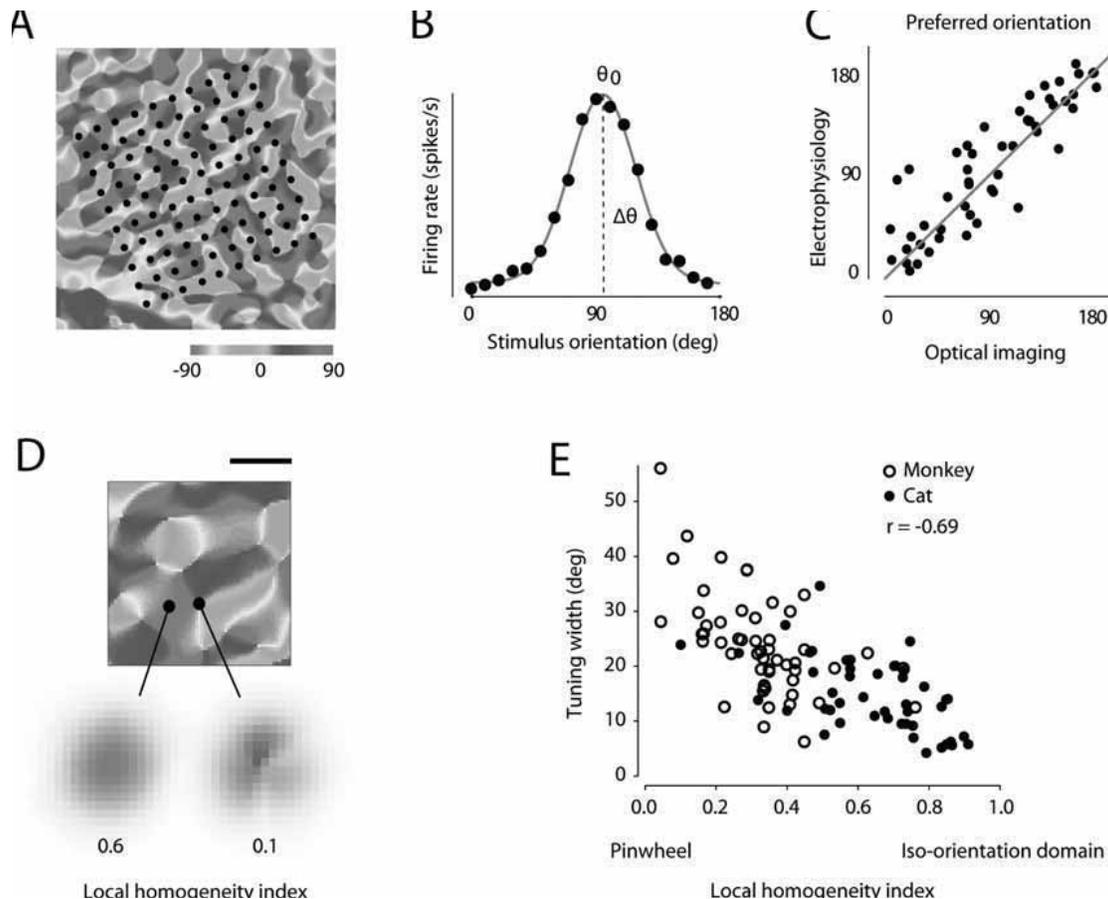

FIGURE 28.2 Orientation tuning bandwidth and local map structure. (A) Example of an orientation preference map in macaque visual cortex along with the recovered location of the microelectrode array. (B) Reverse correlation in the orientation domain (Ringach et al., 1997) was used to measure the tuning curves at each electrode site simultaneously. The example here shows the average spike rate triggered to the presentation of each orientation in a rapid stimulus sequence, yielding a preferred orientation, θ_0 , and tuning width, $\Delta\theta$. (C) The estimated location of the array (solid dots in panel A) was estimated by finding the optimal translation/rotation parameters for which the preferred orientations as measured via reverse correlation matched those measured optically.

centers (figure 28.2E). Using this method, we found that orientation tuning width and homogeneity index are negatively correlated in both monkeys ($r = -0.56$, $p = 0.00001$) and cats ($r = -0.56$, $p = 0.00005$) (figure 28.2E), as predicted by the model.

It should be emphasized that statistical connectivity is not the only possible explanation for this trend. One likely contribution to this relationship comes from the fact that the tuning properties of the local environment of a cell is likely to determine the tuning of the intracortical feedback signal and, in turn, the tuning of the cell (Marino et al., 2005; McLaughlin, Shapley, & Shelley, 2003; Schummers, Marino, & Sur, 2002). These two explanations are not mutually exclusive.

The scatterplot illustrates the optimal correlation in one instance. (D) A local homogeneity index was defined to capture the diversity of orientation preferences around each cortical point. The example illustrates two locations with a low homogeneity index of 0.1 attained near a pinwheel and a location with a high index of 0.6 in an iso-orientation domain. (E) Spatial distribution of the local homogeneity index for the same patch of cortex as the one shown in panel D. (F) Isolation of single units. Only units that could be very well isolated, as is typical of the principal component analysis here, were used in our analyses of tuning bandwidth and local map structure. (See color plate 42.)

Testing statistical connectivity

The status of statistical connectivity as a viable working hypothesis for the early wiring of receptive field and cortical maps derives from the fact that it is an extremely simple concept that can explain a large set of data, including the structure and emergence of simple receptive fields, the relationship between cortical maps, and the dependence of neuronal selectivity across functional maps.

There are many predictions that remain to be tested. A particularly interesting one is the existence of orientation scotomas. However, there are other ways to test the theory directly. If the theory is correct, given the structure of the RGC mosaic in the contralateral eye, one should be able

to predict the structure of the orientation map in the cortex. A positive result would unequivocally show a relationship between these two structures.

One way to proceed is to image cortical maps while recording in the LGN from a location with receptive fields that provide input to the imaged cortical region (Reid & Alonso, 1995). Injection of a retrograde label and subsequent recovery could allow the reconstruction of the RGC mosaic at the same location (Wassle, Boycott, & Illing, 1981). Careful measurement of the magnification factor is necessary to relate the RGC structure to the spatial scale of the orientation map. Ideally, such an experiment should be performed in animals in which the ipsilateral eye has been enucleated and the animal has been reared with only monocular input, as input from the ipsilateral eye can change the original structure of the orientation maps (Crair et al., 1998; Farley, Yu, Jin, & Sur, 2007).

Concluding remarks

In this chapter, I have tried to emphasize some important puzzles that remain unanswered about the early development of the visual system. I explained how in an effort to address these issues, in particular the rapid emergence of simple cells, we were led to a simple idea about how constraints imposed by the distribution of RGCs could establish the early blueprint of receptive fields and maps in the cortex. It was gratifying to discover that these ideas had already been considered in prior studies (Soodak, 1987; Wassle, Peichl, & Boycott, 1981). My contribution to the topic has been to extend the theory to include probabilistic sampling of the RGC mosaic and better understand the implications of these ideas beyond the establishment of orientation maps in the cortex, including the statistics of thalamocortical connectivity, the relationship between different cortical maps, and the dependence of tuning across the functional maps of the cortex. It is worth noting that similar concepts have been invoked as potential explanations for other properties of visual cells, such as their chromatic tuning (Lennie & Movshon, 2005; Solomon & Lennie, 2007).

There are a couple of obvious directions in which the theory can develop. First, if these ideas can be confirmed experimentally for the case of monocular input, it would be important to develop extensions to binocular inputs and investigate what mechanisms are involved in the wiring of binocular simple-cell receptive fields. In this respect, I have speculated that fluctuations in the RGC densities of matching retinal locations as possible seeding the pattern of ocular dominance columns (Ringach, 2007). Second, it is now clear that some rodents develop orientation tuning and simple cells without the presence of an orientation map (Ohki et al., 2005; Van Hooser, Heimel, Chung, Nelson, & Toth, 2005). Investigating the applicability and

limitations of statistical connectivity to other species that lack functional maps can be expected to be an instructive exercise.

As a final observation, I would like to submit the notion that statistical connectivity offers a potential explanation for the evolutionary emergence of simple-cell receptive fields. Given that edgeline filters are a crucial element in the representation of natural images (Bell & Sejnowski, 1997; Olshausen & Field, 1996; Simoncelli & Olshausen, 2001), one may ask what evolutionary path could have led to the appearance of simple-cell receptive fields in so many diverse species. Statistical connectivity suggests a simple recipe with only two ingredients: ON/OFF center cells with appropriate coverage ratios and simple spatial summation of the output of such neurons. Then the emergence of simple-cell receptive fields appears almost unavoidable, and their explicit signaling of object boundaries could have endowed organisms with a survival advantage. Such a route to the development of simple-cell receptive fields seems sensible, and it does not require the evolution of precise connectivity rules or the prior development of complex patterns of spontaneous activity and the learning rules that are required to implement them.

29 Encoding and Decoding with Neural Populations in the Primate Cortex

EYAL SEIDEMANN, YUZHONG CHEN, AND WILSON S. GEISLER

ABSTRACT Environmental stimuli are encoded by large neural populations in sensory cortical areas and subsequently decoded into motor plans by large neural populations in motor cortical areas. Furthermore, large populations of neurons are likely to exhibit new emergent properties that are difficult or impossible to infer from the activity of single neurons, recorded one at a time. Thus, to understand encoding and decoding in the cortex, it is essential to measure and analyze neural population responses, ideally in behaving subjects. In this chapter we review recent progress in experimental techniques for measuring simultaneously the activity of large neural populations; we discuss several important emergent properties of neural population responses; and we describe a Bayesian ideal observer framework that, when applied to simultaneous measurements of neural population responses and behavioral performance, can be used to rigorously explore encoding and decoding strategies at the level of neural populations.

Sensory stimuli are encoded by large populations of neurons in sensory cortical areas and later decoded into motor plans that are implemented by large populations of neurons in motor cortical areas (figure 29.1). The specific encoding and decoding circuits that are implemented in the cortex are undoubtedly shaped by a number of factors, including the natural tasks that the organism performs, the properties of the sensory stimuli and musculature that are relevant to performing those tasks, the biophysical and anatomical properties of neurons, and the available space and metabolic resources.

These considerations raise many fundamental questions. For example, what are the number and identity of neurons in a given cortical area that contribute to a behavioral response? What aspects of the stimulus or behavior are represented in the signals from these neurons, and how are they encoded in the neural response? How are these signals combined over space and time to mediate behavior? Are these encoding and decoding algorithms fixed, or do they depend on the specific

requirements of the task? Addressing such questions is one of the key challenges facing systems neuroscience.

Over the past several decades, the primary approach to addressing these questions has been single-neuron electrophysiology in combination with measurement of the stimuli and/or behavioral responses. While much has been learned by using this approach, it will be difficult, if not impossible, to fully understand how neural circuits in the mammalian cortex encode and decode information on the basis of single-unit electrophysiology. The reason is simply that large populations of neurons are likely to exhibit new and fundamentally different *emergent properties* that might not be evident from recordings of individual neurons, one at a time. Therefore we believe that it is important to shift the focus from single neurons to populations of neurons by directly measuring the properties of neural population responses, ideally in behaving subjects. In addition, to understand the implications of these properties, it is necessary to develop a theoretical framework that would allow a rigorous exploration of possible encoding and decoding strategies at the level of neural populations. In this chapter, we describe recent progress along these two lines of research.

The main focus in this review is on the primary visual cortex (V1) of primates, because this sensory area is arguably the best understood in terms of its anatomy, neuronal response properties, and functional organization (de Valois & de Valois, 1988; Hubel & Weisel, 1977). However, most of the results and theoretical considerations described below are likely to apply to other cortical areas and species. To illustrate some of the general experimental and theoretical issues that are relevant for understanding population coding and decoding, we discuss some of our measurements with voltage-sensitive dye imaging (VSDI) in V1, because these measurements forced us to think generally about the expected response properties of large populations of neurons. Two goals of this chapter are to stimulate more research on population encoding and decoding and to emphasize the importance of using multiple complementary techniques to measure neural population activity.

EYAL SEIDEMANN, YUZHONG CHEN, and WILSON S. GEISLER Department of Psychology and Center for Perceptual Systems, University of Texas, Austin, Texas

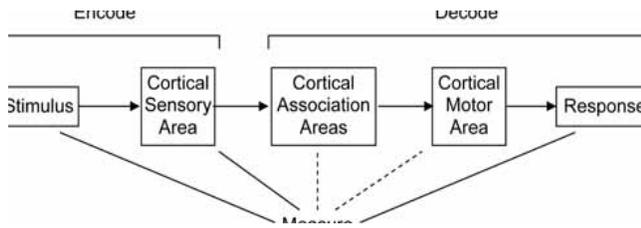

FIGURE 29.1 Schematic representation of processing stages in perceptual tasks. The solid lines indicate the measurements that are the focus of this review.

We begin this review by describing a computational framework that can be used to explore possible population encoding and decoding mechanisms. We then describe the advantages and disadvantages of some of the experimental tools currently available for monitoring population responses in vivo. We next discuss key properties of population responses in the primate cortex. We end with a general discussion that includes open questions and future research directions.

Theoretical framework for studying population encoding and decoding

The responses of the neural population in a given sensory cortical area contain a certain amount of information that is potentially available to support performance in a given task. This information could be characterized, in principle, by measuring the statistical relationship between relevant environmental stimuli and response properties of the neural population at the given stage. Further, this information can be quantified, in principle, by deriving the ideal Bayesian observer (for the given task) that has complete knowledge of the statistical relationship between environmental stimuli and the population response. An ideal observer is a theoretical device that performs a task optimally given the available input signals, knowledge of the prior probabilities of different possible stimuli, and knowledge of the cost and benefits of the possible stimulus-response outcomes (Geisler, 1989; Green & Swets, 1966). The performance of the ideal Bayesian observer is the appropriate measure of the neural information potentially available for specific tasks, and it is the measure we will use here.¹

Not all response properties of a neural population might be relevant for a given task (i.e., would improve the ideal observer's performance); therefore one important goal is to determine which properties of the population's responses carry information relevant to a given task and which do not. On the other hand, there may be relevant response properties that the organism does not use to perform a given task because of limitations of the decoding mechanisms. For example, subsequent stages might be unable to select responses from an individual neuron (or arbitrary subset of neurons) in the population or use precise spike-timing infor-

mation, even if this could lead to improved performance. It is also possible that the organism uses some irrelevant (potentially performance-degrading) properties. Thus a second important goal is to determine which properties of the population responses the organism uses to perform a given task. Finally, a third important goal is to determine how these properties of the population responses are translated by subsequent circuits into behavioral responses. Here we define the *actual code* for a task as those specific properties of the population responses that the organism does use in performing the task, we define the *actual encoder* for the task as those specific neural mechanisms that translate the sensory stimulus into the actual code, and we define the *actual decoder* for the task as the specific subsequent neural mechanisms that translates the actual code into perceptual decisions and motor plans (see figure 29.1).

For any given task and set of neural constraints (e.g., some fixed number of neurons with specified anatomical and biophysical limits), there is an *optimal encoder* that translates the sensory stimuli into the neural population code that carries the most information relevant to performing the task. Similarly, for any given task and population code, there is an *optimal decoder*. The concepts and mathematics of ideal observer theory can be used to derive both optimal encoders and decoders. Determining the optimal encoder and decoder can be very useful in the quest to identify the actual encoder and decoder, because the exercise generally leads to a deep understanding of the computational requirements of the task and often provides principled (and sometimes unexpected) hypotheses for the neural mechanisms.

Although much has been learned and much remains to be learned about encoding mechanisms in sensory areas (e.g., Geisler, 2008; Simoncelli & Olshausen, 2001), because of space limitations the focus in this chapter is on evaluating possible decoding mechanisms based on measured neural population responses in sensory areas.

To further illustrate these ideas, consider a thought experiment in which an organism is required to discriminate between two barely discriminable stimuli. Assume that all the sensory information relevant for performance in this task passes through a single cortical area and that, as experimenters, we have precise access to the responses of all neurons in this area, to the stimulus, and to the behavioral response of the subject. In this case, the Bayesian framework outlined above allows us to determine how to perform the task optimally based on these neural signals and to determine the behavioral sensitivity that could be supported by this optimal decoder. Because we have access to all the neural signals that are available for the organism to perform the task, the optimal decoder must do as well as, or better than, the organism.

The ideal Bayesian observer analysis provides several key benefits. Equal performance of the ideal observer and the organism implies that the organism is using all the relevant

neural information and is employing an optimal decoder; it also implies that subsequent processing stages are effectively noiseless. Significantly better performance for the ideal observer implies that the organism is using either a suboptimal code, a suboptimal decoder or both. (Note that a decoder could be suboptimal because it implements the wrong algorithm and/or because it introduces neural noise.) If the optimal decoder is significantly more sensitive than the organism, one can explore the range of possible codes and decoders that could still account for the subject's performance, assuming noiseless subsequent processing stages. To determine what aspects of the neural responses are essential in order to explain the performance of the organism, one can measure the consequences of ignoring some aspects of the neural signals on the performance of the ideal observer. For example, one can evaluate the importance of the precise timing of spikes by integrating over a temporal window that can be gradually increased to determine when the ideal observer's performance falls short of the subject's. Similarly, one can evaluate the importance of individual neurons by only considering the summed response from pools of m neighboring neurons for various values of m . Any suboptimal code that reduces the sensitivity of the optimal decoder to a level that is lower than the sensitivity of the organism can be rejected. More generally, any combination of code and decoder that falls short of the subject's performance can be rejected as a possible mechanism used by the organism.

While the above thought experiment clearly cannot be achieved in the primate cortex by any single currently available technique (see discussion), we demonstrate below that this framework can still be useful when applied in conjunction with existing neurophysiological methods.

Current techniques for measuring neural population responses in vivo

Currently available techniques for monitoring responses of neural populations fall far short of fulfilling our thought experiment. Here, we briefly review the advantages and limitations of three techniques that seem particularly promising for studying population coding in the primate cortex: multielectrode recording, optical imaging with voltage sensitive dyes, and two-photon imaging of calcium-indicator signals in multiple single cortical neurons.

Large arrays of microelectrodes for extracellular recordings from multiple single cortical neurons are an important emerging technique (e.g., Churchland, Yu, Sahani, & Shenoy, 2007; Kelly et al., 2007; Nauhaus, Benucci, Carandini, & Ringach, 2008; Nicolelis & Ribeiro, 2002). The advantages of this technique are submillisecond temporal resolution and access to spiking activity at the single-neuron level. The main disadvantage is that it samples the activity fairly coarsely over space (typically a few hundred

microns between electrodes, due to electrode density limitations). Therefore it is limited to recording a tiny fraction of the neurons in several square millimeters. This technique may also suffer from sampling biases (e.g., bias toward neurons with large cell bodies and therefore large spikes, bias against very selective neurons with very low spontaneous rate). The spatial sampling of this technique could potentially be improved by also recording multiunit activity and local field potentials from each electrode, but the quantitative relationship between these measurements and the activity of single units still needs to be explored.

VSDI has recently been adapted for studies in alert, behaving primates (Seidemann, Arieli, Grinvald, & Slovlin, 2002; Slovlin, Arieli, Hildesheim, & Grinvald, 2002). In this technique, voltage-sensitive fluorescence dyes are applied topically to the surface of the cortex (for a review, see Grinvald & Hildesheim, 2004). The dyes bind nonselectively to cellular membranes. In the membrane, the dye molecules transduce, essentially instantaneously and linearly, changes in membrane potential into fluorescence signals. The dye signals therefore represent the summed changes in membrane potentials in cell bodies, axons, and dendrites in the superficial cortical layers. The main advantages of this technique are its millisecond temporal resolution and its large field of view (typically 1–2 cm²). As will be discussed below, this large field of view is necessary in order to cover the entire region within a given cortical area that is activated even by a small localized stimulus (figure 29.2). The main limitation of this technique is its spatial resolution. Because dendrites and axons of cortical neurons spread horizontally over several hundred microns, signals collected by each imaging pixel combine responses from large numbers of neurons and neural elements in a nonselective manner. This nonselective summation could significantly degrade the VSDI signals relative to the actual neural code. A second limitation is that the signals are restricted to the superficial cortical layers (approximately the top 500 μ m). However, the superficial layers contain many apical dendrites of neurons whose cell bodies are located in deeper layers. Finally, VSDI signals in vivo are weak and contaminated by various sources of noise. However, our recent results discussed below, suggest that most of the nonneural sources of noise can be removed reliably (Chen, Geisler, & Seidemann, 2006, 2008).

Two-photon imaging of calcium-indicator signals is an exciting new addition to the arsenal of tools that are available for studying population responses in vivo (Kerr et al., 2007; Ohki, Chung, Ch'ng, Kara, & Reid, 2005; Stosiek, Garaschuk, Holthoff, & Konnerth, 2003; for a recent review, see Kerr & Denk, 2008). This is the only technique that allows measuring the activity of all the neurons in a small region simultaneously, with single-neuron resolution. Because changes in the calcium signal are relatively slow, inferring activity at the level of single spikes

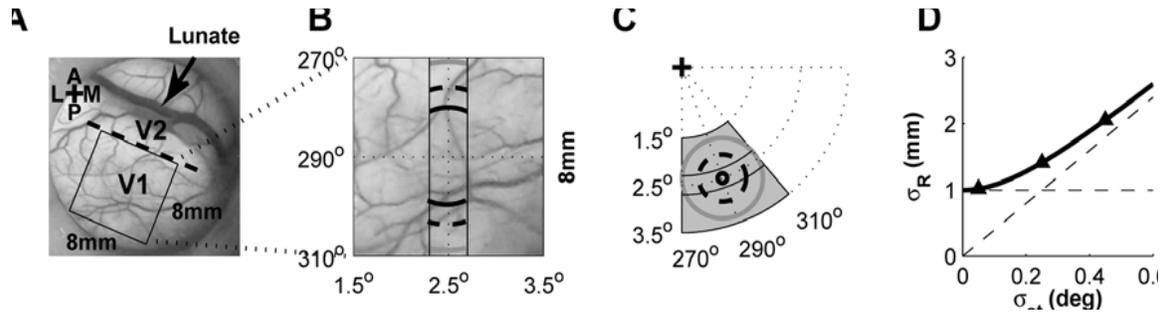

FIGURE 29.2 Expected spread of activity in the visual cortex in response to a small localized visual stimulus. (A) Cranial window over V1 in the left hemisphere of one monkey. The cortical vasculature is seen through a transparent artificial dura (Arieli, Grinvald, & Slovin, 2002). A typical region of interest of $8 \times 8 \text{ mm}^2$ with its anterior border running along the V1/V2 border is indicated by the black square. (B) Expanded view of the cortical vasculature in the $8 \times 8 \text{ mm}^2$ region of interest. (C) Representation of the lower right visual field with a fixation crosshair in the top left. The shaded wedge region is the approximate portion of the visual field that is represented in the patch in panel B. The mapping from visual space to the cortex is indicated in panels C and B, respectively. The solid,

dashed, and gray circles in panel C represent the outline (at $\pm 2\sigma_{st}$) of Gabor patches with σ_{st} of 0.05° , 0.25° , and 0.45° , respectively. The corresponding arcs in panel B indicate the expected spread of activity in response to the three stimuli in a narrow strip of cortex along the representation of 2.5° eccentricity (see text for additional details). (D) Expected spread of cortical activity σ_R as a function of stimulus size σ_{st} . The dashed horizontal line indicates the minimal spread, which corresponds to the average V1 receptive field size (σ_{rf} of 0.25 degree) multiplied by the CMF at this eccentricity (4 mm/degree). The oblique dashed line shows the expected spread of cortical activity based solely on the CMF.

can be challenging, particularly when firing rates are above a few hertz. Also, because this is a scanning technique, there is an inherent tradeoff between frame rate and field of view. At high frame rates, the technique is currently limited to recording several dozen neurons within a fraction of a square millimeter. Finally, as with VSDI, this technique is currently limited to recording from the superficial cortical layers. Overall, this is a promising new technique, but more work is necessary before it will be applicable to alert, behaving primates.

These techniques promise new and exciting discoveries in the coming years. Given their limitations, however, we believe that to address questions of encoding and decoding by populations of neurons, it will be necessary to use complementary techniques and to develop quantitative understanding of the relationship between measurements provided by these and other techniques.

Properties of population responses in the primate cortex—mean response

Here, we focus on three key properties of the mean population response—spatial spread, sparseness, and temporal dynamics—using the primary visual cortex (V1) as an example.

SPATIAL SPREAD OF THE POPULATION RESPONSE Consider the spread of activity in a small patch of $8 \times 8 \text{ mm}^2$ cortex on the dorsal portion of macaque V1 (figure 29.2). V1 contains a topographic map of visual space, with disproportional representation of the center of gaze (fovea). As one moves

from the representation of the fovea toward the periphery (increasing the eccentricity), receptive fields (RFs) of V1 neurons become larger, and the cortical magnification factor (CMF), the distance in cortex that corresponds to a given distance in visual space, decreases, both changing approximately by a power law (Tootell, Switkes, Silverman, & Hamilton, 1988; Van Essen, Newsome, & Maunsell, 1984; Yang, Heeger, & Seidemann, 2007). This patch of cortex represents a wedged-shaped region in visual space (shaded region in figure 29.2C), extending approximately from an eccentricity of 1.5 degrees to 3.5 degrees (degrees of visual angle) and representing directions about the visual axis between 270 and 310 degrees (angular degrees). Here, we consider the population response in a narrow vertical strip that is centered on the cortical representation of 2.5 degrees eccentricity, where the CMF is approximately 4 mm/degree. RFs of V1 neurons have an envelope that is approximately a two-dimensional Gaussian, with a space constant σ_{rf} that is on average around 0.25 degree at this eccentricity (Nienborg, Bridge, Parker, & Cumming, 2004; Palmer, Cheng, & Seidemann, 2007). The dashed circle in figure 29.2C shows a typical RF with diameter of 1 degree ($4 \times \sigma_{rf}$).

The expected spatial profile of the population response in V1 can be obtained by filtering (convolving) the retinotopic projection of the stimulus to the cortex with the average RF expressed in millimeters of cortex (under linearity assumptions, which are approximately true for small localized stimuli). Specifically, if the stimulus has a Gaussian envelope (e.g., Gabor patch), the expected spread of activity in the cortex would also be a Gaussian with a space constant σ_R given by

$$\sigma_R = \sqrt{(\sigma_{st} \cdot CMF)^2 + (\sigma_{sf} \cdot CMF)^2}$$

where σ_{st} is the space constant of the Gabor patch. Thus the spread of the cortical response depends on the size of the stimulus and on the size of the average RF.

Figure 29.2B shows the expected extent of cortical activity in response to the stimuli with Gaussian envelopes indicated by the circles in figure 29.2C (plotted at diameter of $4 \times \sigma_{st}$). Finally, figure 29.2D shows σ_R as a function of σ_{st} . For small stimuli, σ_R asymptotes at $\sigma_{sf} \times CMF = 1$ mm. This simple analysis therefore shows that the smallest activated area in this region of V1 has a diameter of about 4 mm (see McIlwain, 1986, for a related discussion).

In the analysis above, we made several simplifying assumptions. In reality, the spread is likely to be higher, because at any given location in V1, the RF centers are significantly scattered (DeAngelis, Ghose, Ohzawa, & Freeman, 1999). In addition, because there is a wide range of RF sizes at each V1 location, with neurons with larger RFs selective to lower spatial frequencies (De Valois, Albrecht, & Thorell, 1982), the extent of the cortical spread is likely to depend on the spatial frequency of the stimulus. Nevertheless, even for the stimulus that produces the smallest spread, the response is still likely to encompass multiple square millimeters in V1.

So far, we have considered the expected spread of spiking activity in V1 based on retinotopy and average receptive field size. Figure 29.3A shows the spread of VSDI signals in a similar patch of macaque V1 in response to a small Gabor stimulus ($\sigma_{st} = 0.33$ degrees). As expected, activity spreads over a wide region and is well fitted by a two-dimensional Gaussian with space constants that are on the order of 1.5

to 2 mm. The response is elongated, owing to the anisotropy in the retinotopical map in this region of V1 (Tootell et al., 1988; Van Essen et al., 1984; Yang et al., 2007). Although response amplitude depends strongly on target contrast, the spatial profile of the response does not (Chen, Geisler, & Seidemann, 2006). The white ellipse shows the $\pm 2\sigma_R$ contour based on the fitted VSDI response. The black ellipse shows the $\pm 2\sigma_R$ contour that is expected on the basis of the stimulus size and the approximate CMF and average RF size in this area. The predicted σ_R is approximately 30% smaller than the observed σ_R . This difference is expected because of the subthreshold contribution to the VSD signal and because of scatter in receptive centers and sizes. The relatively small difference between the predicted spread of spiking activity and the observed VSDI spread suggests a close relationship between VSDI signals and spiking population responses.

The theoretical and experimental results that are discussed in this section indicate that even the most localized sensory stimulus activates millions of neurons in a region encompassing multiple square millimeters in sensory cortex. Next we consider how neurons in this large population are likely to respond to small localized stimuli.

SPARSENESS OF POPULATION RESPONSES V1 neurons are tuned to multiple stimulus dimensions, including position, size, orientation, spatial frequency, temporal frequency, stereoscopic depth, wavelength, and motion direction (de Valois & de Valois, 1988; DeAngelis et al., 1999; Geisler & Albrecht, 1997). Intuitively, because V1 neurons are tuned across multiple dimensions, any small localized stimulus will activate strongly only a small fraction of the neurons in the population.

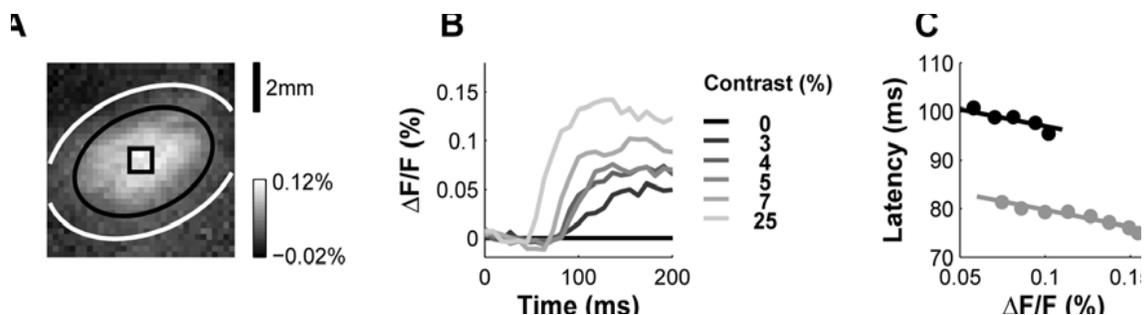

FIGURE 29.3 Spatiotemporal properties of V1 population response to a small Gabor target (σ_{st} of 0.33 degree) as measured by VSDI in one experiment. (A) Spatial profile of response amplitude to the Gabor target at 25% contrast. Response amplitude is computed as the average amplitude in a 200-ms-long temporal interval following target onset. The white ellipse indicates the contour of a two-dimensional Gaussian fit to the evoked response (at 2-standard-deviations). The black ellipse indicates the 2-standard-deviation contour of the expected region of spiking activity (see text). The square shows a 1×1 mm² region centered at the most sensitive location. (B) Time courses of average VSDI signals in response

to targets at different contrasts after subtraction of the average response in target absent trials. (C) Response latency as a function of response amplitude for 25% (gray) and 7% (black) target contrasts. Time courses were averaged in regions with similar response amplitude and fitted with sigmoidal function. To obtain regions with similar response amplitude, the fitted two-dimensional Gaussian was divided into 10 elliptical annuli containing response amplitudes within 10 quantiles (e.g., the second innermost annulus contains location with response between 80% and 90% of R_{max}). Latency is time to half maximum. Lines show best fit linear regression.

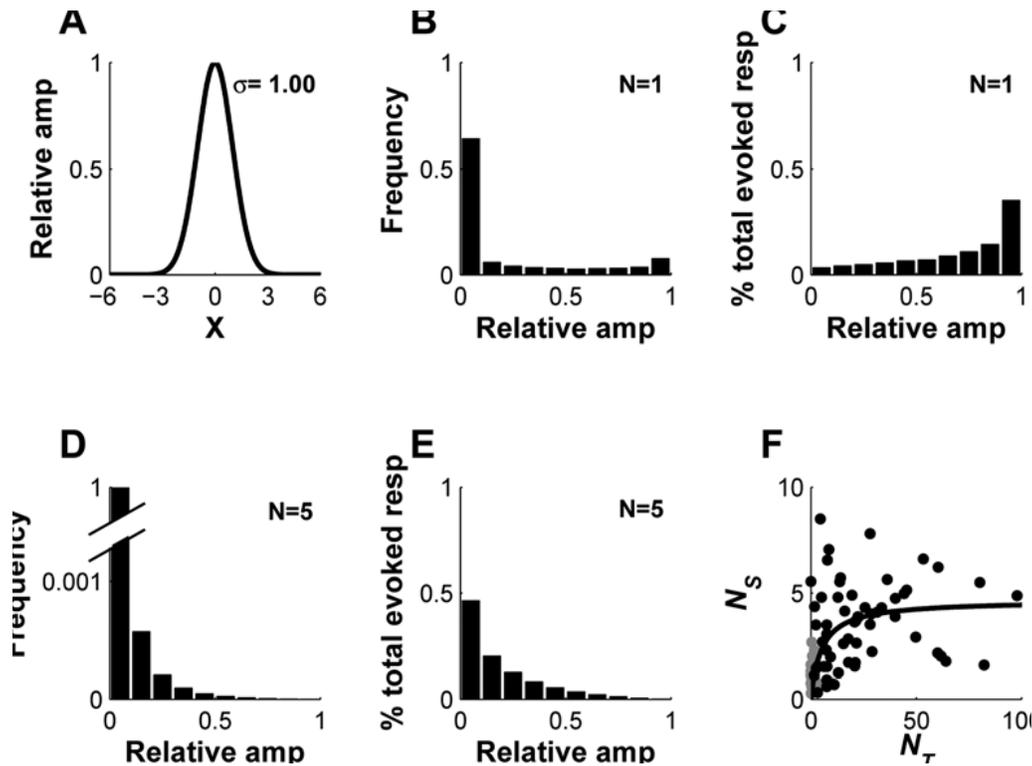

FIGURE 29.4 Interactions between tuning width, number of stimulus dimensions to which neurons are selective, and sparseness of the population response, based on a hypothetical population of neurons. (A) Gaussian tuning curve of one neuron across one stimulus dimension. Neurons in the population are assumed to have the same tuning curve properties across all stimulus dimensions and to uniformly cover the full stimulus range. (B) Frequency histogram of the relative response amplitude to a random stimulus assuming that neurons are tuned to one stimulus dimension. (C) Percentage of the total stimulus-evoked response contributed by neurons in the different bins in panel B. (D and E) Same as

panels B and C but for five independent stimulus dimensions. (F) Quantitative relationship between baseline and stimulus-evoked response of single neurons and multiunits measured in macaque V1. The scatterplot shows the equivalent number of selective single units, N_S , that can account for the multiunit response evoked by an optimal Gabor patch versus the expected total number of single units, N_T , that contribute to the baseline multiunit response. Gray circles represent single units; black circles represent multiple units. The solid curve is the fit to the observed multiunit data with a saturating function. (See Palmer, Cheng, & Seidemann, 2007, for additional details.)

This section considers the relationship between neural tuning width, the number of stimulus dimensions that are represented by the population, and the sparseness of the response within the population. For simplicity, we ignore the specific details of the tuning properties of V1 neurons and consider a hypothetical population of neurons tuned uniformly across n stimulus dimensions. Figure 29.4A shows a Gaussian tuning curve of one neuron across one circular stimulus dimension (such as orientation) with 2σ equal to one-sixth of the full range, a value that is comparable to the average orientation tuning width in V1 (Geisler & Albrecht, 1997). Assume for the moment that this is the only stimulus dimension along which the neurons in the population are tuned and that the neurons uniformly cover the full stimulus range. Given the tuning curve, we can determine the fraction of neurons in the population that are expected to respond at any level of activity to a random stimulus. Figure 29.4B shows a frequency histogram of the expected proportion of the population at each of 10 response-level quantiles.

The distribution is bimodal, with more than 50% of the neurons responding at less than 10% of their maximal response (R_{max}) but a significant fraction of neurons responding at more than 90% of R_{max} . From this distribution, we can also determine the percentage of the total stimulus-evoked population response contributed by neurons at each of the 10 response quantiles (figure 29.4C). In this case, about 30% of the total evoked response is contributed by the most active neurons, and the percentage of the total response decreases monotonically with decreasing mean response. Finally, we can compute ω_1 , the ratio of the average stimulus-evoked response to R_{max} . In this case, ω_1 is about 0.2. (More generally, this ratio is given by $\omega_n = \omega_1^n$, where n is the number of independent stimulus dimensions.)

The picture changes dramatically if we consider five stimulus dimensions (figures 29.4D and 29.4E). Now more than 99.9% of the neurons in the population fall in the lowest amplitude quantile, and the proportion of neurons in the highest quantile is less than 10^{-6} . Similarly, when we con-

sider the percentage of the total stimulus-evoked response across the population, almost half of the response is contributed by the neurons in the lowest quantile, and less than 8% of the response is contributed by neurons responding above 50% of their R_{max} . Finally, in this case, ω_5 is equal to $\omega_1^5 \cong 3 \times 10^{-4}$. In other words, a population of 10,000 neurons is expected to produce a stimulus-evoked response that is equivalent to only three neurons firing at their R_{max} .

These theoretical considerations are qualitatively consistent with findings from a recent study in which we compared the responses of single and multiple units in V1 to small Gabor patches (figure 29.4*F*; see also Palmer et al., 2007). When the baseline of the multiunit activity is consistent with as many as 100 single neurons, the stimulus-evoked response is consistent, on average, with only four to five neurons firing at their maximal rate, indicating that most of the neurons that are contributing to the multiunit signal are only weakly responding to the stimulus.

DYNAMICS OF THE POPULATION RESPONSE The large field of view and high temporal resolution of VSDI allow precise measurement of the spatiotemporal dynamics of the population response. Figure 29.3*B* shows the time course of the VSD response, at the center of the active region, to a Gabor patch at different contrasts. As the contrast is lowered, response amplitude drops and response latency increases. Similar interactions between stimulus contrast and response latency have been observed in single-unit electrophysiology (e.g., Albrecht, Geisler, Frazor, & Crane, 2002).

The spatiotemporal dynamics of the average stimulus-evoked response are illustrated in figure 29.3*C*. For a given contrast, response latency is almost constant across space. For example, the latency of the response to the 25% contrast Gabor patch at the peak location was only 5.7 ms faster than the latency several millimeters away at a region with response amplitudes that are only 20–30% of the peak response. Although response amplitude and latency strongly depend on target contrast, this rapid spatial spread appears to be similar at the two contrasts (for additional details, see Chen, Geisler, & Seidemann, 2008).

Properties of population responses in the primate cortex: Response variability

We now describe several key properties of the response variability of neural populations as measured by VSDI in V1 and discuss possible reasons why these properties are markedly different from those measured at the single neuron level.

ADDITIVE VERSUS MULTIPLICATIVE NOISE In single cortical neurons, the variance of the spike count during a short interval is proportional to the mean (Geisler & Albrecht, 1997; Tolhurst, Movshon, & Dean, 1983). What is the

expected relationship between the mean and the variance of the response in large populations of neurons?

As was noted in the previous section, the vast majority of the neurons in the population are expected to produce a very weak response to any given stimulus. V1 neurons, however, have a significant baseline or spontaneous response even in the absence of any sensory stimulus. Because all the neurons in the population contribute to the baseline response, the variability in the population response is likely to be dominated by the variability of the baseline response, which is, by definition, stimulus independent (for additional details, see Chen et al., 2008). These considerations have two important implications. First, they imply that additive noise is expected in any technique that measures the responses of large populations of cortical neurons. Second, they imply that any decoding mechanism that pools indiscriminately the activity of a large number of neurons is likely to encounter a largely stimulus-independent additive noise.

Figure 29.5*A* shows the mean and standard deviation of the VSDI signals as a function of stimulus contrast. Consistent with the theoretical considerations discussed above, the variability of the population response is contrast independent and additive (see also Arieli, Sterkin, Grinvald, & Aertsen, 1996; Chen et al., 2006).

Two additional factors specific to VSDI may contribute to the additive nature of the observed variability. First, VSDI signals are likely to contain a significant contribution from subthreshold synaptic activity. Intracellular measurements in anesthetized cats suggest that the variability at the level of the membrane voltage may be relatively stimulus independent or even decrease with increasing target contrast (Priebe & Ferster, 2008). Second, it is possible that nonneural sources of noise dominate VSDI measurements. This is unlikely because VSDI signals in anesthetized cat are highly correlated with intracellular measurements from single neurons and with local field potentials recorded simultaneously, and are also correlated with spiking activity in the same area (Arieli et al., 1996; Grinvald et al., 1999). In addition, our results (discussed below) demonstrate that the VSDI measurements are exceedingly sensitive in simple visual detection tasks, suggesting that nonneural sources of noise are unlikely to be large.

In summary, simple theoretical considerations predict that large populations of neurons should exhibit variability that is approximately additive and not multiplicative, consistent with VSDI results. Additional measurements using complementary techniques should be used to verify this important prediction.

SPATIAL CORRELATIONS IN THE POPULATION RESPONSE The magnitude and extent of spatial correlations in response variability can have a large impact on the improvement in performance that can be attained by pooling responses over

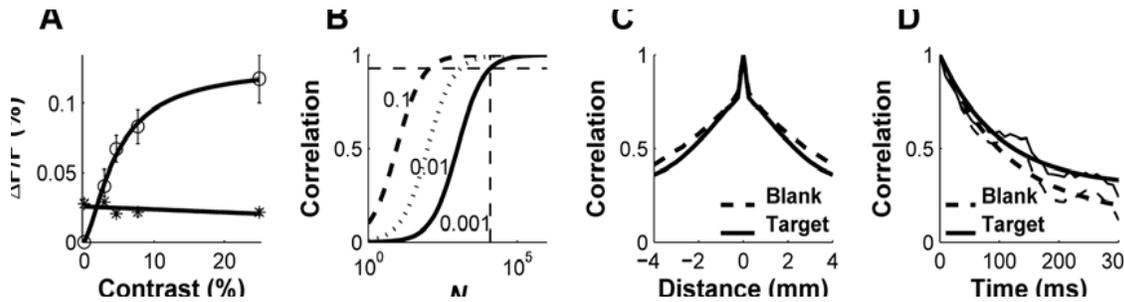

FIGURE 29.5 Statistical properties of population response variability as measured by VSDI. *A*, mean (circles) and standard deviation (asterisks) of response amplitude as a function of stimulus contrast averaged across eight VSDI experiments. Error bars indicate the standard error of the mean. The mean response as a function of contrast is fitted with a Naka-Rashton function; the standard deviation as a function of contrast is fitted with linear regression. The slope of the regression is not significantly different from zero (i.e., stimulus-independent additive noise). *B*, Expected correlations between the summed activity in two pools of neurons with uniform pairwise correlations, as a function of the number of

large populations of neurons (e.g., Abbott & Dayan, 1999; Averbeck, Latham, & Pouget, 2006; Johnson, 1980; Snippe & Koenderink, 1992; Sompolinsky, Yoon, Kang, & Shamir, 2001). Extracellular recording studies have measured the correlations in spiking activity between pairs of nearby cortical neurons (e.g., Bair, Zohary, & Newsome, 2001; Gawne & Richmond, 1993; Lee, Port, Kruse, & Georgopoulos, 1998; Romo, Hernandez, Zainos, & Salinas, 2003; Zohary, Shadlen, & Newsome, 1994). These studies report low but highly significant correlations between pairs of neurons that are recorded from the same electrode. More recent studies with multiple electrodes suggest that these correlations decay over space but remain significant even at distances of multiple millimeters (Kohn & Smith, 2005).

Simple theoretical considerations suggest that in large neural populations, average correlations should be significantly higher than in pairs of single neurons (figure 29.5*B*). The reason is that in large pools of neurons, sources of noise that are independent across the pool are averaged out while leaving the weak correlated noise unaffected; this leads to much higher correlations between the pooled responses. For example, if we assume a uniform pairwise correlation between neurons in two pools, pairwise correlations that are undetectable (e.g., $r = 10^{-3}$; solid curve, figure 29.5*B*) could lead to exceedingly high correlations between the pools for large numbers of neurons. In other words, given reasonable assumptions about the number of neurons contributing to each location in VSDI experiments, much higher correlations than are observed for pairs of single neurons are expected.

As predicted, the correlations in the VSDI signals are very high between nearby locations and fall off exponentially with space constants that are on the order of 2 mm (figure 29.5*C*).

neurons in each pool (see Chen, Geisler, & Seidemann, 2006). The value of the pairwise correlation is indicated near each curve. The dashed vertical line is the approximate number of neurons contributing to each location. The dashed horizontal line is the predicted correlation in VSDI for two locations that are 0.25 mm apart. *C*, Average correlation between two locations in one VSDI experiment as a function of the separation between the locations. *D*, Average temporal correlations between responses in two frames as a function of their separation in time. Smooth curves are exponential fits.

Significant correlations can be observed even at distances exceeding 4 mm.

The strong correlations at the level of the pool could contribute to the additive nature of the variability in population responses. At the level of the pool, the variance is dominated by weak correlated noise between pairs of neurons, which may be relatively stimulus-independent (but see Kohn & Smith, 2005).

TEMPORAL CORRELATIONS IN THE POPULATION RESPONSE

Temporal correlations are an important property of neural population responses with significant consequences for possible decoding mechanisms. Figure 29.5*D* shows the Pearson correlation between the amplitude of the VSDI signals in two frames as a function of their separation in time (Chen et al., 2008). The correlations are high for short intervals and fall off exponentially with a time constant of approximately 100 ms. The temporal correlations are similar in target-present and target-absent trials, consistent with the additive nature of the variability in VSDI responses. The additive variability and long-lasting temporal correlations are consistent with findings from VSDI experiments in the visual cortex of anesthetized cat (Arieli et al., 1996). Significant temporal correlations have been observed in single-unit recordings from primate visual cortex (Osborne, Bialek, & Lisberger, 2004; Uka & DeAngelis, 2003).

There are more subtle questions regarding the nature of the spatiotemporal correlations that we have not discussed here and should be addressed by future research. For example, are there higher-order correlations at the level of pools of neurons? In the retina, the observed correlations can be explained remarkably well if we assume only pairwise correlations between neighboring retinal ganglion cells

(Schneidman, Berry, Segev, & Bialek, 2006; Shlens et al., 2006). Whether this also holds in the cortex remains to be seen. Second, it is important to determine the effect of the stimulus, the behavioral state of the subject, and the specific demands of the task on the structure of the correlations. Our preliminary results suggest that at the level of large pools of neurons, the spatiotemporal correlations and the magnitude of the variability are relatively constant. More work using different complementary techniques is necessary to fully address this issue.

Exploring possible decoding mechanisms

Earlier, we presented the rationale for using the ideal Bayesian observer as a framework for exploring possible decoding mechanisms. Here, we demonstrate this approach using our own VSDI study in V1 of monkeys that were trained to perform a reaction-time detection task near the perceptual threshold (figure 29.6) (Chen et al., 2006, 2008).

Our goal was to derive the ideal Bayesian decoder for detecting the target from the monkey's VSDI signals and to compare its performance with that of several suboptimal decoders and with the performance of the monkey. For simplicity, we first describe the optimal strategy for spatial decoding, ignoring the temporal dimension by averaging the VSDI signals over a short temporal interval. We then

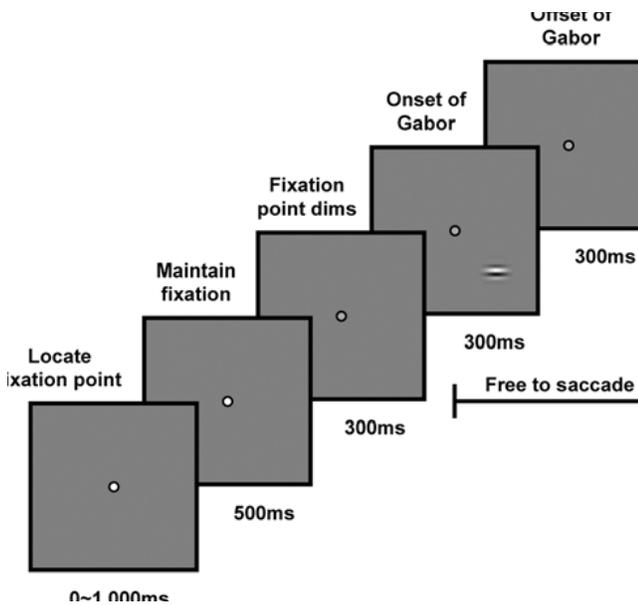

FIGURE 29.6 Visual detection task. Monkeys were required to detect a low-contrast Gabor patch that appeared at a known location in half of the trials. The target appeared 300 ms after the dimming of the fixation point. The monkey indicated detection by making a saccadic eye movement to the target location when it was detected but no later than 600 ms after target onset. The monkey indicated target absence by maintaining fixation for 1.5 s after fixation point dimming.

describe the optimal strategy for decoding population responses over time, ignoring the spatial dimension by averaging the responses over a small region. This approach is reasonable because in this task the spatial responses are largely independent of time and the temporal responses are largely independent of space (e.g., figure 29.3C).

SPATIAL DECODING OF NEURAL POPULATION RESPONSES
