has been localized in any of these regions, and further mapping studies are under way. However, one recent investigation employed an alternative strategy to traditional mapping, using functional genetic analyses of a monogenic speech and language disorder (described further later on) to identify novel candidates for involvement in SLI. This approach enabled successful identification of the first gene to be significantly associated with language deficits in children with SLI (Vernes et al., 2008). The gene, called *CNTNAP2* (located on chromosome 7q35), is strongly down-regulated by the *FOXP2* transcription factor in neurons (see the section on developmental verbal dyspraxia) and is a member of the neurexin family, a set of proteins implicated in synaptic adhesion (Dean & Dresbach, 2006). Its association with SLI remains to be replicated. It is worth noting that none of the known SLI linkage sites overlap with those reported for dyslexia, despite frequent comorbidity and similar neurological findings. However, there is notable overlap with autism linkage sites. Furthermore, *CNTNAP2* has been associated with autism in several studies (Alarcon et al., 2008; Arking et al., 2008; Bakkaloglu et al., 2008). This issue will be further discussed in the comorbidity subsection.

Speech sound disorder

Although most children make speech errors when they begin to speak, children with speech sound disorder (SSD) present with persistent difficulties in the accurate and intelligible production of speech sounds within words. Their prevalence is estimated to be around 15% of 3-year-old children and 3.8% of 6-year-olds (Shriberg, Tomblin, & McSweeney, 1999). Typically some speech sounds are omitted or mapped to other sounds (this disorder is different from stuttering). The definition of SSD does not commit to a particular locus for the underlying deficit (phonological or articulatory), and it is likely that the population is heterogeneous in this respect. Unfortunately, cognitive studies of SSD are currently insufficient to provide a clear typology and shed more light on the precise nature of the deficits. It should be noted that the field of (normal) child language is itself plagued by the issue of whether deviant speech productions should be attributed to constraints in articulatory skills or to stages of phonological acquisition (Ramus et al., in press).

The brain basis of SSD has to our knowledge not been investigated independently from that of SLI or dyslexia. There have been, however, genetic linkage studies. Investigations have tended to focus on the chromosomal regions implicated in dyslexia and, intriguingly, have thereby uncovered SSD linkages on the dyslexia-related sites of chromosomes 3, 6, and 15 (Stein et al., 2006, 2004). One possible reason for this result is that there is comorbidity between dyslexia and SSD, so that a fair proportion of preschool children who are diagnosed with SSD grow up to become

dyslexic. Thus cohorts of children with SSD participating in genetic studies may well be largely composed of dyslexic children. Another more interesting potential explanation is that, beyond actual comorbidity, common biological factors may participate in the etiology of different cognitive deficits. Confirmation of the latter awaits identification of particular allelic variants that play functional roles in both SSD and dyslexia. Curiously, at this point there is less evidence of genetic risk factors that are shared between SSD and SLI, although there may well be functional pathways that are common to both (see the next section).

In conclusion, speech sound disorder has the potential to reveal important information about the genetic bases of phonology and speech articulation. Unfortunately, the findings on SSD in general are rather scarce, so this disorder warrants more investigation. However, one particular form of SSD, namely developmental verbal dyspraxia, is currently at the center of a very fruitful line of research, which is detailed in the next section.

Developmental verbal dyspraxia

Developmental verbal dyspraxia (DVD)—also referred to as childhood apraxia of speech (American Speech-Language-Hearing Association, 2007)—is a speech-sound disorder that leans clearly on the articulation side, involving problems with coordinating and sequencing movements of the tongue, lips, jaw, and palate that cannot be explained by muscle weakness, paralysis, or other overt neurological or physical factors. A diagnosis of DVD can encompass a range of severities and impairments, and there may also be some degree of impairment in performing nonspeech orofacial movements on command, such as puffing out cheeks or licking lips (oral dyspraxia). In recent years substantial advances have been made in understanding one particular genetically mediated subtype of DVD, a rare form of the disorder showing monogenic inheritance (Fisher, Vargha-Khadem, Watkins, Monaco, & Pembrey, 1998; Lai, Fisher, Hurst, Vargha-Khadem, & Monaco, 2001). In this section we focus on the behavioral, cognitive, and neural features of this well-studied subtype, given that its genetic basis has now been firmly established.

Much of our understanding of links between genes and DVD stems from intensive studies of one multigenerational pedigree, known as the KE family, first reported in the early 1990s (Hurst, Baraitser, Auger, Graham, & Norell, 1990). Around half of the members of this family—15 individuals across three successive generations—display a severe speech and language disorder, inherited as a Mendelian trait with an autosomal dominant mode of transmission. While some linguists initially characterized the KE family's disorder as one primarily affecting certain features of grammatical processing (Gopnik, 1990; Gopnik & Crago, 1991), other

researchers noted that the most profound problems were impaired speech articulation reminiscent of DVD (Hurst et al., 1990). Indeed, subsequent reports showed that word and nonword repetition tasks provided the most robust diagnostic marker of the disorder (Vargha-Khadem et al., 1998). Consistent with a diagnosis of DVD, the deficits of affected members are already evident when repeating shorter utterances, but become more dramatic with increases in syllable number and complexity (Watkins, Dronkers, & Vargha-Khadem, 2002). Tests of nonspeech praxis in the KE family indicate reduced performance when making simultaneous and sequential oral movements on command (Alcock, Passingham, Watkins, & Vargha-Khadem, 2000; Vargha-Khadem et al.). This is again reminiscent of other cases of DVD, which (as noted earlier) often show evidence of oral dyspraxia affecting nonspeech movements. Notably, affected members of the KE family are not significantly impaired in making single simple oral movements or in limb praxis, and they do not show gross oromotor dysfunction, for example, in feeding or swallowing (Alcock et al.).

The speech difficulties of the KE family are accompanied by linguistic impairments that are not confined to spoken language or to the expressive domain. For example, affected members perform worse than unaffected members on written tests of verbal fluency and nonword spelling, as well as in lexical decision tasks assessing receptive vocabulary, and they display significant deficits in reception and production of grammar (Watkins, Dronkers, et al., 2002), albeit not as selectively as proposed in initial linguistic studies (Gopnik, 1990). They show difficulties in generating word inflections and derivations, but tests of past-tense production indicate similar levels of deficits for both regular and irregular words, and their receptive impairments extend to syntax at the word-order level (Gopnik & Crago, 1991; Watkins et al.). The relationship between the motoric and linguistic aspects of the disorder in the KE family is the subject of continuing debate. One hypothesis is that a primary deficit in articulation could lead to more general impoverishment in language representation at many other levels (Watkins et al.). However, it is not clear why accurate speech articulation would be necessary to acquire all the other dimensions of language, and indeed it has been shown that it is not (Fourcin, 1975a, 1975b; Lenneberg, 1962; Ramus, Pidgeon, & Frith, 2003). A plausible alternative is that multiple components of language (articulation, phonology, the lexicon, morphology, and syntax) are concurrently affected, without one deficit being responsible for all the others.

The brains of affected people from the KE family appear overtly normal in structure on standard evaluation of MRI scans (Vargha-Khadem et al., 1998). However, statistical comparisons to unaffected members using voxel-based morphometry revealed subtle anomalies affecting multiple brain regions (Belton, Salmond, Watkins, Vargha-Khadem,

& Gadian, 2003; Vargha-Khadem et al.; Watkins, Vargha-Khadem, et al., 2002). These include putative abnormalities in cortical language-related regions, with decreased gray matter density in the inferior frontal gyrus (containing Broca's area) and increased density in the posterior portion of the superior temporal gyrus (Wernicke's area). Notably, the sites of pathology suggested by such analyses were not limited to the cerebral cortex, but extended to the cerebellum and the striatum, where there were significant reductions in gray matter density in the caudate nucleus accompanied by increases in the putamen. Functional neuroimaging of the KE family during language tasks identified abnormal patterns of neural activation in the affected members, even under covert (silent) conditions when there was no requirement for spoken output (Liegeois et al., 2003). Broca's area, other cortical language-related regions, and the putamen were significantly underactivated in affected individuals, who showed a more posterior and bilateral pattern of activation than unaffected members of the family. Sites of abnormalities include both areas associated with motor control and areas associated with language, mirroring the co-occurrence of motor and linguistic symptoms at the cognitive level. It has been suggested that abnormalities in development and function of distributed frontostriatal and/or frontocerebellar circuits are responsible for the DVD and accompanying linguistic impairments of the family (Vargha-Khadem, Gadian, Copp, & Mishkin, 2005).

Genomewide scanning of the KE family identified a region of chromosome 7q31 showing highly significant linkage to the disorder (Fisher et al., 1998), which was found to contain at least 70 genes (Lai et al., 2000). The search was cut short by the serendipitous discovery of another child affected with DVD (unrelated to the KE family) who had a gross chromosomal abnormality mapping within the region of interest (Lai et al., 2000, 2001). The child, known as CS, carried a balanced translocation involving exchange of material between chromosomes 5 and 7, with a breakage in the 7q31 band. It was shown that the chromosome 7 break-point of this child directly interrupted a novel gene, known as FOXP2 (Lai et al., 2001). Analysis of the gene in the KE family uncovered a heterozygous single-base change in all 15 affected members, which was not found in any unaffected members or in several hundred independent controls (Lai et al., 2001). This mutation was predicted to disrupt the function of the protein encoded by FOXP2, a hypothesis that has since been robustly confirmed (Groszer et al., 2008; Vernes et al., 2006).

FOXP2 encodes a protein belonging to the "Forkhead bOX" (or FOX) family of transcription factors, which act to regulate the expression of suites of genes during embryogenesis and development and in adulthood (Carlsson & Mahlapuu, 2002). The single-base missense mutation in the FOXP2 gene of affected KE family members alters one

amino-acid residue at a crucial part of the DNA-binding domain of the encoded protein (Lai et al., 2001). Functional experiments show that the substitution impedes the DNA-binding ability of the mutated FOXP2 protein, dramatically disturbing its capacity to regulate transcription of downstream targets (Vernes et al., 2006).

Targeted screening of FOXP2 in different disorders has indicated that disruption of this gene is not unique to the KE family and CS case, but still represents only a rare cause of speech and language deficits in the wider population. Initially, comprehensive mutation searches were carried out across all known FOXP2 exons in groups of children with SLI and autism (Newbury et al., 2002; Wassink et al., 2002), syndromes that typically occur in the absence of DVD. These studies concluded that FOXP2 is not a major genetic risk factor for SLI or autism, a finding that has been generally borne out by subsequent work. MacDermot and colleagues (2005) reported the first specific assessment of FOXP2 contribution in a cohort of children diagnosed with DVD. The study screened 49 unrelated probands with a primary diagnosis of DVD and identified three distinct coding changes. One was a heterozygous nonsense mutation predicted to severely truncate the encoded FOXP2 protein, such that it would lack crucial functional domains, including the DNA-binding motif. The nonsense mutation was also found in the proband's affected sister and mother, and was absent from normal controls (MacDermot et al.). Functional analyses suggest that the truncated product is unstable, is mislocalized within the cell, and lacks transcription factor function (Groszer et al., 2008; Vernes et al., 2006). In recent years, cases of gross chromosome abnormalities in which FOXP2 is disrupted or deleted have also been reported, with speech articulation difficulties emerging as a common symptom (Feuk et al., 2006; Shriberg et al., 2006; Zeesman et al., 2006).

Since FOXP2 encodes a transcription factor, functional genomic methods are now being used to successfully identify the downstream target genes that it regulates in neurons (Spiteri et al., 2007; Vernes et al., 2007). Exciting new data from these screening efforts indicate that pathways downstream of this regulatory factor may have broader relevance for language-related disorders, even in the absence of mutations of FOXP2 itself. Vernes and colleagues (2008) identified a novel direct target that is strongly down-regulated by FOXP2 in neurons (the CNTNAP2 gene, described earlier) and went on to show that the allelic variants of this target were significantly associated with language impairments in a large cohort of children with typical SLI. Not only do these findings establish a functional genetic link between rare monogenic forms of DVD and common forms of SLI, but similar allelic variants in the target gene are also associated with language deficits in autistic disorder (Alarcon et al., 2008).

FOXP2 is expressed in the brain during embryogenesis and early development, both in humans and in mice (Lai, Gerrelli, Monaco, Fisher, & Copp, 2003). It is not expressed ubiquitously throughout the brain, but localized to a number of structures, including the deep layers of the cerebral cortex, the striatum, the thalamus, the Purkinje cells of the cerebellum, and the inferior olives. Most notably, FOXP2 expression in the caudate nucleus and in the cerebellum coincides with known sites of neuroanatomical anomalies in the KE family. Beyond sensorimotor processing and motor-skill learning, the contribution of these brain regions to language function is becoming more and more appreciated (Booth, Wood, Lu, Houk, & Bitan, 2007; Friederici & Kotz, 2003; Justus, 2004; Marien, Engelborghs, Fabbro, & De Deyn, 2001; Teichmann, Dupoux, Kouider, & Bachoud-Levi, 2006; Ullman, 2001).

More insights into human FOXP2 function have come from animal models. Heterozygous mice carrying the same missense mutation as that found in the human KE family display abnormal synaptic plasticity in neural circuits where FOXP2 is expressed, including loss of long-term depression in parts of the striatum (Groszer et al., 2008). In addition, they show subtle but significant motor-skill learning deficits during species-typical behaviors. Homozygous mouse pups that have no functional FOXP2 have severe motor dysfunction, general developmental delays, and delayed maturation of the cerebellum, and they do not emit innately specified ultrasonic calls on isolation from their mother (Groszer et al.; Shu et al., 2005). They do not survive beyond a month of life. Whether the homozygous mouse phenotype is relevant for understanding the syndrome observed in heterozygous humans remains a controversial question. More convincing evidence of a role for FOXP2 in vocalization skills of nonlinguistic species comes from studies of vocal learning in songbirds (S. A. White, Fisher, Geschwind, Scharff, & Holy, 2006). In particular, zebra finches show changes in FOXP2 expression levels in a key striatal nucleus (called Area X) that appear to correlate with vocal plasticity (Haesler et al., 2004; Teramitsu & White, 2006). Haesler and colleagues (2007) used RNA interference to selectively knock down expression of FOXP2 in Area X of juvenile zebra finches during song learning. This treatment yielded inaccurate and incomplete copying of the tutor's song, which was suggested to show parallels to DVD in humans (Haesler et al., 2007).

Finally, analyses of the evolution of FOXP2 in primates indicated that two amino-acid substitutions occurred on the human lineage after splitting from the chimpanzee, and found evidence of recent Darwinian selection (Enard et al., 2002; Zhang, Webb, & Podlaha, 2002). Although initial studies suggested this accelerated evolution may have occurred within the last 200,000 years of human history (Enard et al.; Zhang et al.), investigations of the gene in bone

samples from Neanderthals indicate that they also carried the human amino-acid substitutions, which would suggest a more ancient origin (at least 300,000–400,000 years) for the changes (Krause et al., 2007). At the moment, nothing is known about the functional consequences of these two amino-acid changes, but this finding raises the possibility that FOXP2 might have acquired new functional roles in humans.

In summary, FOXP2 may simultaneously contribute to human language pathways by at least two routes. The first route is through an evolutionarily conserved role related to motor sequencing and vocal learning, as observed in non-linguistic species (studies of birds and mice). Deficits in these processes are likely to mediate parts of the DVD phenotype associated with FOXP2 disruption. Second, the human version may have putative novel functions that remain to be understood but that might conceivably contribute to more human-specific aspects of language.

Perspectives for language genetics

COMORBIDITY AND PLEIOTROPY Until now we have largely described the different forms of language disorders as if they were distinct entities; however, this approach is an oversimplification. Many children with SLI, although not all of them, grow up to become dyslexic (Bishop & Snowling, 2004; Flax et al., 2003; Marshall, Harcourt-Brown, Ramus, & van der Lely, in press; McArthur, Hogben, Edwards, Heath, & Mengler, 2000). Some children with dyslexia or SLI also present some form of speech sound disorder, if only in early development (Bishop & Adams, 1990; Shriberg et al., 1999). This pattern of multiple comorbidities is hardly surprising if one considers that the different components of language, albeit functionally independent, may partly depend on each other in the course of development. But beyond this observation, it is likely that comorbidity can be largely ascribed to common underlying biological factors, as is indeed suggested by several lines of converging evidence:

- As we have noted, the neural bases of dyslexia and SLI partly overlap.

- Familial aggregation studies have found that in families having one member with SLI or SSD, the likelihood that other members will show another form of language impairment (whether dyslexia, SLI, or SSD) was increased (Flax et al., 2003; Lewis, 1992).

- Twin studies have provided evidence for shared genetic influences between SSD and dyslexia, suggesting that the cofamiliality has at least partly a genetic basis.

- Genetic linkage sites seem to overlap between dyslexia and SSD. Two caveats, however. First, the fact that linkage sites overlap does not guarantee that a single gene is associated with both disorders: linkage sites may contain many

genes, including two affecting different disorders. And indeed none of the genes associated with dyslexia has been associated with SLI or SSD so far. Second, there is no hint as yet of any overlap between dyslexia and SLI linkage sites, a fact that may seem puzzling. However, it is not all that surprising, given the statistical power of most linkage analyses (Marlow et al., 2003), and this gap may well be bridged sooner or later.

- Genetic linkage sites also overlap between SLI and autism. Furthermore, the CNTNAP2 gene, identified as a downstream target of FOXP2, also appears to be associated with common cases of SLI (Vernes et al., 2008), as well as with autistic spectrum disorder (Arking et al., 2008; Bakkaloglu et al., 2008). One study further suggested the association between CNTNAP2 and language abilities in autism, as measured by age at first word (Alarcon et al., 2008). This finding suggests etiological overlaps between SLI and autism.

The possibility that some gene variants might increase the susceptibility to several disorders makes sense in functional terms. For instance, there is no reason to expect that dyslexia is the only disorder arising from slight disturbances in neuronal migration (indeed, others are known, such as nodular periventricular heterotopia). Therefore genes involved in neuronal migration and associated with dyslexia could plausibly be expected to be associated with other disorders such as SLI. Furthermore, genes typically have more than one function, and therefore can have effects on multiple phenotypes: this condition is known as pleiotropy. For instance, all the genes discussed in this chapter are expressed not only in the developing brain, but also in other organs at various stages of life, showing that they have multiple functions, some as remote from cognition as digestion or reproduction.

These considerations have led Kovas and Plomin (2006) to hypothesize that genes affecting cognition are “generalist genes” affecting most cognitive functions and disorders, and indeed that they produce their effects relatively uniformly on a “generalist brain.” It is certainly true that many genes affect many brain areas and many cognitive functions, yet the “generalist genes” hypothesis is likely to be an overgeneralization. Some twin studies find that certain cognitive functions share little genetic variance—for instance, phonological and morphosyntactic abilities (Bishop et al., 2006). And although many genes seem to be expressed more or less uniformly across the cortex, few studies have actually compared the expression of the genes of interest across different cortical areas. FOXP2 is a good case in point. It may well have multiple effects on development, but it certainly does not have uniform effects throughout the brain. As we have seen, it is expressed in particular brain areas that turn out to bear a clear relationship with the neurological and

cognitive phenotypes associated with a *FOXP2* mutation. This kind of neuroanatomical specificity is not uncommon among transcription factors. Performing a systematic search over more than 1000 known transcription factors, Gray and colleagues (2004) have found 349 whose expression pattern is restricted to specific areas of the mouse brain and which are together sufficient to explain its architecture. Far from being generalist genes, their expression is rather specific and has equally specific functional consequences. Similar considerations hold for *CNTNAP2*, the only gene so far suggested to be associated with SLI (Vernes et al., 2008), which turns out to demonstrate particularly enriched fetal expression in human frontal cortex (including inferior and middle frontal gyri), as well as in subcortical areas (including the caudate nucleus) (Abrahams et al., 2007).

In the case of genes associated with dyslexia, while expression patterns in human fetal brains are available (Paracchini et al., 2006), comparisons between neocortical areas have been carried out in adult brains only, and with a relatively rough cortical parcellation (lobe by lobe, without distinguishing left from right hemisphere). Yet they do not turn out to be particularly uniform (Meng et al., 2005; Paracchini et al., 2007). Most importantly, the sites of brain disturbance themselves are clearly not uniform, whether one looks at histological studies, brain morphometry, or diffusion tensor imaging. The relationship between genes and neuropathological sites remains to be fully understood. More detailed studies might reveal that genes associated with dyslexia are expressed more in left perisylvian areas, but this possibility can be considered unlikely for genes generally involved in neuronal migration. Then why do the disruptions occur precisely there? One reason could be just chance: in many individuals with the same gene variants, they may by chance occur elsewhere and produce other effects (SLI, SSD, or any other cognitive deficit for that matter). We would see them in left perisylvian areas because we look only at dyslexic individuals. Yet if chance were the only factor at play, one would predict complete cross-transmission between disorders: dyslexic parents would be as likely to beget SLI as dyslexic children. However, this is not the case (Flax et al., 2003; Lewis, 1992). Another possibility would be that left perisylvian areas are, for unrelated (say, vascular) reasons, more vulnerable to all forms of insult, including disturbances of neuronal migration (Geschwind & Galaburda, 1985; McBride & Kemper, 1982). One way or another, neuroanatomical location matters more than anything else for determining the precise nature of a cognitive phenotype.

Another alternative would be that genes implicated in neuronal migration interact with other genes, which do have more specific expression patterns (Ramus, 2004). The combination of certain alleles in these different genes could result in disruptions of neuronal migration confined to certain cortical areas. For instance, a number of genes have been

found whose expression is asymmetric between left and right hemispheres in early embryonic development and could thus explain the predominance of certain anomalies on one side or the other. Furthermore, one of these genes (*LMO4*) is expressed more specifically in perisylvian regions, and more so in the right than in the left hemisphere (Sun et al., 2005). Other genes have been found with expression enriched (or specifically impoverished) in language-relevant areas in midgestation (Abrahams et al., 2007). Alleles of these or similar genes, interacting with alleles of genes associated with neuronal migration, could potentially explain the occurrence of neuronal migration anomalies specifically in left perisylvian regions such as in dyslexia.

In light of the preceding discussion on comorbidity and pleiotropy, one does expect to find genes associated with dyslexia as well as SSD and/or SLI, and perhaps even with other developmental disorders. However, this does not imply that all disorders are the same or that genes are “genes for everything.” Not all dyslexic children have SSD or SLI, not all brain areas are involved in all language functions, not all genes have an impact on all brain areas and functions, and therefore it is also to be expected that some genes will be uniquely associated with one disorder, alongside other genes that will be more general susceptibility factors for a certain class of neurodevelopmental disorders.

A “GENE FOR LANGUAGE”? When the KE family was first investigated in the early 1990s, speculations about the existence of a “gene for grammar” flourished in the press. The story turned out to be much more complex, and when *FOXP2* was discovered more than ten years later, it became clear that it was neither a gene for grammar, nor a gene for language, nor a gene for the brain, nor even a specifically human gene. It is a highly conserved transcription factor, found in similar form in many distantly related vertebrate species, where it is expressed in a range of tissues during embryonic development, postnatally, and in the mature organism, including the lung, heart, and intestines as well as the brain (Bonkowsky & Chien, 2005; Haesler et al., 2004; Lai et al., 2001, 2003). Genes associated with dyslexia and other language disorders are turning out to show similar characteristics. Thus, the very notion of a “gene for something,” in particular a gene coding directly, specifically, and uniquely for a given cognitive function, is flawed (Fisher, 2006). But this fact does not mean that the notion of genetic bases of language is itself flawed. Rather it should be understood in less naive ways than it sometimes has been.

The data reviewed in this chapter show that variations in many genes may cause variations in language abilities, and in particular language disorders. Rather than being “genes for language,” these genes perform several different functions, in various organs at various stages of development. But they have in common that they have an influence on brain

development and that certain of their variations may alter the development and/or function of particular brain areas, which in turn are useful for some aspects of language acquisition. Thus these genes are necessary for normal language acquisition, but they are of course not sufficient, and furthermore they have not necessarily evolved for the purpose of language acquisition. Some of them (like *FOXP2*) have indeed undergone some human-specific modifications, apparently under selection pressure, and within a time frame that is compatible with the evolution of language in the human lineage. In such a case it is possible that these changes were one of the steps that made it possible for humans to develop language. Other known genes associated with language disorders also differ slightly between humans and other mammals, but so far there is no evidence that these differences are functionally significant and may have played a role in language evolution (Fisher & Francks, 2006). Nevertheless, this lack of evidence does not make those genes uninteresting.

The language faculty is very unlikely to be an entirely new organ that has appeared from scratch in the human brain (Fisher & Marcus, 2006). Rather, it should be seen as a product of “descent with modification,” that is, a new combination of old and possibly new cognitive ingredients (Marcus, 2006). Old ingredients may include auditory perception, primate vocalization, long-term, short-term, and working memory, sequence processing, a conceptual system, and many more. Of course each of these components must have to some extent evolved in human-specific ways in order to be harnessed for linguistic purposes, a fact that implies that some of the genes that were already implicated in the construction of the corresponding brain areas either have undergone some functional changes or have been triggered in new ways by upstream transcription factors and other regulatory elements. Thus even a human gene identical to an ancestral primate version could nowadays be important for language, if for instance it is involved in the construction of a relevant brain area in virtue of being expressed in new ways by a transcription factor such as *FOXP2*. As for new cognitive ingredients, it is not yet entirely settled what (if anything) should fall into that category. An influential and controversial proposal is that a capacity for recursion is the unique new cognitive ingredient required for language, together with an adaptation of “interfaces” between this new component and the old ones (Fitch, Hauser, & Chomsky, 2005; Hauser, Chomsky, & Fitch, 2002; but see Jackendoff & Pinker, 2005; Pinker & Jackendoff, 2005).

Taking this as a working hypothesis, it is unlikely that such a new cognitive capacity could have evolved overnight thanks to a single mutation. Even if it is truly new in a cognitive sense, it is likely to be much less novel in biological terms. For instance, a change in a single gene producing a signaling molecule (or a receptor, channel, etc.), could lead

to creating new connections between two existing brain areas. Even an altogether new brain area could evolve relatively simply by having a modified transcription factor prenatally define new boundaries on the cortex, push around previously existing areas, and create the molecular conditions for a novel form of cortex in Brodmann’s sense: still the basic six layers, but with different relative importance, different patterns of internal and external connectivity, and different distributions of types of neurons across the layers. This would essentially be a new quantitative variation within a very general construction plan, requiring little new in terms of genetic material, but this area could nevertheless present novel input/output properties that, together with the adequate input and output connections, might perform an entirely novel information-processing function of great importance to language. Even if the ultimate form of that brain area turns out to require many genetic changes, there is no necessity that all the changes coevolved simultaneously. Once the area is delineated, further genetic changes could progressively shift its boundaries and refine its cellular makeup and thus its information-processing capabilities. Thus even the creation of a new neuroanatomical and cognitive module is not as unlikely as one might imagine and does not require improbable assumptions about dramatic genetic changes. Dramatic effects can be obtained by small changes in the way the construction plan is laid out.

In a nutshell, there is no need of a “gene for language” to explain the genetic basis of language. Having said that, it is now known that some human genes (perhaps 150 to 300) really are human specific, in the sense that they are entirely new concatenations of bits of other genes that have no equivalent in other species (Bailey et al., 2002; Nahon, 2003). Very little is known about those genes, but it is of course possible that one or more of them could have been important in the evolution of the neural bases for language. The point is that even if this is not the case, more standard genetic changes in ancestral genes would still be adequate to explain the emergence of a new cognitive ability such as language.

PERSPECTIVES The picture laid out in this chapter is of course very incomplete. Many more genes associated with language disorders remain to be found, and genes associated with normal variations in language abilities remain even to be searched for. Nevertheless, the data that we have discussed are probably a reasonable illustration of what can be expected in the future. We can expect more genes involved in aspects of brain development (neuronal migration being just one possibility), as well as more transcription factors and other genes with a restricted cortical expression that may affect the development of more specific brain areas. Genes involved in neurotransmission, however, are currently out of the picture (although implicated in other disorders such as ADHD), but there is of course no guarantee that they will remain so.

One point that may change is that until now the genetic variations considered have been mostly deletions, insertions, or substitutions of single nucleotides. This approach has led to a pattern where mutations (such as those in FOXP2 or DYX1C1) appear to be scarce, while most of the variation in language abilities seems to be explained by susceptibility alleles that simply modulate the probability of developing the disorder. However, mutation-screening efforts are very preliminary; for instance, the genes already known to be associated with dyslexia have typically not been systematically screened for mutations in most available dyslexia cohorts. Furthermore, a wider range of mutations is now going to be analyzed, such as copy number variants, whereby entire stretches of DNA are sometimes deleted or duplicated, to an extent that previously has been vastly underestimated (Redon et al., 2006; Stranger et al., 2007). Thus there may be etiological mutations in a much higher proportion of individuals with language disorders than has been appreciated before.

One final area where entirely novel results should be expected in the coming years is that of gene-environment interactions. All genetic studies of language disorders have until now focused on detecting main effects of gene variants. This is of course the first step necessary to the identification of candidate genes. However, the effects of genes sometimes differ as a function of other factors, some genetic, some environmental. Evidence for nonadditive effects between genetic and environmental factors has begun to be uncovered in the case of other disorders, such as conduct disorder (Caspi et al., 2002) or depression (Caspi et al., 2003). Does a susceptibility allele for a language disorder produce a different effect depending on the presence of other risk factors (such as mild hearing impairment)? Or on the familial linguistic environment? Or on the language itself? Or on schooling practices? Or symmetrically, does a given environmental factor produce a different effect depending on the genotype of the child? Answers to these fascinating questions are now within arm's reach.

NOTES

1. Monozygotic MZ twins share 100% of their genome, while dizygotic DZ twins share only 50% of their gene variants (like ordinary siblings). Note that the MZ-DZ twin method usually assumes that environmental factors are not more similar for MZ twins than for DZ twins; this assumption may not necessarily be valid.
2. A minority of cases of dyslexia are likely due to disorders in the visual modality. They are not further discussed here, as they are less well understood and they are of course not relevant for

language genetics. Regarding theories of the phonological deficit as part of a pansensory disorder, we refer the reader to Ramus (2003).

59 The Biology and Evolution of Language: “Deep Homology” and the Evolution of Innovation

W. TECUMSEH FITCH

ABSTRACT The last decade has seen rapid and impressive progress in understanding the biology and evolution of complex “innovative” traits (e.g., insect wings or vertebrate eyes), and the fruits of this understanding are beginning to have an impact on our understanding of that most innovative of human traits: language. Although language, as a whole, is unique to *Homo sapiens*, many of the neural and cognitive mechanisms supporting language are shared with other species. An empirically based, mechanistic understanding of the evolution of language therefore requires research on both unique aspects of language (such as complex syntax) and broadly shared features. Evolutionary developmental biology (“evo-devo”) has added a new twist to this distinction, with the discovery that traits shared due to *convergent* evolution (such as vocal learning in humans and birds) may nonetheless be based on *homologous* genes and developmental pathways. Such “deep homologies” may involve convergence at the phenotypic level and homology at the genotypic level, and illustrate the need to rethink traditional ideas about homology. Studies of eyes, limbs, and body plans have revealed deep homologies in all these systems. Here, I suggest that language is also likely to have its share of deep homologies, and that this possibility provides a powerful rationale for investigations of convergently evolved traits in widely separated species. I illustrate the potential of this new approach with an exploration of the neural and genetic basis of vocal learning in humans and birds. I conclude that neuroethological investigations of diverse vertebrate species, from fish to birds to mice, will powerfully augment more traditional work on primates in the search for the neural mechanisms underlying language.

Humans (like most species) are unique in many ways, but language is the jewel in our cognitive crown. Language makes possible the greatest human cultural achievements, ranging from quantum physics to the novel to the Internet, because knowledge can be conveyed from mind to mind, across generations, with progressive refinements and elaboration. Without language and the community of minds that it creates, our species would be little more than an unusually clever bipedal ape. It is clear that human language rests on a unique, recently evolved, biological basis: our nearest

living relatives, the chimpanzees, are unable to acquire language past the level of a young child. Sometime in our recent evolution, in the last 5–7 million years since we diverged from our last common ancestor with chimpanzees, a suite of important innovations have occurred, which together comprise the human capacity to acquire language. The nature of, and biological basis for, this capacity is a core focus of contemporary research on the biology of language.

Languages themselves, like English or Chinese, are obviously not inborn. We each acquire the language of our local community through an experience-dependent process of language acquisition. In Darwin’s words “language is an art . . . not a true instinct, for every language has to be learnt. It differs, however, widely from all ordinary arts, for man has an instinctive tendency to speak, as we see in the babble of our young children; whilst no child has an instinctive tendency to brew, bake, or write” (Darwin, 1871, p. 55).

Today there is wide agreement that the language acquisition process has a strong biological basis and represents an “instinct to learn” that is part of every normal child’s genetic heritage. Although this human capacity is unique when considered as a whole (sometimes termed the “faculty of language in a broad sense,” or FLB), most of the component mechanisms underlying language are not unique to our species. Factors shared with chimpanzees and other primates (e.g., mechanisms underlying lexical acquisition) are traditionally believed to be homologies, traits that were present in our shared common ancestor. Other traits are shared with more distant biological relatives but *not* with other primates (e.g., mechanisms underlying imitative vocal learning). Such traits are traditionally considered to represent convergent evolution, analogy, or “homoplasy.”

This latter category is of particular interest to neuroscientists, because animal species sharing linguistically relevant traits like vocal learning (e.g., songbirds) are more amenable to experimental analysis than are chimpanzees or other nonhuman primates. It is becoming increasingly clear that traits that have evolved independently (“mere” analogies) may nonetheless be based on shared genetic developmental

W. TECUMSEH FITCH School of Life Sciences, University of Vienna, Vienna, Austria

pathways: a situation sometimes termed *deep homology*. Recent discoveries suggest that deep homology is common in evolution (Shubin, Tabin, & Carroll, 1997; Wilkins, 2002). In deep homologues the genetic pathways leading to a trait are shared, even though the structures that they build are not necessarily themselves homologous, because they were absent in phylogenetically intermediate taxa. Examples include limbs in vertebrates and crustaceans, wings in birds and insects, and the eye in vertebrates and cephalopods (squids or octopuses).

The discovery of deep homology provides an exciting new range of empirical possibilities for scientists interested in the evolution of complex innovations, including human language. The very concept of deep homology would have been considered fanciful 20 years ago, and its reality has profound consequences for both the concept of homology and our understanding of the evolution of complex innovations. The purpose of this article is to explore some of the consequences of this new understanding for human language.

Understanding human cognitive evolution

THE GENETIC CHALLENGE OF LANGUAGE Humans are unusual animals in many respects. Our most prominent morphological differences from our nearest extant relatives, the chimpanzees, are upright posture and bipedal locomotion, relatively large brains, small teeth, and relative hairlessness, as well as a host of cognitive differences including sophisticated tool use and language. What are the genetic determinants of these differences? Now that both human and chimpanzee genomes have been sequenced, and given that there is only roughly 1.2% genetic divergence at the sequence level (Chen & Li, 2001), one might expect this question to be an easy one to answer. Unfortunately, this is far from being the case: the human genome contains roughly 3×10^9 base pairs, predicting a whopping 18 million changes during our recent evolution (assuming that chimpanzees and humans each account for half of the difference from a common ancestor, and thus that 0.6% of the changes occurred in the human genome). Many of these changes will be “silent” in the sense of having no effect on the phenotype, constituting “noise” in our search for the underlying cause of human-specific traits (Carroll, 2003). Thus only a small proportion of these 18 million changes will be biologically meaningful, and an even smaller proportion may be expected to correlate specifically with human cognitive differences. Finding out which genes these are and what specific changes led to which phenotypic effects is a great challenge facing our attempts to understand the genetic mechanisms underlying human evolution.

The challenge is made greater by the fact that, based on what is known from “model organisms” such as mice or *Drosophila*, many of the critical changes are expected to involve the expression of regulatory genes and noncoding

DNA regions to which these genes bind, rather than protein-coding genes (Carroll, 2003). Protein-coding genes account for a modest 1.5% of the human genome, and many base-pair changes are synonymous, so only some 200,000 base-pair changes (about 1% of the total) will lead to protein differences. Current techniques for finding such coding differences are well developed and allow us to discover genes that have been subjected to selection (e.g., Fay, Wyckoff, & Wu, 2001). Unfortunately, the noncoding portion of the genome remains far more difficult to analyze. Differences in gene expression between humans and other nonhuman primates reveal substantial differences in the levels at which the same genes are expressed in the brain and suggest that humans are unusually divergent in this respect (Enard, Khaitovich, Klose, & Paäbo, 2002). Thus we have good reasons to believe that changes in gene regulation and in noncoding regions of DNA will be central to understanding the evolution of human cognitive capabilities including language. Given that many of the genetic differences between us and chimpanzees have to do with immunity, olfaction, and reproduction (Chimpanzee Sequencing and Analysis Consortium, 2005), finding and understanding the genes underlying human cognitive capacities resembles the proverbial search for a needle in a haystack. This is the central challenge that needs to be faced if progress is to be made understanding the genetic basis of language. Researchers hoping to meet this challenge will need all the help they can get, from all the disciplines potentially involved.

THE NEURAL CHALLENGE OF LANGUAGE The evolution of language has been argued to be one of the “hardest problems in science” (Christiansen & Kirby, 2003), because its solution requires progress on so many different disciplinary fronts (including neuroscience, linguistics, psychology, and evolutionary biology). Real solutions will require successful interdisciplinary interactions across these traditionally separate scientific domains. For the cognitive neuroscientist, the fact that language enables us to express virtually any aspect of our thoughts and feelings suggests that any aspect of conscious brain function, across many cortical areas, may potentially be tapped for expression during linguistic encoding. Exclusive focus on Broca’s area or other traditional “language” areas will not by itself be sufficient. Language takes all of cognition as its potential domain, and a well-developed neural theory of cognition will be required for a full understanding of the neural basis of language. Such a theory is still far off. Furthermore, it is now clear that much of the neural machinery for language is epigenetically specified (there is no “hard-coded” language processor in a fixed brain region). Adequate language skills develop even after complete removal of the left hemisphere (Liégeois et al., 2004), and bilinguals can recruit different brain regions when processing different languages (Hull & Vaid, 2007).

Thus an adequate neural model will also need to incorporate a rich theory of neural epigenesis: the interactions between gene expression in independent cells as influenced by their local neural processing environment within the brain and the external sensory world. This understanding also appears far off, though recent progress driven by molecular techniques is cause for hope. It will require the abandonment of *scala natura* models of brain evolution (cf. Striedter, 2004), and accepting the broad and deep similarities among *all* vertebrate brains, from fish to humans, while simultaneously allowing for the equally important differences among the brains of even closely related species.

THE LINGUISTIC CHALLENGE For the (psycho)linguist, the cognitive revolution in psychology and the associated generative revolution in linguistics have led to both considerable progress and a confusing profusion of theoretical frameworks and perspectives. While there is widespread agreement that the capacity for language has a strong biological basis, unique when considered as a whole to our species, there is little consensus about the detailed nature of this capacity. Plausible hypotheses include a continuum from a broad and general “capacity for culture” (Tomasello, 1999; Tomasello, Carpenter, Call, Behne, & Moll, 2005) to a detailed computational system specific to language and to humans (Pinker & Jackendoff, 2005). Intermediate positions include the possibility that language is built on a broadly shared cognitive foundation, with a few powerful but novel computational operations knitting shared mechanisms together (Hauser, Chomsky, & Fitch, 2002; Fitch, Hauser, & Chomsky, 2005). We can refer to *all* of the cognitive/neural mechanisms involved in language production, perception, or processing as the “faculty of language in a broad sense,” or FLB; the subset of processing mechanisms specific to language and to our species can then be referred to as the “faculty of language in a narrow sense,” or FLN (Hauser et al.). Because the nature of this latter, more specific, subset remains highly controversial (Fitch et al.; Pinker & Jackendoff, 2005), I conservatively take the FLB as a whole as the explanandum here, emphasizing that this is a multicomponent system. The FLB includes the mechanisms underlying phonetics, phonology, syntax, semantics, and pragmatics, without regard to whether each component is specific to humans or not. Many components of the FLB will be shared with nonhuman animals and thus can be studied comparatively, and such studies are required to determine the contents of FLN.

THE EVOLUTIONARY CHALLENGE For the evolutionary biologist, language evolution raises a number of challenges as well. One is that the cultural transmission of language and the resultant process of language change (“glossogeny”) raise important issues beyond those raised by the interaction of

ontogeny and phylogeny for all traits. Because language changes, the linguistic target of the learner has been filtered through the minds of previous humans, and this process leads to an “evolutionary” dynamic of its own (Darwin, 1871; Fitch, 2007b; Kirby, Smith, & Brighton, 2004; Pagel, Atkinson, & Meade, 2007). The importance of this interposition of an additional form of glossogenetic change, with a time scale between that of ontogeny and phylogeny, is increasingly recognized (Deacon, 1997; Hurford, 1990; Kirby et al.; Nettle, 1999), but scientists are only beginning to resolve some of the problems in gene/culture coevolution that this raises (Richerson & Boyd, 2005). Fortunately, we have other biological examples of cultural change for comparison (e.g., bird or whale “song”).

The same is not true for the central feature of semantics: the ability to express arbitrary thoughts. Current understanding of animal communication strongly suggests that humans are unique in this ability: if there are nonhuman species with open-ended semantics, they are remarkably clever at hiding these abilities from generations of dedicated ethologists (Bradbury & Vehrencamp, 1998; Hauser, 1996). Efforts at training nonhuman species with languagelike systems reveal both commonalities and significant differences (Kako, 1999; Tomasello & Call, 1997). One of the sharp differences is the apparent drive in our species to express our thoughts and feelings to others. This drive poses significant evolutionary problems, for the evolution of such apparently “altruistic” behavior is not predicted by standard models of the evolution of communication and cooperation (Axelrod & Hamilton, 1981; Dawkins & Krebs, 1978; Trivers, 1971; Zahavi, 1993), while the kin-selection route to cooperative communication (Hamilton, 1964; Maynard Smith & Harper, 2003) appears confounded by the fact that humans do not communicate exclusively with kin (cf. Fitch, 2004). Thus language evolution still poses deep evolutionary puzzles, if not the “embarrassment to evolutionary theory” once proclaimed by Premack (1986).

This brief survey should convince any skeptics that the biology and evolution of language involve a profusion of challenging scientific problems. For many years the topic of language evolution was neglected as a result. However, a series of methodological advances have combined with theoretical progress in a number of disciplines to reawaken hope that “biolinguistics,” as this field is sometimes called, can become a productive, empirical scientific discipline. This hope is exciting, because language is such a central aspect of human nature that a failure to understand it entails a fundamentally incomplete understanding of ourselves. I optimistically believe that the challenges I have sketched, though daunting, are within the realm of scientific inquiry and will eventually yield to concerted empirical research. Indeed, I think that with collaborative interdisciplinary effort

many of them can be solved in this century. One reason for optimism is the success of the new synthesis of evolutionary and developmental biology, which has revolutionized contemporary understanding of the interactions of genes, development, and evolution in the last decades.

“Evo-devo”: The recent marriage of evolutionary and developmental biology

At an interdisciplinary conference on adaptation and evolution in 1979, the great evolutionary biologist John Maynard Smith remarked that evolutionary theory will remain incomplete until integrated with a similarly advanced theory of developmental biology. Because it is genes, not individuals, that are passed down across the generations, mathematical approaches to evolutionary biology take changes in *genotypes* as the core phenomenon of interest (specifically, population-level changes in allele frequency), and yet Darwin’s theory focuses on variant *phenotypes* (the material form of individual organisms). Clearly, a bridging theory between genotype and phenotype is required: molecular developmental biology and a successful theory of ontogenesis. Today, by means of a happy series of consilient advances, the foundations of such a theory are now available in a discipline called *evolutionary developmental biology*, or “evo-devo” (Carroll, 2005; Carroll, Grenier, & Weatherbee, 2005; Wilkins, 2002). Central to this discipline is the recognition that genes do not direct development in a vacuum, but that gene expression within a cell always occurs in an environment made up of other cells and structured by the past behavior of previous cells. Genes do not provide a blueprint of adult form, but rather a development “recipe” that relies heavily on the local extracellular environment to determine the differentiation and growth of individual, semi-independent cells. This continual process of interaction between DNA within the cell and the extracellular environment is termed *epigenesis*, a term connoting the inadequacy of genetic determinism and traditional “gene as blueprint” models of ontogeny.

NEURAL EPIGENESIS Although our understanding of the epigenetic cycles of interaction between cells and their local environment is currently most advanced for morphological features such as animal limbs (Carroll et al., 2005), an epigenetic perspective is equally crucial for understanding brain development (Nottebohm, 1989; Rakic, 1985). This is particularly true of the vertebrate neocortex, characterized by extreme plasticity during fetal development. For example, temporal cortex, normally slated to function as “auditory cortex” in the adult, can be “rewired” to serve as visual cortex early in ontogeny (von Melchner, Pallas, & Sur, 2000). Such data extend the long-appreciated dependence of the developing brain on organism-external stimulation (Held & Hein, 1963; Hubel & Wiesel, 1965)

to the organism-internal “environment” that influences cellular differentiation. The importance of this plasticity, though greatest in early development, never ceases in the vertebrate brain (Nottebohm, 1989; Nottebohm, Kasparian, & Pandazis, 1981; Schlaug, Jäncke, Huang, & Steinmetz, 1995). Thus the epigenetic perspective of evo-devo is just as pertinent to understanding the brain as for the development of the hand or the eye (Carroll, 2003; Fernald, 2000; Shubin et al., 1997). Under this broad epigenetic umbrella, one of the most crucial recent advances has been the discovery of deep conservation of genetic mechanisms and pathways involved in development.

“Deep homology” and the conservation of developmental pathways

The great evolutionist Ernst Mayr once wrote that “the search for homologous genes is quite futile except in very close relatives” (Mayr, 1963, p. 609). A recent revolutionary finding of modern molecular biology is that Mayr was quite wrong about this. We now know that genes, particularly those involved in development, can be conserved over extremely long periods of evolutionary time (e.g., the 1200 million years separating contemporary arthropods and vertebrates). This discovery occurred initially in the context of HOX genes (“homeobox” genes, which play a crucial role in patterning the anterior-posterior body axis; cf. Duboule, 1994; Lewis, 1978). However, it is now apparent that many other developmental genes are equally strongly conserved (Wilkins, 2002), especially those that code for transcription factors (proteins that bind to DNA and influence subsequent gene expression) and their binding sites. Further examples include the Pax6 gene involved in the specification of eyes in diverse species from flies to squid to mice to humans (Gehring & Ikeo, 1999; Tomarev et al., 1997; van Heyning & Williamson, 2002).

What makes the existence of such shared genes and genetic pathways (Duboule, 2007) deeply surprising is that they control the development of structures that evolved convergently. For example, the wings of birds and flies evolved independently: the common ancestor of insects and birds did not possess wings (it was a wormlike terrestrial organism sometimes known as the Ur-bilaterian; De Robertis & Sasai, 1996). Fly and bird wings are thus “analogues” rather than homologues. It is thus surprising that the same underlying genetic mechanisms build these structures. This example is not particularly troubling, because in both cases we can consider the wings to be evolved from simple generalized appendages that were present in the Ur-bilaterian. The case of Pax6 in eye development is more significant, because virtually all pre-evo-devo scholars interested in eye evolution agreed that complex eyes have evolved convergently in insects, molluscs, and vertebrates. Indeed the camera eye,

with lens and retina, of vertebrates and cephalopods (squid and octopus) is a textbook case of convergent evolution. But we now know that Pax6 controls eye development in both. We must thus hypothesize that some simple eyespots in the Ur-bilaterian were, in some sense, ancestral to modern complex eyes, but this hypothesis greatly stretches the traditional morphological definition of homology.

The solution to this problem has been to recognize a new possibility, that *developmental programs*, down to the detailed level of gene sequences and expression patterns during development, may be shared by virtue of common descent (and thus homologous in one sense) while the *structures that they build* are not. From a structural viewpoint, squid and human eyes are convergently evolved analogues, but from a developmental viewpoint the genetic tools *utilized* to build them are homologues. This superficially paradoxical situation results from deep homology, and it demands wholesale rethinking of traditional notions of homology (Rutishauser & Moline, 2005; Shubin et al., 1997). Given increasing evidence that developmental pathways are highly conserved, across all metazoan phyla, deep homology may be common and indeed may be the rule rather than the exception in development. This evidence raises the possibility that shared homologous developmental pathways underlying the evolution of such innovative traits as eyes, wings, limblessness in reptiles, or echolocation in bats might have implications for debates in the biology and evolution of language.

Deep homology and evolutionary innovation in cognition and language

A persistent debate in cognitive science, inherited by cognitive neuroscience, may be characterized as the “specialist/generalist” debate. At the “specialist” end of the continuum, often typified by neuroethologists, organisms are seen as supremely adapted to their particular way of life: echolocating bats have evolved specializations of hearing and vocal production, electroreceptive fish have evolved innovative electrical field production and perception mechanisms, and food-caching birds have evolved prodigious memories (Camhi, 1984; Schnitzler, Menne, Kober, & Heblich, 1983). However, this perspective has not gone unchallenged by researchers who point out that underlying mechanisms may be shared across superficially different cognitive domains (cf. Bolhuis & Macphail, 2001). Similarly, a dominant contemporary paradigm in human evolutionary psychology favors a view of the human mind/brain as a “Swiss army knife”: a series of domain-specific adaptive modules (Barkow, Cosmides, & Tooby, 1992). Opponents of this nativist/modularist view emphasize the deep similarities in cognitive performance both across cognitive domains and between species (for a balanced review see Laland & Brown, 2002). We might characterize these different viewpoints as emphasizing

“modularist specialization” versus “generalist universality.” Both viewpoints have been applied to human language.

As cogently observed by Heyes (2003), these different viewpoints about cognitive evolution need not be in opposition. A multicomponent perspective on language suggests that some components (e.g., long-term memory for lexical items) might be broadly shared between species and cognitive domains, while others (e.g., mechanisms underlying recursive syntax) might be unique to our species (Hauser, Chomsky, et al., 2002). Such a mixed bag is expected from Darwinian evolution, and a theoretical framework for understanding language evolution must fully encompass both possibilities if we are to empirically resolve the issue. Arguments that “language” is monolithically modular or domain-general both oversimplify the situation to the detriment of empirical progress. Instead, humans have multiple mechanisms (biologically based predilections, biases, and constraints) crucial to language. Once we have accurately specified the particular mechanism of interest (e.g., vocal learning, syntax comprehension, lexical acquisition, “theory of mind,” etc.), it becomes an empirical question whether the components underlying such traits constitute widely shared mechanisms making up a general vertebrate or mammalian “cognitive tool kit” or highly specific components uniquely tuned to human language. Probably, some will be shared, and some will be unique to our species. We expect even “unique” mechanisms to function in a context of a suite of shared cognitive mechanisms that both predated them in evolutionary time and are shared with nonhuman species. A broad comparative approach is a logical prerequisite for addressing such questions, because no valid claim of “human uniqueness” can be made without a search for similar mechanisms in other animals.

The discovery of deep homology raises the fascinating possibility that even “unique” innovations, evolved during recent human evolution and isolated to our small branch of the primate lineage, might derive from more widely shared developmental processes. If so, the developmental pathways involved may be expected to impose certain constraints (or biases) on the system thus evolved, constraints that can be understood by examining the nature of the developmental process in nonhuman species. This approach provides an exciting empirical possibility: that the nature of the neural developmental processes that give humans our unique capacity for language can be probed, at a detailed molecular genetic level, by examining analogous processes in other vertebrates. Indeed, such inquiry could actually aid in *gene discovery* and thus help solve the “needle in a haystack” problem discussed earlier. To the extent that nature repeatedly uses the same developmental tool kit to solve similar evolutionary problems, generating deep homology, we can expect investigations of widely separated organisms, from honeybees to birds, to offer valuable cues to the genes and

genetic pathways involved in human language. This endeavor requires that we specify the nature of the computations that a particular linguistic mechanism performs, and then search for analogues of these computations in other species, regardless of how closely related to us they might be. Although we don't expect this strategy to work in every case (no one expects that *every* convergently evolved trait will involve deep homology), the recent evo-devo literature suggests that deep homology is common enough to constitute a winning bet in many cases (Carroll, 2006; Carroll et al., 2005; Shubin, 2008; Wilkins, 2002). Thus the concept of deep homology opens exciting routes for empirical enquiry.

In the remainder of this chapter I review a specific set of neural and genetic mechanisms, relevant to speech, from a comparative evolutionary viewpoint. These data illustrate the reality of a deep homology underlying vocal learning, demonstrating the potential for this approach to the biology and evolution of human language more generally.

An illustrative example: Mechanisms underlying speech and vocal learning

Among primates, humans appear unique in our capacity for complex vocal learning, but we share this capacity with dolphins, seals, and birds (Fitch, 2000; Janik & Slater, 1997) and probably elephants (Poole, Tyack, Stoeger-Horwath, & Watwood, 2005). It has recently become clear that vocal learning in birds and humans nonetheless involves identical genes, and in particular that the FOXP2 gene involved in human oromotor control (see chapter 58 in this volume by Franck Ramus and Simon E. Fisher) also plays a crucial role in vocal learning in zebra finches (Haesler et al., 2007; Scharff & Haesler, 2005). Thus FOXP2, the first gene known to be specifically involved in human spoken language, also appears to be a case of deep homology, in the same vein as the well-studied examples of HOX genes in body plan development or PAX6 in eye development.

A core prerequisite of a flexible communication system is that it include a mechanism for innovation (of new words, phrases, or syntactic rules) and a way of sharing these among those using the language. These requirements entail a capacity for imitation: children learning this system must be able to copy lexical items or rules that are not part of their innate behavioral repertoire. Because language can be expressed either vocally-auditorily (speech) or visually-manually (sign), this prerequisite is a general one. However, it is clear that great apes, and thus our common ancestor with chimpanzees, have a poor or nonexistent capacity for vocal imitation, while their visual/gestural imitation is more like our own (Call & Tomasello, 2007; Hayes, 1951; Janik & Slater, 1997). Thus a "key innovation" (Liem, 1973) in the evolution of spoken language was our novel capacity for vocal imitation.

A key component of vocal motor control, present in humans but lacking in other primates, is the direct connections between motor neurons in the inferior frontal neocortex to the motor neurons in the brain stem that control the larynx and respiration (Deacon, 1997; Jürgens, 2002; Kuypers, 1958a, 1958b). Mammalian vocalization, including innate vocalizations like screams and laughter in humans, generally relies upon an ancient medial "limbic" system, incorporating command neurons in the periaqueductal gray (PAG) that project to the medullary nuclei that are home to vocal motor neurons, particularly the nucleus ambiguus. While this ancient "chassis" controlling vocalization includes a medial cortical component (the anterior cingulate), neurons in the lateral cortex play little role in controlling vocalization and lack any direct connections onto vocal motor neurons in most vertebrates (Jürgens, 2002, 1994). Humans have evolved an additional set of vocal connections, constituting a novel system for vocal control, parallel to this ancient mammalian system. Kuypers and Jürgens hypothesized that this system, with its direct connections from motor cortex to vocal motor neurons, is a crucial component in the human ability to voluntarily control the acoustic details of vocalization: an ability not present in monkeys or apes (Larson, Ortega, & DeRosier, 1988; Larson, Sutton, Taylor, & Lindeman, 1973). Consistent with this hypothesis, no such direct connections have been revealed in detailed studies of many different nonhuman primates (reviewed in Jürgens, 2002).

This *Kuypers/Jürgens hypothesis*—that direct corticomotor connections are necessary for complex vocal control—is testable by examinations of nonprimate species in which vocal learning is or is not present. For example, vocal learning has independently evolved in three clades of birds, all of which show surprisingly similar patterns of connectivity that differentiate them from nonvocal learners (Jarvis, 2007). The best-studied of these three groups, by far, are the oscine passerine birds ("songbirds") all of whom appear to learn their songs. Consistent with the Kuypers/Jürgens hypothesis, direct telencephalic/vocal-motor neuron connections exist in songbirds and parrots (Jarvis, 2004; Wild, 1993) comparable to those documented in our own species. This finding illustrates the power of the comparative method to use convergently evolved traits to test adaptive, mechanistic hypotheses.

The connections discussed in the previous paragraph are probably necessary for vocal control but not alone sufficient for vocal learning, which further requires a capacity to utilize auditory input to control vocal output. This process, too, is well understood in songbirds (Marler & Slabbekoorn, 2004), often relying on a developmental process in which the young bird is exposed to song during a sensitive period, and then fine-tunes its song and its control over the vocal apparatus during a practice period termed *subsinging*. Songbirds deprived of either "template" songs or the opportunity for subsong

do not typically develop species-typical song. The subsong phenomenon in birds provides a striking parallel with human babbling, which appears to play a similar functional role in human vocal learning (Doupe & Kuhl, 1999; Locke & Pearson, 1990). This, then, is a shared behavioral mechanism, similar to the neural mechanisms just discussed, that underpins the convergence of vocal learning in humans and birds.

Finally, recent genetic studies of birdsong learning demonstrate further similarities. Recent experimental work in the laboratory of Constance Scharff has now clearly documented a role in avian vocal learning of a gene that was originally discovered in the context of human vocal motor control and learning: forkhead-box P2, or FOXP2 (cf. Ramus and Fisher, chapter 58 in this volume). Like the HOX and PAX genes discussed earlier, FOX genes code for a transcription factor: a protein that binds to DNA and enhances or inhibits the expression of other genes. Also like HOX and PAX, FOX genes are members of a large and highly conserved family of transcription factors. Perhaps surprisingly, given this conservatism, a human-specific mutation in this gene leads to a specific deficit in oral and vocal motor control, first discovered in a family living in England (Vargha-Khadem, Gadian, Copp, & Mishkin, 2005; Vargha-Khadem & Passingham, 1990; Vargha-Khadem et al., 1998). The discovery of this gene (Fisher, Vargha-Khadem, Watkins, Monaco, & Pembrey, 1998) was groundbreaking in that it uncovered the first, presumably of many, genes involved in human cognition and language. A decade later FOXP2 remains the clearest example of a gene involved in spoken language, shared by all nonclinical human populations, and different from chimpanzees and other primates.

In a striking new demonstration of deep homology, Scharff and her colleagues have shown that FOXP2 (and other closely related FOX genes, including FOXP1) is expressed in similar brain regions in birds and humans and plays a role in vocal learning (Haesler et al., 2004; Scharff & Haesler, 2005). In the most direct evidence of this role, Haesler and colleagues (2007) showed that a novel lentivirus-mediated knockdown of FOXP2 expression, via RNA interference, decreased the quality and quantity of vocal learning in zebra finches. The effect occurred only with injections in brain regions specifically evolved in vocal learning (Area X, homologous to basal ganglia in humans) and not injections in nonsong areas, providing strong evidence for a key role of FOXP2 in vocal learning in birds. Although the ability for vocal learning evolved separately in birds and humans, the behavioral and neural mechanisms involved show that there are fundamental similarities at the computational and circuit levels, and that the genetic mechanisms involved are identical. Thus FOXP2 constitutes a deep homology: a conserved homologous developmental pathway underlying a convergently evolved trait.

Although there are presumably many genes involved in vocal motor control, and many more involved in language more broadly, the example of FOXP2 shows that deep homology is not a phenomenon restricted to peripheral morphology. Furthermore, it illustrates the power of a model system like birdsong to illuminate our understanding of human vocal control. Experiments like those just discussed in birds are impossible in humans for ethical reasons and in primates for practical reasons: primates are incapable of complex vocal learning. While FOXP2 knockout mice have been created that show various motor deficits (Shu et al., 2005) and knockin mice with human versions of FOXP2 have been engineered (Groszer et al., 2008), there is no evidence of vocal learning in mice, and thus interpretation of these results will remain problematic. Indeed, the developmental processes in which FOXP2 is involved almost certainly require a suite of other coevolved mechanisms that are not present in most mammals. In contrast, in species like songbirds with a fully developed vocal learning ability, the discovery of one of the genes involved opens the door to targeted search for other genes in the system. The use of large-scale gene-expression assays, targeted on genes known to be up-regulated during vocal learning in birds (Wada et al., 2006), will play an important role in the discovery of such genes. Thus the undisputed fact that birdsong and human speech evolved independently may turn out to be quite irrelevant to the question of the genetic mechanisms involved, which may well be largely homologous.

Conclusions and prospects

In this chapter I have argued that the discovery of deep homology is relevant to cognitive neuroscience, and in the case of FOXP2 to spoken language. However, I fully appreciate that speech is not language (Fitch, 2000) and constitutes just one component of a set of diverse mechanisms necessary for human language. What of these other mechanisms? In particular, what of semantics and syntax, which most scholars agree are more central to human language than is speech (though see Lieberman, 1998, 2000)? At present we know far less about the neural and genetic mechanisms underlying semantics or syntax than those underlying speech, but a combination of brain imaging, gene expression profiling, and exploitation of the comparative method gives reasons for optimism concerning these components of language. I will thus end by listing some open questions concerning these additional factors.

SEMANTICS A central challenge language poses for evolutionary theory is the readiness humans exhibit to share information with other, unrelated, individuals. This drive is striking in its absence in most animals, even in language-trained chimpanzees who have the machinery for transmitting

considerable information about the world (Tomasello, 2001, 2007). Although our loquacious tendency has no specific name in English, the German term *Mitteilungsbedürfnis* (denoting a drive to share one's thoughts) captures it nicely. This drive is puzzling to evolutionary biologists because the standard explanation of apparently altruistic behaviors in animals is that they are genetically "selfish" in the sense that they are doled out preferentially to related individuals, and can thus be explained by means of kin selection (Foster, Wenseleers, & Ratnieks, 2006; Maynard Smith, 1964). But humans share information not only with unrelated individuals, but also with perfect strangers, a practice for which there can be little evolutionary advantage. One way out of the conundrum is the suggestion that language evolved initially in a kin communication context and only later was "exapted" out of this context to serve unrelated individuals exchanging information reciprocally (Fitch, 2004, 2007a). By this model, the friendly sharing of information with total strangers might remain a nonadaptive characteristic of human language. Alternatively, this may have supported the evolution of novel mechanisms for more Machiavellian reciprocity among unrelated adults. These issues remain largely unstudied empirically.

Another deep problem in the evolution of semantics is the evolution of "Theory of Mind" (ToM) in our species. Many aspects of the pragmatics of normal conversation require not just a *desire* to be informative, but also a complex mental model of what one's interlocutor knows and does not know (Grice, 1975). Being informative in the simple sense of relaying new information is not enough: to be *relevant* also requires a further notion of what the other person is trying to accomplish in a particular conversation (Sperber & Wilson, 1986). My mother's birthday or grandfather's shoe size are likely to be novel to most interlocutors but will rarely be relevant to their interests. Although there has been considerable progress in recent years in comparative research addressing the capacities of nonhuman primates and birds to model the minds of others (Bugnyar, Stöwe, & Heinrich, 2004; Hare, Call, Agnetta, & Tomasello, 2000; Hare & Tomasello, 2004), the high-level ToM involved in human language appears to be another "key innovation" our species acquired before language could reach its full, modern form. Because the possession of language itself almost certainly aids our capacity to model the minds of others, this may be a chicken-and-egg question: without ToM you can not have language, and without language you do not have full ToM. Resolution of this issue remains a central issue in the evolution of language.

SYNTAX Syntax is a core component of language because of its mediating role between the perceptual world of speech and sign and the conceptual world of thoughts, imagery, and memory. Because it is clear that our prelinguistic ancestors

had both complex perceptual and motor control, and complex cognition, syntax is often supposed to be the most recent evolutionary advance, and thus to constitute a "key innovation" during the phylogenesis of human language. Nonetheless, there is every reason to expect that syntax built upon a preexisting ability of organisms to find patterns in perceptual input, and that these pattern-discovery mechanisms can be studied comparatively.

One promising development in this regard is the use of "artificial grammar learning" to probe spontaneous capacities for pattern induction. Such work involves exposing subjects to a set of experimentally generated stimuli (the "exposure" phase) and then testing to see what patterns participants have extracted, by examining their reactions to novel stimuli that either fit into or violate the "rules" implicit in the exposure set. This work was originally developed with adult humans (Reber, 1967), but methodological advances now allow similar techniques to be used with human infants (Gómez & Gerken, 1999; Marcus, Vijayan, Bandi Rao, & Vishton, 1999; Saffran, Aslin, & Newport, 1996) and nonhuman animals (Hauser, Newport, & Aslin, 2001; Hauser, Weiss, & Marcus, 2002; Toro & Trobalón, 2005). Using the well-developed formalism of formal language theory to generate stimuli, Fitch and Hauser (2004) tested the abilities of humans and cotton-top tamarin monkeys to learn either a simple finite-state grammar or a more complex phrase-structure grammar. The results suggest that these monkeys are limited to the former class. These results have been extended with other species, and these recent data suggest that the ability to parse hierarchical phrase structure relies on a particular computational component that is clearly present in humans, lacking in at least some nonhuman primates, and perhaps present in starlings (a songbird species) (Fitch & Hauser, 2004; Gentner, Fenn, Margoliash, & Nusbaum, 2006). Furthermore, brain-imaging data suggest that humans process such grammar classes using different cytoarchitectonic regions in the inferior frontal cortex (Friederici, Bahlmann, Heim, Schubotz, & Anwander, 2006). Although the genetic mechanisms involved remain unstudied at present, this may be another example where birds provide a better model species for human language than nonhuman primates. If so, this will be excellent news for neurobiologists interested in understanding such mechanisms, since empirical techniques applicable to the developing avian brain are, and seem likely to remain, more sophisticated and advanced than those available for nonhuman primates (and of course for humans).

Conclusion

While the genetic bases underlying syntactic or semantic abilities in our species remain unknown, there is good reason to expect rapid progress in uncovering them. This will usher

in an exciting new world, both for cognitive neuroscientists interested in tying complex cognition to the underlying neural architecture and for evolutionary biologists interested in uncovering the phylogenetic trajectory that led to human language. In this new era, the identification of deep homologies may play a central role. This is excellent news for comparative biologists, because it suggests that a far broader range of vertebrates, and even nonchordates, may offer valuable windows into the genetic basis of that most human of traits, language.

Introduction

TODD F. HEATHERTON AND
JOSEPH E. LEDOUX

IN THE PREVIOUS edition of this book we noted that the neuroscientific study of emotion was flourishing, and this led scientists to recognize that other hot aspects of cognition—namely, the social aspects of cognition—were equally due for attention. In the past five years the field of social neuroscience has exploded, as evidenced by the launching of new journals and major initiatives from many federal funding agencies. At the core of this emphasis on social cognition is the importance of emotional processing. The social and emotional aspects of the brain are inexorably linked, the adaptive significance of emotions being closely linked to their social value, and nearly all social interaction produces affective responses. It is clear from the chapters in this section that the study of emotion and social cognition remains at the forefront of cognitive neuroscience.

The interdisciplinary field of cognitive neuroscience has provided ample evidence of the benefits of examining psychological constructs across multiple levels of analysis, from the molecular to the cultural. The chapters in this section cross many levels, from the role of systems, cellular and molecular mechanisms in learning and memory in adult animals (LeDoux, Schiller, and Cain) and during early development (Sullivan and colleagues), to human studies of emotion (Vuilleumier and Brosch, Whalen and Davis) and emotion regulation (Beer) using functional imaging, including imaging genomics (Hariri), and studies of brain regions that support social cognition (Mitchell and Heatherton), sensitivity to others (Singer and Leiberg), and moral transgressions (Greene), many of the chapters emphasizing how these systems interact. It is clear that research that uses multiple approaches is moving the field toward the ultimate goal of developing coherent models of how the brain makes emotion and performs its social function.

In the last edition there was remarkable convergence of evidence highlighting the important role of the amygdala across animal species and paradigms. The importance of the amygdala continues to hold center stage in the neuroscience of emotion, as is evident in many of the chapters. LeDoux, Schiller, and Cain provide a timely review of the importance of the amygdala in normal and pathological fear, especially the cellular molecular mechanisms that underlie learning and memory. For instance, they update research demonstrating the important role of gene expression in long-term potentiation, which is perhaps the most likely candidate for the physiological basis of fear conditioning and other forms of memory. The chapter by Sullivan and colleagues demonstrates that the role of the amygdala in fear learning depends on its developmental maturity. During the sensitive period associated with a rat pup's attachment to its mother (about 10 days postnatal), fear learning is attenuated due to a lack of amygdala functioning. This process allows the pup to attach to its mother irrespective of whether the mother is treating it harshly or gently. Vuilleumier and Brosch present exciting new evidence that attention and emotion can influence basic visual processing. That is, the emotional significance of stimuli, not just the strictly visual properties of the retinal image, influences basic perceptual processing. They provide compelling evidence that the amygdala plays an important role in the modulation of sensory information. Whalen and Davis address how context influences amygdala activity and subsequent interpretations of emotional stimuli; that is, they describe how amygdala activity is strongly affected by the context in which biologically relevant cues are encountered. Hariri provides examples of how imaging genetics can lead to insights about the biological mechanisms underlying individual differences in complex behavioral traits, such as how abnormal gene expression in the serotonin system can affect how the amygdala responds to facial expressions. Taken together, these chapters not only reinforce the important role of the amygdala in emotional processing but also demonstrate how new techniques and approaches are continuing to provide important insights.

The last four chapters in this section focus more on the social basis of emotional processing. These chapters demonstrate that there continues to be growing interest among

social psychologists and cognitive neuroscientists in using brain imaging to study social aspects of cognition, such as recognition of faces and emotional expressions, theory of mind, social emotions such as empathy, judging trustworthiness and attractiveness, and cooperation. Mitchell and Heatherton outline the basic components necessary for a social brain, including a sense of self, mentalizing ability, capacity for self-regulation, and threat detectors for ingroup and outgroup threats, and they discuss the discrete neural signatures of these basic components. Beer describes research on how people are able to regulate their emotions so that they can function in their social groups. She outlines evidence that damage to areas of frontal cortex interferes with emotion regulation. Singer and Leiberg describe fascinating new research on the neural basis of empathy and how it is influenced by both dispositional and contextual factors. Finally, Greene describes research on how human brains make moral judgments. The ethical brain reflects perhaps the greatest achievement of human evolution, and researchers are just beginning to identify how people make these types of important decisions.

Considering the section as a whole, it is clear that the study of emotion continues to be a strong growth area in cognitive neuroscience. Moreover, it has expanded to include the closely connected social brain. As an organ that has evolved to solve adaptive problems, the brain relies on emotional processes to solve challenges to successful adaptation. For humans, many of the most pernicious adaptive problems involve other humans, such as selecting mates, cooperating in hunting and gathering, forming alliances, competing over scarce resources, and even warring with neighboring groups. Interacting with other humans produces emotion, and these emotions serve as guidelines for successful group living. For example, behaviors such as lying, cheating, and stealing are discouraged by social norms in all societies because they decrease survival and reproduction for other group members. They also elicit vigorous emotional responses. Hence any true understanding of human nature will require a full consideration of both the emotional brain and the social brain. We expect that research on this topic will continue to be on the cutting edge of cognitive neuroscience in the next decade.

60 Ontogeny of Infant Fear Learning and the Amygdala

REGINA M. SULLIVAN, STEPHANIE MORICEAU,
CHARLIS RAINEKI, AND TANIA L. ROTH

ABSTRACT To support attachment to the caregiver, altricial infants, including humans and rats, must identify, learn, and remember their caregiver. The early attachment process in the rat is distinguished by its behavior and underlying neural circuitry, which are both exquisitely suited to promoting the infant-caregiver relationship. Foremost, infants have the enhanced ability to acquire learned preferences, and this behavior is supported by the hyperfunctioning locus coeruleus and experience-induced changes in the olfactory bulb and anterior piriform cortex. But of equal importance, infants have a decreased ability to acquire learned aversions and fear, and this behavior is facilitated through attenuated amygdala activity. Presumably, this attachment circuitry constrains the infant to form only preferences for the caretaker regardless of the quality of the care received. With maturation and the end of the infant-caregiver attachment learning period, the developing rat's social behavior and underlying circuitry transition to accommodate life outside the nest. However, early-life environmental and physiological stressors can alter the dynamic nature of this circuitry, particularly in respect to the amygdala. Such changes likely provide a framework for the lasting effects of early stress on emotional and cognitive outcome.

The altricial infant's social world revolves around the caregiver, and as evolution would have it, the infant's emotional and social behaviors have been well crafted to form and maintain the infant-caregiver relationship. Infants of many altricial species must learn to recognize their caregiver as the target of their social behavior and continue to express proximity-seeking behaviors toward their caregiver to receive the food, protection, and warmth necessary for survival. This learning about the caregiver and the emergence of social behavior directed toward the caregiver are referred to as attachment, and this process has wide phylogenetic representation, including chicks, rodents, nonhuman primates, and humans.

REGINA M. SULLIVAN, STEPHANIE MORICEAU, AND CHARLIS RAINEKI Emotional Brain Institute, Nathan Kline Institute and Child and Adolescent Psychiatry, New York University Langone Medical Center, Orangeburg, New York

TANIA L. ROTH Department of Neurobiology and the Evelyn F. McKnight Brain Institute, University of Alabama at Birmingham, Birmingham, Alabama

The social environment of the developing altricial animal is very different at birth and weaning. For example, social behavior in the infant rat following birth is limited to proximity-seeking of the caregiver. And though the complex social behavior of the developing and preweanling rat pup still involves proximity-seeking of the caretaker, it now must also facilitate interactions with peers as well as the unfamiliar social world outside the nest. Thus the rapid maturation of most altricial mammals and the ultimate transition to adult social behavior require dynamic neural circuitry that is capable of responding to these contrasting environments. In this chapter, we will review the literature on infant attachment learning and the underlying neural circuitry that mediate early infant-caregiver social interactions, the transition role of this behavior and circuitry during development, and the enduring effects of stress on both the attachment circuitry and adult behavior.

Early-life social behavior: Attachment learning

Altricial infants of many species, including the human and rat, must learn to identify, orient and approach, and prefer their own mother (Bowlby, 1969; Polan & Hofer, 1998; Shair, Masmela, Brunelli, & Hofer, 1997). This attachment learning begins during fetal life and continues after birth. For example, human infants recognize, orient toward, and prefer their own mother's voice when tested within hours of birth (DeCasper & Fifer, 1980). Furthermore, two-day-old newborns will increase suckling at the sound of their own mother's voice versus any other human voice, indicative of a learned preference for maternal voice (Fifer & Moon, 1995). This recognition is also true regarding maternal odor. At birth, a human infant who is placed on the mother's ventrum will slowly approach a breast scented with amniotic fluid in preference to an untreated breast (Varendi, Porter, & Winberg, 1996), and a change in maternal diet, which will alter the odor of the amniotic fluid, directly influences this preferential response (Lecanuet & Schaal, 1996; Mennella, Johnson, & Beauchamp, 1995; Schaal, Marlier, & Soussignan, 1995). This early odor preference appears to be learned and modulates interaction with

the mother (Schaal, Marlier, & Soussignan, 1995; Sullivan et al., 1991).

Odor learning about the mother for infant attachment appears phylogenetically widespread. Similar learning controls early social behavior in rats (Alberts & May, 1984; Blass & Teicher, 1980; Polan & Hofer, 1998; Risser & Slotnick, 1987; Teicher, Flaum, Williams, Eckhert, & Lumia, 1978), rabbits (Distel & Hudson, 1985; Hudson, 1985; Hudson & Distel, 1983), and mice (Armstrong, DeVito, & Cleland, 2006; Coppola, Coltrane, & Arsov, 1994; M. B. Hennessy, Li, & Levine, 1980; Moles, Kieffer, & D'Amato, 2004). In these species, an infant's social world after birth is the nest; therefore social behavior is mostly directed toward the mother. Indeed, during this time of dependency upon the mother, behavior is centered on maintaining contact with the mother, and this behavior is guided and controlled by the presence of maternal odor (Galef & Kaner, 1980; Leon, 1992). Specifically, maternal odor drives an infant to approach the mother and induces nipple attachment, while chemical removal of the natural maternal odor disrupts these behaviors (Hofer, Shair, & Singh, 1976; Teicher & Blass, 1977).

Infant rats learn their mother's odor naturally within the nest (Brunjes & Alberts, 1979; Campbell, 1984; Galef & Kaner, 1980; Leon, 1975; Miller, Jagielo, & Spear, 1989; Pedersen, Williams, & Blass, 1982; Rudy & Cheatle, 1977; Sullivan, Brake, Hofer, & Williams, 1986; Sullivan, Hofer, & Brake, 1986; Sullivan, Wilson, Wong, Correa, & Leon, 1990; Terry & Johanson, 1996). However, this learning can be mimicked in classical conditioning experiments outside the nest (Camp & Rudy, 1988; Haroutunian & Campbell, 1979; Moriceau & Sullivan, 2006; Roth & Sullivan, 2005; Spear, 1978; Sullivan, Hofer, & Brake, 1986; Sullivan, Landers, Yeaman, & Wilson, 2000). Specifically, paired presentations of odor and reward are sufficient to produce both learned odor preferences (demonstrated by an approach to the odor) and nipple attachment. Furthermore,

as illustrated in figure 60.1, a broad range of stimuli have been shown to function as a reward capable of producing learned odor preferences in infant rats outside the nest (Alberts & May, 1984; Brake, 1981; Galef & Sherry, 1973; Johanson & Hall, 1979; Johanson & Teicher, 1980; Leon, 1975; McLean, Darby-King, Sullivan, & King, 1993; Pedersen et al., 1982; Sullivan, Brake, et al., 1986; Sullivan, Hofer, & Brake, 1986; Weldon, Travis, & Kennedy, 1991; Wilson & Sullivan, 1994).

Though it is well established that the infant rat shows excellent learning and memory ability, particularly for learned odor preferences, we still understand very little of the neural framework that is responsible for this early behavior. Indeed, the neural structures that are well documented to support learned behavior in adult rats (e.g., hippocampus, frontal cortex, and amygdala) are not yet fully functional in infants. This suggests that the neural circuitry that mediates attachment learning and memory in the developing rat might differ from that in the adult. Our work as well as that of others has shown that indeed this is the case. Together, data implicate a unique neural framework in the infant that is responsible for the olfactory-based attachment learning.

Attachment learning circuitry

Both anatomical and physiological changes within the olfactory bulb have been documented to support odor preference learning and memory in infant rats (Fillion & Blass, 1986; Fleming, O'Day, & Kraemer, 1999; Johnson, Woo, Duong, Nguyen, & Leon, 1995; Moore, Jordan, & Wong, 1996; Sullivan & Wilson, 1991; Wilson, Sullivan, & Leon, 1987; Woo, Coopersmith, & Leon, 1987; Yuan, Harley, Darby-King, Neve, & McLean, 2003; Zhang, Okutani, Inoure, & Kaba, 2003). These changes occur not only in response to odors experienced in the nest (Sullivan et al., 1990), but also in controlled learning experiments outside the nest (Sullivan & Leon, 1986; Johnson et al., 1995; Moriceau & Sullivan,

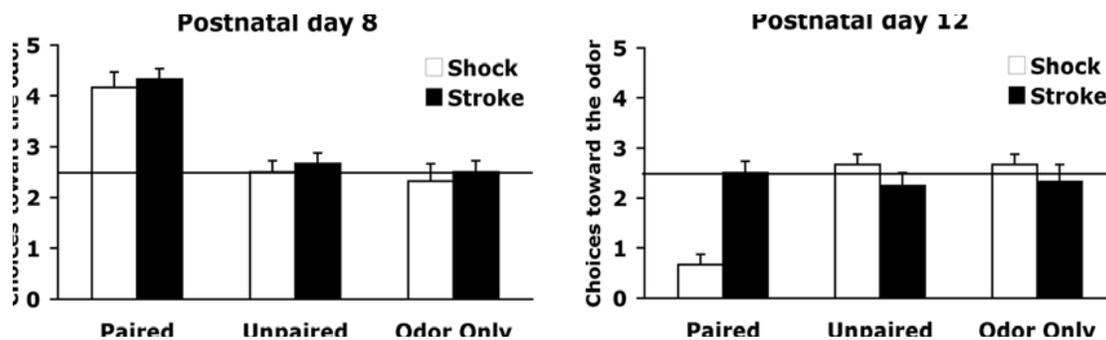

FIGURE 60.1 This graph illustrates pup preference learning from stroking (mimicking mother licking) and shock (mimicking pain received from mother) and developmental changes. During a sensitive period, eight-day-old rat pups readily form a learned odor preference to contiguous presentations of odor and stroking or tail-

or foot-shock (0.5 mA). With the close of the sensitive period, twelve-day-old pups no longer show learned-odor associations with stroking and, in contrast to younger pups, show learned aversions to odor-shock presentations.

2004; Roth & Sullivan, 2005; Yuan, Harley, McLean, & Knopfel, 2002; Sullivan & Wilson, 1991; Wilson, Sullivan, & Leon, 1987). These learning-induced olfactory bulb changes are attributable to the large influx of norepinephrine (NE) released from the locus coeruleus (LC) (McLean & Shipley 1991; Shipley, Halloran, & de la Torre, 1985), which prevents the mitral cells of the olfactory bulb from habituating to continual olfactory stimulation (Okutani, Kaba, Takahashi, & Seto, 1998; Sullivan, Stackenwalt, Nasr, Lemon, & Wilson, 2000; Sullivan, Wilson, & Leon, 1989; Sullivan, Zyzak, Skierkowski, & Wilson, 1992; Wilson, Sullivan, & Leon, 1987). At the molecular level, NE also increases CREB phosphorylation (pCREB) via cAMP stimulation (McLean, Harley, Darby-King, & Yuan, 1999; Yuan et al., 2003; Zhang et al., 2003). This ultimately activates the transcription of immediate-early and late-response genes whose readouts support synapse formation, neurogenesis, and learning (Bekinschtein, Cammarota, Izquierdo, & Medina, 2008; Tao, Finkbeiner, Arnold, Shaywitz, & Greenberg, 1998). This is a common cellular cascade that mediates learned behavior in many species across development (Carew, 1996; Carew & Sutton, 2001; Rankin, 2002).

In the infant, the abundant amount of NE released to the olfactory bulb is inducible by a wide range of sensory stimuli (Nakamura & Sakaguchi, 1990; Rangel & Leon, 1995). Furthermore, NE is both necessary and sufficient for the learning-induced behavioral and neural changes that are displayed in the infant. Specifically, either lesioning the LC or blocking NE receptors in the olfactory bulb prevents associative learning. An odor preference is also readily learned with paired presentations of NE (LC stimulation or intrabulbar NE infusions) and an odor (Sullivan et al., 1992; Sullivan, Wilson, Lemon, & Gerhardt, 1994; Sullivan, Stackenwalt, 2000; Yuan et al., 2003; Langdon, Harley, & McLean, 1997).

The infant LC releases substantially more NE into the olfactory bulb than the adult LC (Rangel & Leon, 1995). In fact, there is a sharp contrast between the functioning of the infant and adult LC. Unlike the adult LC, the infant LC responds to a broader range of sensory stimuli and fails to habituate after repeated sensory stimulation (Kimura & Nakamura, 1985; Nakamura & Sakaguchi, 1990; Foote, Aston-Jones, & Bloom, 1980; Harley & Sara, 1992; Sara, Dyon-Laurent, & Herve, 1995; Vankov, Herve-Minvielle, & Sara, 1995). Differences in the functioning of the autoreceptors that are located on the somadendritic membranes of the LC neurons appear to be responsible for the development-related differences in stimulus-response times (Marshall, Christie, Finlayson, & Williams, 1991; Nakamura & Sakaguchi, 1990; Winzer-Serhan, Raymon, Broide, Chen, & Leslie, 1997). Specifically, an infant LC's $\alpha 2$ inhibitory autoreceptors, while present, do not appear functional; therefore the excitatory $\alpha 1$ autoreceptors ensure a prolonged response upon sensory stimulation. At the end of the attach-

ment learning period, "adultlike" characteristics of the LC emerge, including a shorter stimulus-evoked response time and stimulus habituation. These adult characteristics parallel the functional emergence of the $\alpha 2$ inhibitory autoreceptors, and this functional change in physiology of the LC dovetails when NE begins to play a more modulatory role (verses the necessary and sufficient role) in learned behavior (Ferry & McGaugh, 2000; McGaugh, 2006).

Thus far, we have discussed the experience-induced changes in the olfactory bulb and LC that are responsible for early-life learned-odor associations. One additional structure that we recently added to the infant attachment circuit is the piriform "olfactory" cortex. Axons of the mitral cells of the olfactory bulb project directly to the piriform cortex (Haberly, 2001; Schwob & Price, 1984a), and the piriform cortex can be divided, both anatomically and physiologically, into two distinct structures: (1) the anterior piriform cortex, which is more influenced by direct olfactory bulb input, and (2) the posterior piriform cortex, which is more influenced by input from other limbic structures and intracortical connectivity (Swanson & Petrovich, 1998; Wilson & Stevenson, 2003). While cellular and physiological changes in the olfactory bulb play a prominent role in the early learning process, the piriform cortex appears to have an important role in assigning the hedonic value to a learned odor. In particular, early-life learned odor preferences engage the anterior piriform cortex (with no detectable activity in the posterior piriform), while learned odor aversions in older pups and adults engage posterior piriform cortical activity (Moriceau & Sullivan 2006; Moriceau et al., 2006; Raineki, Shionoya, Sander, & Sullivan, 2009; Roth & Sullivan 2005).

In summary, the data that we have reviewed thus far suggest that the contingent events of stimulus-induced NE release from the LC and NE-induced physiological and molecular changes in the olfactory bulb and anterior piriform cortex support the neural plasticity that is responsible for the acquisition of olfactory-based attachment behavior in the infant rat.

Fear and amygdala are attenuated in early life

In addition to enhanced preference learning supported by the neural circuitry discussed above, infant social behavior is also characterized by limitations on aversive learning. For example, shocking a chick during imprinting actually enhances following of the surrogate caregiver, although shock supports avoidance just hours after the imprinting critical period closes (Hess, 1962; Rajecki, Lamb, & Obmascher, 1978; Salzen, 1970). Similarly, shocking an infant dog or rat results in a strong attachment to the caregiver (Camp & Rudy, 1988; Roth & Sullivan, 2005; Spear, 1978; Stanley, 1962; Sullivan, Brake, et al., 1986;

Sullivan, Landers, et al., 2000). Finally, nonhuman primate and human infants exhibit strong proximity-seeking behavior toward an abusive mother (Harlow & Harlow, 1965; Maestripieri, Tomaszycski, & Carroll, 1999; Sanchez, Ladd, & Plotsky, 2001; Suomi, 2003).

Certain types of inhibitory learning, including fear of predators, cued- and contextual-fear conditioning, inhibitory conditioning, and passive avoidance, do not emerge until after postnatal days 10–11 (Blozovski & Cudennec, 1980; Camp & Rudy, 1988; Collier, Mast, Meyer, & Jacobs, 1979; Goldman & Tobach, 1967; Haroutunian & Campbell, 1979; Myslivecek, 1997; Stehouwer & Campbell, 1978; Sullivan, Landers, et al., 2000). Indeed, aversive stimuli such as moderate shock (as shown in figure 60.1) and tailpinch elicit learned odor preferences in infant rats (Camp & Rudy, 1988; Haroutunian & Campbell, 1979; Moriceau & Sullivan, 2006; Moriceau et al., 2006; Roth & Sullivan, 2005; Spear, 1978; Sullivan, Hofer, and Brake, 1986; Sullivan, Landers, et al., 2000), despite an apparent pain response (Barr, 1995; Collier & Bolles, 1980; Emerich, Scalzo, Enters, Spear, & Spear, 1985; Fitzgerald, 2005; Shair, Masmela, Brunelli, & Hofer, 1997; Stehouwer & Campbell, 1978).

What could explain this paradoxical preference learning to aversive stimuli? Evidence suggests that the lack of amygdala plasticity may play a leading role. Indeed, the limitations on fear learning, passive avoidance, active avoidance, and inhibitory conditioning during the sensitive period correspond to the period during development when the amygdala does not participate in the learning process (Blozovski & Cudennec, 1980; Collier et al., 1979; Myslivecek, 1997). Specifically, the amygdala is not evoked during infant learning in classical fear-conditioning or natural fear paradigms (Moriceau, Roth, Okotoghaide, & Sullivan, 2004; Moriceau & Sullivan, 2006; Moriceau et al., 2006; Roth & Sullivan, 2005; Wiedenmayer & Barr, 2001). On the contrary, in other animals ranging from *Caenorhabditis-elegans* to rodents and humans, the amygdala is a brain area that is readily evoked by aversive stimuli in classical conditioning and natural fear paradigms (Blair, Schafe, Bauer, Rodrigues, & LeDoux, 2001; Davis, 1997; Fanselow & Gale, 2003; Fanselow & LeDoux, 1999; Herzog & Otto, 1997; Maren, 2003; McGaugh, Roozendaal, & Cahill, 1999; Pape & Stork, 2003; Pare, Quirk, & Ledoux, 2004; Rosenkranz & Grace, 2002; Sananes & Campbell, 1989; Schettino & Otto, 2001; Sevelinges, Gervais, Messaoudi, Granjon, & Mouly, 2004; Sigurdsson, Doyere, Cain, & LeDoux, 2007).

One contributing factor for the apparent lack of amygdala plasticity in early-life learning may be functional amygdala immaturity. The development of the amygdala is considered protracted and extends into adolescence, though peak neurogenesis and nuclei subdivision occur as early as the first week of life (Bayer, 1980; Berdel & Morys, 2000a, 2000b; Berdel, Morys, & Maciejewska, 1997; Bouwmeester,

Smits, & Van Ree, 2002; Cunningham, Bhattacharyya, & Benes, 2002; Morys, Berdel, Jagalska-Majewska, & Luczynska, 1999; Nair & Gonzalez-Lima, 1999). Synaptic development begins to appear around PN5, with a dramatic increase between PN10 and PN20, but adult levels are not reached until early adolescence (Mizukawa, Tseng, & Otsuka, 1989). Furthermore, the typical long-term synaptic plasticity (LTP) that is inducible in the adult basolateral amygdala does not emerge until the end of the attachment learning period (Thompson, Sullivan, & Wilson, 2008).

Thus far in this review, we have discussed the literature that presents the case that it is difficult for infants to learn aversions. Sadly, attachment occurs regardless of inadequate caregiving. Specifically, children tolerate considerable abuse while remaining strongly attached to an abusive caretaker (Helfer, Kempe, & Krugman, 1997; Pollak, 2003). Moreover, attachment despite abuse is spread throughout the animal kingdom (Camp & Rudy, 1988; Maestripieri et al., 1999; Rajecki et al., 1978; Salzen, 1970; Sullivan, Landers, et al., 2000). An evolutionary explanation that we have provided for this paradoxical attachment is that it is better for an altricial infant to have a bad caretaker than no caretaker, as an altricial infant is dependent upon access to the mother's milk, warmth, and protection (Hofer & Sullivan, 2001).

However, it is important to discuss the data that demonstrate that infants can learn aversions under some circumstances. Infant rats are able to learn to avoid odors if these are paired with malaise, such as that produced by a LiCl injection or 1.0-mA shock (Abate, Spear, & Molina, 2001; Alleva & Calamandrei, 1986; Campbell, 1984; Coopersmith, Lee, & Leon, 1986; Gruet, Richer, & Hars, 2004; Haroutunian & Campbell, 1979; J. W. Hennessy, Smotherman, & Levine, 1976; Hoffmann, Hunt, & Spear, 1990; Hoffmann, Molina, Kucharski, & Spear, 1987; Hunt, Molina, Rajachandran, Spear, & Spear, 1993; Hunt, Spear, & Spear, 1991; Miller, Molina, & Spear, 1990; Molina, Hoffmann, & Spear, 1986; Richardson & McNally, 2003; Rudy & Cheate, 1983; Shionoya et al., 2006; Smotherman, 1982; Smotherman, Hennessy, & Levine, 1976; Smotherman & Robinson, 1985, 1990; Spear, 1978; Spear & Rudy, 1991; Stickrod, Kimble, & Smotherman, 1982). Interestingly, while in adult and preweaning rats, the amygdala responds to odor-malaise conditioning (Bermudez-Rattoni, Grijalva, Kiefer, & Garcia, 1986; Gale et al., 2004; LeDoux, 2000; Touzani & Sclafani, 2005), in infants, odor-malaise uses a nonamygdala neural circuit for odor aversion learning that includes the olfactory bulb (Raineke et al., 2009; Shionoya et al., 2006). Another remarkable constraint exists on aversion learning during infancy: If neonatal rats are nursing during odor-LiCl conditioning, this prevents a learned odor aversion and instead produces a learned odor preference (Gubernick & Alberts, 1984;

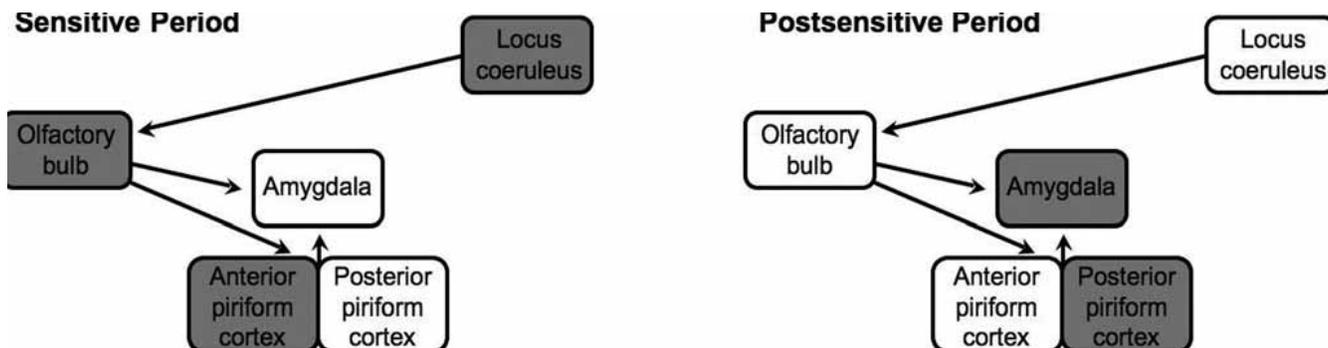

FIGURE 60.2 This graph illustrates the neural basis of attachment learning with odor–0.5-mA shock conditioning during the early life sensitive period for attachment and its maturational changes to the fear neural circuit in older pups. The olfactory bulb, anterior piri-

Martin & Alberts, 1979; Melcer, Alberts, & Gubernick, 1985; Shionoya et al., 2006).

Together, data indicate that aversions are not readily learned by infants, and we attribute this to unique neural circuitry optimized to facilitate attachment to the caregiver, regardless of the quality of care provided. In figure 60.2, we provide a model of our current understanding of this early social attachment circuit and how this circuitry changes to transition the developing animal from attachment learning to learning that can accommodate both learned preferences and avoidances.

Role of corticosterone in early life

As was discussed in the previous section, the developmental emergence of fear learning parallels amygdala plasticity and maturation (Berdel & Morys, 2000b; Berdel et al., 1997; Bouwmeester et al., 2002; Cunningham et al., 2002; Morys et al., 1999; Nair & Gonzalez-Lima, 1999; Schwob, Haberly, & Price, 1984; Schwob & Price, 1984b; Thompson et al., 2008; Wilson, Best, & Sullivan, 2004). Pharmacological manipulations of corticosterone (CORT) levels in the infant have allowed us to further define the early social circuit, and furthermore have provided us a platform to assess how changes in the early environment can affect the developing brain and subsequent transition to adultlike behavior.

In infant rats, CORT levels are relatively low (Henning, 1978; Walker, Sapolsky, Meaney, Vale, & Rivier, 1986), and the ability of most stressful stimuli, that is, restraint or shock (Grino, Paulmyer-Lacroix, Faudon, Renard, & Anglade, 1994; Levine, 1962, 2001; Rosenfeld, Suchecki, & Levine, 1992), to evoke CORT secretion is greatly reduced in comparison to that in older animals (Butte, Kakihana, Farnham, & Noble, 1973; Cate & Yasumura, 1975; Guillet & Michaelson, 1978; Guillet, Saffran, & Michaelson, 1980; Levine, 1967). This period of reduced hypothalamic-pituitary-adrenal (HPA) axis responsiveness during neonatal development has been termed the *stress hyporesponsive period*

form cortex, and LC constitute the attachment neural circuit, while the fear-conditioning neural circuit activates the posterior piriform cortex and the amygdala during fear conditioning in older postsensitive period pups.

(SHRP). Sensory stimulation provided by the mother during nursing and grooming seems to control the pups' low CORT levels (Levine, 1962; Van Oers, Kloet, Whelan, & Levine, 1998). In fact, prolonged maternal separation (~24 hours), which deprives pups of maternal sensory stimulation, increases pups' CORT levels (Levine, 2001), while the replacement of maternal sensory stimulation or maternal presence is able to reinstate the low level of CORT (Stanton & Levine, 1990; Stanton, Wallstrom, & Levine, 1987; Suchecki, Rosenfeld, & Levine, 1993). This reduced stress reactivity experienced by neonates is hypothesized to protect the developing organism from the negative influences of stress hormones (Sapolsky & Meaney, 1986). Indeed, high doses of CORT administered to the neonatal rat causes decreased mitosis, myelination, and altered granule cell genesis (Bohn, 1980). Furthermore, animals treated during infancy with CORT show reduced DNA content and brain size as well as impaired adult behavior (Bohn, 1984) and neuroendocrine function (Erkine, Geller, & Yuwiler, 1979). But it is important to note that moderate exposure to CORT during the developmental stage may be beneficial. For example, juvenile rats who were exposed to CORT via the dam's milk show superior performance on the Morris water maze task, a test of spatial memory (McCornick et al., 2001).

In adolescents and adults, while stress is generally considered to be detrimental to social behavior, in moderation it has an adaptive role and facilitates social interactions, learning, and the expression of learned social behavior (DeVries, 2002; McEwen, 2002). Indeed, social stimuli directly influence the CORT response. Specifically, maternal presence in adolescent guinea pigs, peers in nonhuman primates, and mate presence in voles reduce CORT (Carter & Keverne, 2002; DeVries, Glasper, & Detillion, 2003; M. B. Hennessy, Maken, & Graves, 2002; M. B. Hennessy, Nigh, Sims, & Long, 1995), while social affiliation in humans blocks stress-induced CORT release (Kirschbaum, Klauer, Filipp, & Hellhammer, 1995). Higher stress levels can produce a defensive/offensive system under perceived danger that is

controlled, at least in part, by the amygdala (Korte, 2001). Thus an adult's ability to balance the stress response determines whether social interactions occur or are inhibited by a fear/anxiety response.

Like the role of NE, the role of CORT in mediating learned behavior changes with maturation. While CORT is considered to play a modulatory role in adult fear conditioning (Corodimas, LeDoux, Gold, & Schulkin, 1994; Hui et al., 2004; Pugh, Tremblay, Fleshner, & Rudy, 1997; Roozendaal, Carmi, & McGaugh, 1996; Roozendaal, Quirarte, & McGaugh, 2002; Thompson, Erickson, Schulkin, & Rosen, 2004), CORT is able to switch whether infants learn an aversion or a preference. Specifically, increasing CORT by systemic injections or by intra-amygdala infusions during 0.5-mA odor-shock conditioning or presentation of naturally aversive stimuli is sufficient to elicit both a fear response (learned or unlearned fear) and amygdala participation in the infant (Moriceau et al., 2004; Moriceau & Sullivan, 2004, 2006; Takahashi, 1994). Maternal presence in older animals will lower CORT levels following stressful stimuli such as shock (Stanton et al., 1987; Suchecki et al., 1993), block fear learning, reinstate the attachment learning (preference), and prevent the participation of the amygdala in learning (Moriceau & Sullivan, 2006). After PN15, only fear will be learned during an odor-shock conditioning (Upton et al., in prep). Furthermore, we have verified the causal relationship between maternal presence and suppression of a shock-induced CORT release in pups' odor aversion learning by systemic and intra-amygdala CORT infusions, which then permit pups to learn odor aversions even in the presence of the mother.

To summarize, data indicate that during the attachment period, the mother maintains low infant CORT levels and attenuates amygdala activation, preventing infants from responding to fear/aversive stimuli. Furthermore, through manipulation of CORT levels, we have highlighted a transition period of co-occurrence between the infant attachment learning system and the amygdala-dependent fear learning system (figure 60.3). This suggests that environmentally

induced alterations of CORT levels and amygdala activity have the potential to disrupt the learning transition and underlying neural circuitry.

Consequences of early-life alterations in CORT and amygdala activity

The importance of the early environment in the regulation of behavior throughout the life span has been long recognized in both clinical and experimental studies. Indeed, it suffices to say that adult behavior is dependent on the caregiver and the quality of the caregiving environment. In particular, early-life experiences in the context of early social attachment have the most profound impact on adolescent and adult emotion and cognition in rodents, nonhuman primates, and humans (Bell & Denenberg, 1962; Denenberg, 1963; Harlow & Harlow, 1965; Levine, 1962; Rosenzweig et al., 1969; Schore, 2001). For example, the learned attachment odor in rodents is retained and preferred well into adulthood (Coopersmith & Leon, 1986; Fillion & Blass, 1986; Moore et al., 1996; Sevelinges et al., 2007; Shah, Oxley, Lovic, & Fleming, 2002; Woo & Leon, 1988), although the role of the odor in modifying behavior changes from that used during infancy (attachment to the mother) to that used in adulthood (reproduction). Specifically, following odor-stroke attachment learning in infancy, adult male rats exhibit enhanced sexual performance when exposed to the same odors that they experienced in infancy (Fillion & Blass, 1986; Moore et al., 1996).

These results are consistent with observations in other species on the influence of early experiences on adult mate preferences (Slagsvold, Hansen, Johannessen, & Lifjeld, 2002). Infant-learned attachment odors also continue to elicit both enhanced neural responses of the olfactory bulb and attenuated amygdala activation in the adult (Sevelinges et al., 2007). In particular, an odor that is paired with pain to produce the learned attachment odor attenuates adult fear conditioning as well as attenuating amygdala neural activity supporting the learning (Sevelinges et al., 2007).

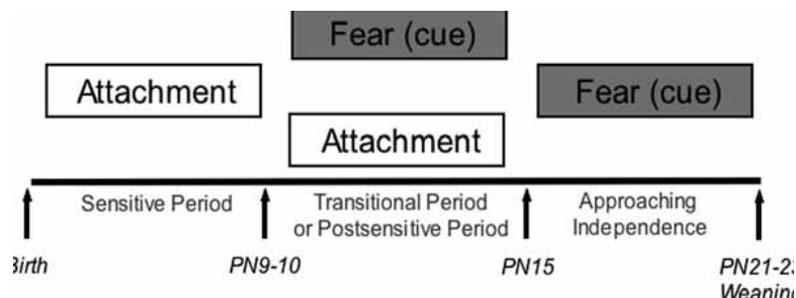

FIGURE 60.3 This schematic represents pups' developmental learning transitions with odor-0.5-mA shock conditioning. Our previous work suggests that PN10 is a transitional age for the onset

of amygdala-dependent fear conditioning, although this can be advanced or retarded by increasing or decreasing CORT either pharmacologically or naturally (maternal presence lowers CORT).

Though it is becoming increasingly clear that disruptions to infant attachment have profound maladaptive effects on adult behavior, the question of *how* this occurs remains largely unclear. Different models studying the involvement of early-life environment and its enduring effect have been developed over the years (maternal separation/deprivation, rearing environment alteration and CORT manipulation, neonatal handling), and data from these models in addition to data from our rat model of attachment are providing a clearer understanding of the common loci between infant attachment learning and the damaging effects of early stress on adult behavior.

MATERNAL SEPARATION/DEPRIVATION The maternal deprivation or maternal separation paradigm is a model of infant neglect. This paradigm, in rats, consists of removing pups from the nest for an extended period of time (3–24 hours) either once or multiple times during the first and second postnatal weeks. Such separation removes multiple sensory stimuli, including odor, warmth, and physical contact, that regulate various aspects of pups' physiology, including CORT, temperature, and heart rate (Hofer, 1973). The difference in removing more or less of these sensory stimuli that are normally provided by the mother, siblings, and the nest has led to variable results between labs.

Rat pups' initial behavioral responses to maternal separation consist of increased behavioral activity and vocalizations, including ultrasonic vocalization (Hofer, Shair, Masmela, & Brunelli, 2001). But within approximately an hour, this response changes to hypoactivity (Hofer & Shair, 1991). Such behavioral responses can be greatly attenuated if pups are provided with adequate warmth and a source of maternal odor (Hofer & Shair, 1978; Sokoloff & Blumberg, 1997). The long-term effects of prolonged periods of maternal separation appear to produce an animal that is more behaviorally responsive to stressful situations (Andersen, Lyss, Dumount, & Teicher, 1999; Kosten, Miserendino, Bombace, Lee, & Kim, 2005). Furthermore, in rats and nonhuman primates, maternal separation during infancy increases the magnitude of the neuroendocrine responses to stress and thus the susceptibility to stress-related diseases (Caldji, Diorio, & Meaney, 2003; Hall, Wilkinson, Humby, & Robbins, 1999; Higley, Hasert, Suomi, & Linnoila, 1991; Ladd et al., 2000; Liu, Caldji, Sharma, Plotsky, & Meaney, 2000; Meaney, 2001; Plotsky & Meaney, 1993; Suomi, 1997). For example, rats that are separated from their mother show greater ACTH and CORT peak responses and a more prolonged response to stress (Ladd et al., 2000; Liu et al., 2000). A reduction in hippocampal glucocorticoid receptors (GR) and thus the reduced glucocorticoid negative feedback appears to be responsible for this increased stress response (Meaney et al., 1996).

REARING ENVIRONMENT ALTERATION Nest building begins in pregnancy and continues throughout lactation, although nest quality can vary considerably between mothers. Disruption of a mother's nest-building ability thus provides another avenue to study the effects of early stress on the brain and behavior. In this model, insufficient bedding material is used to provide a continuous stressor for the mother and pups, which ultimately alters mother-pup social interactions. The mother spends a longer time away from the pups, transports the pups more frequently, and engages in more self-directed behaviors that are nonmaternal (grooming) but still nurses normally (Avishai-Eliner, Gilles, Eghbal-Ahmadi, Bar-El, & Baram, 2001; Gilles, Schultz, & Baram, 1996).

The chronic nest alteration paradigm not only raises CORT levels in the infant, but also changes gene expression at multiple levels of the HPA axis and within the frontal cortex (Avishai-Eliner et al., 2001; Gilles et al., 1996; Hatalski, Guirquis, & Baram, 1998; Lightman & Harbuz, 1993; van Oers, de Kloet, Li, & Levine, 1998). In the behavioral realm, this early-stress model produces significant deficits in adult hippocampal learning and memory (Brunson et al., 2005; Fenoglio, Brunson, & Baram, 2006). Finally, we have data showing that attachment learning is modified. Specifically, fear conditioning in infants (which normally produces a learned preference) that are raised in an altered nest environment produces odor aversion learning, and this atypical infant behavior is correlated with the early emergence of amygdala participation and increased CORT levels (Moriceau et al., in prep).

NEONATAL HANDLING Early handling is defined as the experimenter picking up the pup, removing it from the home cage, and isolating it in a different environment for 3–15 minutes daily between birth and weaning. Infant-handled rats show reduced fear as expressed by the increased exploratory activity, a decrease CORT response following stressors, and a more rapid return of CORT to the baseline in adulthood (Hess, Denenberg, Zarrow, & Pfeifer, 1969; Levine, 1962, 1967; Meaney et al., 1993; Meerlo, Horvath, Nagy, Bohus, & Koolhaas, 1999). This rapid return is attributable to a more sensitive HPA axis feedback. Indeed, infant-handled rats have an increase in the number of GRs in the hippocampus and frontal cortex as early as PN23 (Avishai-Eliner et al., 2001; Levine, 1994; Meaney et al., 1993; Sapolsky, 1994). Also, there is a decrease in GRs in the central nucleus of the amygdala around PN9 (Fenoglio, Brunson, Avishai-Eliner, Chen, & Baram, 2004). Both the reduction of GR expression in the amygdala and the increase in the hippocampus may function to reduce the sensitivity of the HPA axis to stressors. However, a maladaptive consequence of neonatal handling is its impact on adult social behavior, which includes a decrease in adult sexual

behavior, ovulation, and sperm production (Gomes, Frantz, Sanvitto, Anselmo-Franci, & Lucion, 1999; Gomes et al., 2005; Mazaro & Lamano-Carvalho, 2006; Padoin, Cadore, Gomes, Barros, & Lucion, 2001; Raineke et al., 2008).

Summary and implications

The clinical literature has clearly shown that early-life adverse experiences (physical and/or emotional) can compromise adult mental health and social behavior (Gunnar & Quevedo, 2007; Teicher et al., 2003). The infant's primary environment is the caregiver, and while the environment expands as the child becomes more mobile and independent, the child's primary environmental force remains the caregiver. Clinical literature suggests that the infant's relationship with the caregiver is of the utmost importance in shaping the child's behavior (Gunnar & Quevedo, 2007; Schore, 2001; Teicher et al., 2003). For example, a child with a healthy and secure attachment is likely to mature into a mentally healthy adult, while a child in an abusive situation has a greater probability of experiencing adult mental dysfunction and physical health problems. Indeed, the clinical effects of an abusive relationship inside and outside of the attachment dyad have different clinical outcomes, with greater vulnerability to later mental health problems when the abuse occurs within the attachment system (Zeanah, Keyes, & Settles, 2003). The neurobiological effects of abuse within versus outside the attachment system remain elusive, especially with respect to the specific physical mechanism that causes such differential effects. Most of the clinical work suggests that both mental and physical health is compromised and expressed during childhood and that this continues through adolescence into adulthood (Bremner, 2003; Nemeroff, 2004).

The importance of these clinical studies has recently been highlighted with brain imaging research showing that these early adverse events are correlated with aberrant adult brain functioning, most notably in the limbic system, frontal cortex, and cerebellum (Bremner, 2003; Kaufman, Plotsky, Nemeroff, & Charney, 2000; Nemeroff, 2004; Teicher et al., 2003). Presumably, these changes arise through maltreatment-induced compromises in the trajectory of brain development (Stien & Kendall, 2004). However, owing to ethical and practical issues, functional imaging of the immature human brain is not feasible under most circumstances. These procedures generally require the child to remain motionless, and therefore anesthesia is required. Thus we are left guessing when a particular brain area function emerges on the basis of anatomical, neurotransmitter, and synaptic development. This problem is potentiated by difficulty in assessing connectivity within and between brain areas as well as deciding whether a child's brain area has the same or different function as that area in the adult.

Our rodent animal model of attachment enables us to assess some factors potentially associated with the clinical outcome. This model of attachment accommodates both abusive and pleasant attachment, yields an experimental paradigm in which the effects of both endogenous and exogenous pharmacological insults to the developing brain and behavior can be assessed, and allows us to identify the basic neural circuitry for early social behavior (attachment learning).

In this review, we have outlined the neural circuitry that underlies the infant rat's attachment to the mother, highlighting its predisposition to support proximity-seeking behaviors. We suggest that the infant rat's attachment circuit is due not simply to the absence or immaturity of brain structures but rather to the brain having unique characteristics (LC hyperfunctioning and amygdala hypofunctioning) that enable the infant to survive in the environment unique to infancy. More important, we have discussed how temporal characteristics of attachment can be manipulated by both environmental and physiological factors and how these factors may render the animal vulnerable to maladaptive brain development.

While human children show behavior within the attachment system (proximity seeking, tolerance of pain) remarkably similar to that of other species (rat, dog, and nonhuman primate), it is unclear whether this attachment circuitry exists in human infants. However, it does suggest that the human infant's brain is *likely* organized to ensure rapid, robust attachment to their caregiver. This further suggests that environmental and physiological factors may likewise alter attachment and adult emotional and cognitive well-being through disruption of the brain areas involved in the early attachment process.

61 Emotional Reaction and Action: From Threat Processing to Goal-Directed Behavior

JOSEPH E. LEDOUX, DANIELA SCHILLER, AND CHRISTOPHER CAIN

ABSTRACT Fear was traditionally studied by using instrumental aversive responses, such as avoidance. This work on instrumental actions failed to lead to a clear understanding of the underlying fear circuitry. Over the past several decades, research on Pavlovian fear reactions has elucidated the circuits that mediate fear. Armed with this information, we return to a consideration of fear-based instrumental actions. While both reactions and actions depend on the amygdala, somewhat different circuits are involved. Fear reactions require connections from the lateral to the central nucleus and from there to the brain stem, while fear-based actions (or at least some such actions) involve connections from the lateral to the basal amygdala and from there to forebrain targets (possibly the striatum). Elucidating the neural mechanisms underlying interactions between Pavlovian and instrumental aversive learning will enhance our understanding of how the brain shifts from passive reactions to actions in the face of danger. This knowledge might aid in understanding how to break the vicious cycle of pathological avoidance in anxiety disorders and could also lead to better coping strategies and other therapeutic interventions.

In 1996, a bomb exploded in Olympic Village in Atlanta. As soon as the explosion occurred, everyone in the crowd was frozen in fear. A few seconds later, they began to run away. This scene, captured on video, illustrates two fundamental ways in which people respond in emotional situations. First we react, then we act (LeDoux, 1996a; LeDoux & Gorman, 2001). Reactions are inflexible responses that are automatically elicited by the stimulus, while actions are instrumental responses that are emitted. Reactions are inevitable consequences that have been programmed by evolution or individual experience, while actions are cognitively controlled responses that are flexibly selected at the moment to achieve a goal.

Research on the neural basis of emotion in animal models has traditionally focused on how emotional stimuli come to elicit fear reactions. Much has been learned over the past several decades, especially about how the brain acquires and

controls reactions related to fear-arousing stimuli. Less is known about how emotional actions are acquired and controlled.

Because pathological states involving fear often include the performance of instrumental responses that are maladaptive, this is an important topic to understand. For example, a characteristic feature of pathological anxiety is the escape and avoidance of fear-arousing situations. These can be effective strategies in the short run, since they reduce exposure to situations in which fear-arousing stimuli occur and prevent threat escalation. Avoidance can also be effective in the long run, as long as it does not interfere with normal daily life. However, avoidance becomes maladaptive when routine activities are disrupted by excessive or inappropriate avoidance.

In this chapter, we give an overview of the relation between reaction and action in the context of fear. However, we will also consider positive or appetitive emotional states, as research in this area has provided both insights into, and challenges to, work on fear.

Behavioral distinctions between reaction and action

To clarify the distinction between emotional reaction and action requires that we consider these in more detail. To do this, we will put these into the context of a more general taxonomy of behavior.

TAXONOMY OF BEHAVIOR Many behaviors that people and other animals perform fall into one of four categories: reflex, reaction, action, and habit. (For other discussions of this topic, see Balleine & Dickinson, 1998; Cardinal, Parkinson, Hall, & Everitt, 2002; Lang & Davis, 2006; H. H. Yin & Knowlton, 2006.)

A reflex is a stimulus-evoked response that usually involves a single muscle or a limited group of muscles. A puff of air to the eye, for example, elicits a closure of that eye, while painful stimulation of the foot elicits withdrawal of that foot.

JOSEPH E. LEDOUX, DANIELA SCHILLER, and CHRISTOPHER CAIN New York University, Center for Neural Science, New York, New York

A reaction is similar to a reflex in that it is elicited by a specific stimulus, but in contrast to a reflex, it usually involves the whole organism (or at least multiple muscle groups) rather than an isolated muscle group. Freezing behavior, the fearful cessation of movement, is an example of such an organismic response involving muscles throughout the body. Reactions are similar to what ethologists call *species-typical behaviors* or *fixed action patterns* (Bolles, 1970; Lorenz & Tinbergen, 1938; Tinbergen, 1951).

Reflexes and reactions are hard-wired responses that are naturally elicited by certain innate stimuli. In other words, with reflexes and reactions, there is a genetically programmed relationship between certain stimuli and the response. Nevertheless, both reflexes and reactions can come under the control of novel events through associative learning. Rodents, for example, are naturally afraid of cats and foxes. A rat that has been born in a laboratory as part of a family that has been removed from these predators for many generations will still express defensive reactions such as freezing behavior in their presence or when exposed to odors from their hair, urine, or feces (C. D. Blanchard & Blanchard, 1972; R. J. Blanchard & Blanchard, 1969b; Rosen, 2004). However, stimuli associated with predators or pain can, through associative learning, come to elicit freezing reactions (C. D. Blanchard & Blanchard, 1972; R. J. Blanchard & Blanchard, 1969b; Bolles, 1972; Fanselow, 1980). As we will discuss below, novel stimuli come to elicit reactions through Pavlovian conditioning. Such reactions are thus called *learned fear responses*. However, it is important to point out that it is not the response that is learned through Pavlovian conditioning. The response is innate, and learning mainly changes the stimuli that have the capacity to elicit the innate response.

Actions, like reactions, occur at the level of the organism but are not automatically elicited by stimuli. Instead, they are emitted in the presence of certain stimuli that direct behavior toward goals. For this reason, actions are said to be purposive or goal-directed and involve motivation (Balleine & Dickinson, 1998; Niv, Joel, & Dayan, 2006). They are instrumental responses—responses that are instrumental in attaining goals. Running away from the source of a bomb is an example of a behavior that is performed to attain a goal, as is approach toward stimuli related to food or sex. These responses are usually based on past learning and/or information stored in memory that is used to make a decision about what to do. Further distinguishing an action and a reaction is the fact that actions are flexible rather than fixed responses (Ikemoto & Panksepp, 1999). One's natural inclination after freezing momentarily to an explosion might be to run away from the location where the explosion occurred, but if a loved one were closer to the explosion, then the response would probably be to run toward the explosion. Thus a reaction, being hard-wired, is always expressed in the same way in an individual and across indi-

viduals in a species. An action, on the other hand, is an arbitrary response that is performed because of its relationship to the goal. You may run, crawl, or swim to escape from a bomb, depending on the situation, but you will likely react first with startle and freezing.

When an instrumental response is performed repeatedly in the presence of certain stimuli, it can become strongly connected to those stimuli and occur inflexibly in the presence of such stimuli. When this situation exists, a stimulus-response (S-R) habit is said to have developed. S-R habits, or just habits, are like reflexes and reactions in that they are elicited by stimuli. However, in contrast to habits and reactions, they are not hard-wired innate responses. Instead, they are based on the transformation of flexible, learned instrumental responses into inflexible responses that have lost their relationship to goal attainment. Habits are often discussed in the context of bad habits, such as nail biting, smoking, overeating, and the like. But not all habits are bad habits. Habits are adaptive and useful when they simplify your life and allow you to perform routine activities faster without having to devote brain resources to them. Habits become pathological when they control behavior in maladaptive ways; for example, a patient who habitually stays home for fear of having a panic attack if she goes outside is stuck in a maladaptive pattern of avoidance behavior. Habits are closely related to skills. Bike riding involves deliberate instrumental learning reinforced by successful movements until the actions become habitual and the skill is acquired. Habits and skills can refer to cognitive as well as behavioral responses.

HISTORICAL NOTE ABOUT RESEARCH METHODOLOGY IN THE STUDY OF FEAR Having placed reactions and actions in a broader behavioral context, we will now focus on reactions and actions in the context of fear-arousing or threatening situations. However, before we turn to contemporary research on the reactions and actions and the neural systems that are involved, it will be useful to review the history of this field briefly.

A learned fear reaction is a Pavlovian conditioned fear response. Pavlovian fear conditioning is a procedure in which an emotionally neutral conditioned stimulus (CS), such as a tone, is paired with an aversive unconditioned stimulus (US), typically electric shock. Following pairing, the CS acquires the capacity to elicit freezing behavior (R. J. Blanchard & Blanchard, 1969a; Bolles & Fanselow, 1980). Freezing is often said to be a conditioned response (CR). However, freezing is itself not learned. As was noted above, what is learned is an association between the CS and US that allows the CS to elicit a response that it did not elicit previously. This is why Pavlovian conditioning is typically described as a form of stimulus-stimulus (S-S) learning in which the CS acquires emotional potency by its relation to the US. In addition to behavioral responses such as freezing,

physiological changes inside the body also come under the control of the CS, such as changes in autonomic and endocrine activity (Kapp, Frysinger, Gallagher, & Haselton, 1979; LeDoux, Sakaguchi, & Reis, 1983; Schneiderman, Francis, Sampson, & Schwaber, 1974). These are important in providing physiological support for the behavioral responses and in general are part of the integrated organismic response to danger.

Fear conditioning was studied by Pavlov (1927), who called it *defense conditioning*. It was then used by Watson (1929) in his famous study of Little Albert. However, studies of learning in psychology emphasized Thorndike's (1898) instrumental conditioning procedure over Pavlov's approach through the middle of the 20th century and beyond. The behaviorists dominated psychology during this time and believed that instrumental learning was the key to understanding complex human behaviors (Hull, 1943; Skinner, 1938). As a result, a form of instrumental learning called *avoidance conditioning* emerged as the primary behavioral approach to study learned fear (Miller, 1948, 1951; Mowrer, 1947; Mowrer & Lamoreaux, 1946).

In avoidance conditioning studies, animals learn to perform a response (active avoidance) or withhold a response (passive avoidance) in order to avoid harm (typically electric shock). We will be focusing on active avoidance, which we will refer to as *avoidance conditioning* throughout. Some examples of responses that are measured in avoidance studies are shuttling in a runway maze or pressing a lever. Avoidance conditioning is traditionally viewed as a two-stage process. First, stimuli associated with the shock via Pavlovian conditioning are learned about, and then instrumental responses are performed that reduce exposure to those fear-arousing stimuli (Brown & Jacobs, 1949; Kalish, 1954; Levis, 1989; McAllister & McAllister, 1971; Miller, 1948, 1951; Mowrer, 1947; Mowrer & Lamoreaux, 1946; Overmier & Lawry, 1979; Solomon & Wynne, 1954). Therefore the avoidance response could be used to study fear. Pavlovian conditioning was thought to be involved but was not itself measured or studied.

Much research attempted to understand the neural basis of fear through studies of avoidance (Gabriel et al., 1983; Goddard, 1964; Isaacson, 1982; Sarter & Markowitsch, 1985; Weiskrantz, 1956). This research generated complex results that were not easily integrated into a coherent view of the brain mechanisms of avoidance, much less fear. Several factors probably contributed to this, including a failure to separate the Pavlovian and instrumental components of the tasks and the use of a variety of different kinds of avoidance tasks that made different demands on behavior and the brain (Cain & LeDoux, 2007; LeDoux, 1996a).

In the meantime, research on the neural basis of learning and memory, which had also been focused on instrumental behaviors during the behaviorist heyday, turned to

Pavlovian conditioning, first in invertebrate studies (Alkon, 1983; Carew, Hawkins, & Kandel, 1983; Dudai, Jan, Byers, Quinn, & Benzer, 1976; Kandel & Spencer, 1968; Walters, Carew, & Kandel, 1979) and then in vertebrates (Cohen, 1974; Thompson, 1976). Research on fear followed suit, and by the early 1980s, the neural mechanisms of fear learning in mammals were much more likely to be studied by using Pavlovian fear conditioning than instrumental avoidance (Davis, 1986; Kapp et al., 1979; Kapp, Pascoe, & Bixler, 1984; LeDoux, Sakaguchi, & Rice, 1984; LeDoux, Thompson, Iadecola, Tucker, & Reis, 1983). Pavlovian conditioning allows the measure of fear directly as CS-elicited reactions rather than indirectly through fear-based instrumental avoidance responses. Because simpler behaviors involve simpler circuits, much progress was made rapidly in understanding the brain mechanisms of fear learning, as is discussed below.

DIVERSE FUNCTIONS OF AN EMOTIONAL STIMULUS It is natural to think of a Pavlovian CS as eliciting Pavlovian CRs. However, this is only a part of what goes on. That is, a Pavlovian CS can have effects other than the automatic elicitation of hard-wired, inflexible CRs. Two of these consequences are conditioned reinforcement and conditioned motivation. These are important to consider, as they will help us to revisit the topic of avoidance and instrumental fear.

CONDITIONED REINFORCEMENT IN AVOIDANCE: THE ESCAPE FROM FEAR HYPOTHESIS As has been noted, the avoidance-conditioning literature suggested that a Pavlovian CS contributes to the learning of avoidance responses. How exactly does it do this? A leading view is the escape from fear (EFF) hypothesis (Levis, 1989; McAllister & McAllister, 1971; Miller, 1948; Mowrer, 1947; Rescorla & Solomon, 1967). According to this idea, classical conditioning first establishes the CS as a fear-arousing stimulus, one that elicits fear reactions. As avoidance conditioning proceeds, behaviors that terminate exposure to the fear-arousing CS are reinforced by the reduction in fear that results. Formally, this is called *conditioned negative reinforcement of a stimulus-response association*. *Negative* in this case refers not to the aversive nature of the conditioning but to the fact that the reinforcement comes from termination of the stimulus. A more precise term is *aversive negative conditioned reinforcement*.

Because the Pavlovian and instrumental aspects of avoidance task are intermixed, such tasks cannot be used to directly test the EFF hypothesis. Tasks were therefore developed in which Pavlovian conditioning occurs first and then the CS is presented in a separate chamber. Results showing that behaviors associated with CS termination are learned and repeated support the EFF hypothesis (McAllister & McAllister, 1971). However, the EFF hypothesis of

avoidance has been controversial, due largely to methodological problems with past EFF tasks but also to competing theories of psychological mechanisms underlying avoidance learning (Bolles, 1972; Herrnstein, 1969; Levis, 1989; McAllister & McAllister, 1971; Seligman & Johnston, 1973).

In an effort to address the EFF controversy, we developed a new procedure that controls for many of the factors raised in past critiques (Cain & LeDoux, 2007) (figure 61.1). In our new task, rats learned to rear on their hind legs to terminate a fear-arousing CS. This learning is long-lasting (24 hours) and response-specific (no increase in other nonrein-

forced behaviors). Interestingly, successful EFF learning also resulted in a transition from passive freezing reactions to escape actions; rats that learned the EFF response showed no spontaneous recovery of freezing following the extinguishing CS presentations that were used for EFF training. Importantly, expression of EFF learning was also controlled by the CS, since animals that went through EFF training did not respond differently than yoked controls until the CS was presented. Thus our data lead us to conclude that instrumental responses can be reinforced by the fear-reducing effects of CS termination.

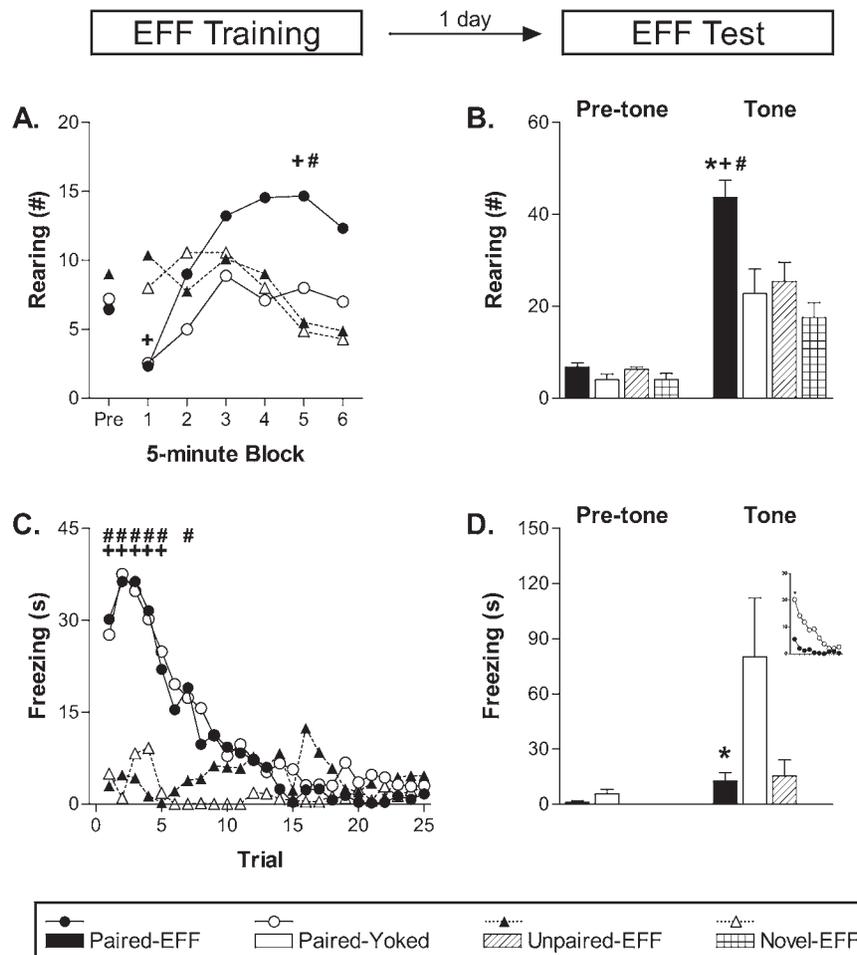

FIGURE 61.1 Escape from fear learning represents instrumental learning that is motivated by fear and reinforced by fear reduction. We designed a new EFF task that controls for factors that made past results inconclusive about the role of fear reduction in EFF learning (Cain & LeDoux, 2007). One day after Pavlovian tone-shock pairings (Paired), tone-shock unpairings (Unpaired), or no training (Novel), rats were presented with 25 tone-alone presentations in a new context (EFF training, left). For EFF rats, rearing during a tone presentation led to its immediate termination (response-reinforcement pairing). Yoked rats received identical tone presentations independent of their behavior. One day after EFF training, rats were presented with a single, continuous 10-minute tone presentation to assess long-term EFF memory (EFF

test, right). Rearing and freezing were assessed during both phases. Paired-EFF rats showed a twofold increase in the EFF escape response (rearing) during the training and testing session compared to Paired-Yoked rats (A and B). Unpaired-EFF and Novel-EFF rats had no fear of the CS and did not acquire the EFF response (enhanced rearing). Successful acquisition of this active escape response was also associated with less passive freezing to the tone (D; inset = minute-by-minute freezing during the EFF test). Further analysis demonstrated that EFF learning was response-specific and performance was motivated by fear (no difference in rearing in the absence of the CS; data not shown). Figure adapted with permission from *Journal of Experimental Psychology: Animal Behavior Processes* (Cain & LeDoux, 2007).

Note that fear-arousing CSs can also serve as positive reinforcers, or punishers. Thus behaviors performed when an aversive CS is presented are less likely to be performed in the future. In this case, the reinforcement is “positive” because learning depends on the delivery of the aversive CS. This contrasts with the role of CS termination in reinforcing escape/avoidance responses. Conditioned punishment, which involves the suppression of response performance by a stimulus, may also be a contributing factor in avoidance and EFF learning (Bolles, 1972). Conditioned punishment is especially relevant to passive avoidance and will not be a focus of this chapter.

CONDITIONED MOTIVATION In EFF learning (and presumably in avoidance conditioning), the CS functions as a conditioned reinforcer that establishes the acquisition of a new instrumental action. However, once learned, the CS can also function as an incentive that contributes to the performance of the instrumental response.

A conditioned incentive is a stimulus that enhances or suppresses the performance of an existing (previously learned) instrumental action. This incentive-based function of a CS is referred to as *conditioned motivation*. While conditioned motivation probably occurs during the performance of previously conditioned EFF or avoidance responses, as was noted, the preferred test for studying conditioned motivation is something called *Pavlovian-to-instrumental transfer* (PIT). In such tasks, a separately conditioned CS is presented while an animal performs an instrumental behavior.

Most research on PIT and its neural basis has involved appetitive tasks. In these tasks, a previously conditioned CS (say, a tone paired with food) is presented while the subjects perform appetitive instrumental responses (such as food-motivated lever pressing) (Balleine & Killcross, 2006; Blundell, Hall, & Killcross, 2001; Corbit & Balleine, 2005; Everitt, Cardinal, Parkinson, & Robbins, 2003; Holland & Gallagher, 2003; Talmi, Seymour, Dayan, & Dolan, 2008). The typical result is that the CS enhances the performance of the instrumental response, indicating an increase in the motivation to perform the response. The PIT assay is the preferred measure of conditioned motivation because the critical test does not rely on new learning. Independent Pavlovian and instrumental associations are established prior to the test in separate sessions, allowing an uncontaminated assessment of CS-elicited motivation.

The main aversive PIT task in common use is conditioned suppression of appetitive instrumental behavior (Bouton & Bolles, 1980; Estes & Skinner, 1941; Hunt & Brady, 1955). However, this task differs significantly from appetitive PIT tasks. An aversive PIT test that is comparable to appetitive PIT would involve an enhancement of aversive instrumental responding by an aversive CS rather than suppression of appetitive instrumental responding. Such tasks have in fact

been used (Brackbill & Overmier, 1979; Grossen & Bolles, 1968; LoLordo, 1967), although virtually no information regarding the neural mechanisms that mediate such aversive PIT exists to date.

REACTION VERSUS ACTION: A SUMMARY Behavioral studies have shown that a Pavlovian CS elicits Pavlovian CRs (reactions) but can also influence instrumental actions in at least two ways. One of these is by serving as a conditioned reinforcer that mediates the learning of a new instrumental action, and the other is by serving as a conditioned incentive that affects the motivation to perform a previously learned instrumental action. These are not completely independent functions, since once conditioned reinforcement is used to acquire an instrumental response, the same CS functions as an incentive that motivates the performance of the response. Next we consider what is known about the neural basis of these three functions of a CS, focusing first on reactions.

Neural basis of fear reactions

Research over the past two decades has clearly pointed to the amygdala as a key site where CS-US associations are formed during Pavlovian fear conditioning as well as a necessary site for the later expression of fear reactions elicited by the CS. Below, we will review the role of the amygdala in the fear-conditioning circuitry.

ORGANIZATION OF THE AMYGDALA The amygdala was first recognized as a distinct brain region in the early 19th century (Burdach, 1819–1822). The name, derived from the Greek, was meant to denote an almond-like shape structure in the medial temporal lobe. Like most brain regions, the amygdala is not a single mass but is composed of distinct subareas or nuclei (figure 61.2).

One long-standing idea is that the amygdala consists of an evolutionarily primitive division associated with the olfactory system (cortical, medial, and central nuclei) and an evolutionarily newer division associated with the neocortex (lateral, basal, and accessory basal nuclei) (Johnston, 1923). The areas of the older division are sometimes grouped as the corticomедial region (cortical and medial nuclei) and sometimes as the centromedial region (the central and medial nuclei), while the newer structures related to the neocortex are often referred to as the basolateral region (figure 61.3). The almond-shaped structure that originally defined the amygdala involved the basolateral region rather than the whole structure that is now considered to be the amygdala (Swanson & Petrovich, 1998).

In recent years, there have been a number of attempts to reclassify the amygdala and its relationship to other areas. For example, Heimer (2003) has argued for the concept of an extended amygdala. In this view, the central and medial

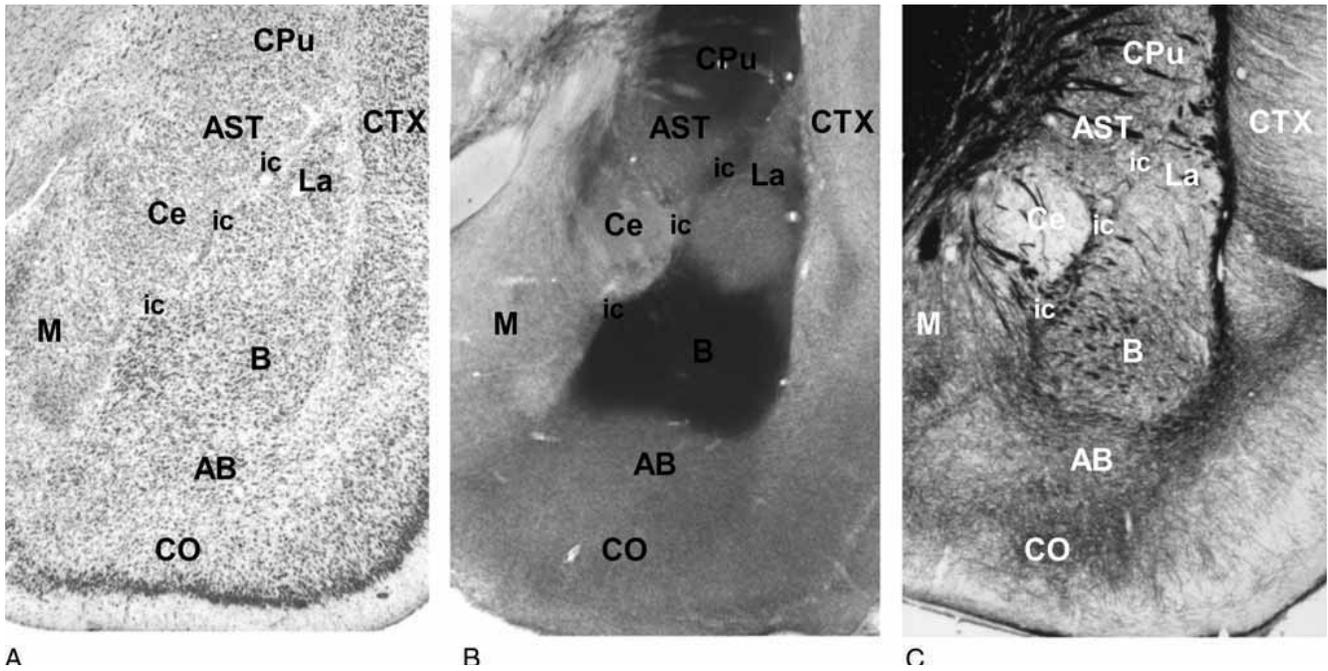

FIGURE 61.2 The rat amygdala. The amygdala of mammals, including humans, consists of at least 12 distinct nuclei. Different staining methods show some of the major nuclei from different perspectives. (A) Nissl cell body stain. (B) Acetylcholinesterase stain. (C) Silver fiber stain. Abbreviations: Amygdala areas: AB, accessory

basal; B, basal nucleus; Ce, central nucleus; CO, cortical nucleus; ic, intercalated cells; La: lateral nucleus; M, medial nucleus. Non-amygdala areas: AST, amygdalo-striatal transition area; CPu, caudate putamen; CTX, cortex. (See color plate 75.)

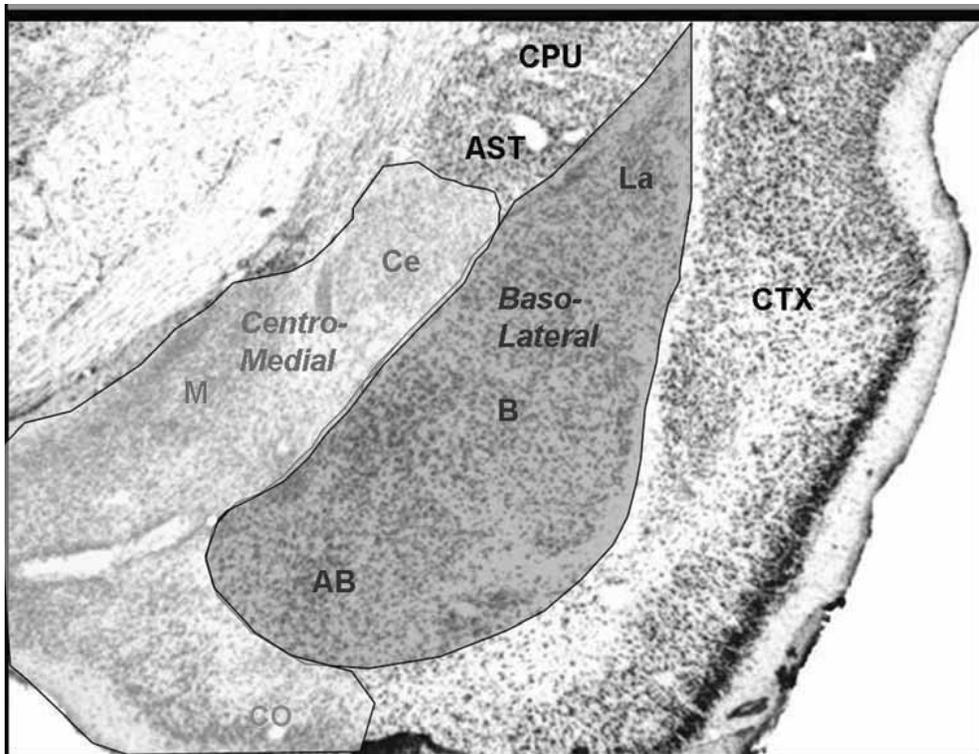

FIGURE 61.3 Groupings of amygdala nuclei. The various nuclei of the amygdala are often partitioned into an evolutionarily old division (the centromedial or corticomedial region) and an evolutionarily newer division (the basolateral region or basolateral complex). While these divisions have some value in understanding the phylogenetic and ontogenetic origins of the amygdala, they do

not represent meaningful function divisions, since functions are mediated by cells within much more localized regions, especially subnuclei and even subdivisions of subnuclei. Abbreviations: AB, accessory basal; AST, amygdalo-striatal transition area; B: basal nucleus; Ce, central nucleus; CPu, caudate putamen; CTX, cortex; La, lateral nucleus; M, medial nucleus. (See color plate 76.)

amygdala are continuous (anatomically and neurochemically) with the lateral and medial divisions of the bed nucleus of the stria terminalis and should be considered a structural unit with functional significance, especially for psychopathology. Swanson and Petrovich (1998) proposed a more radical idea, arguing that “the amygdala,” whether extended or not, does not exist as a structural unit. Instead, they argue that the amygdala consists of regions that belong to other regions or systems of the brain and that the designation “the amygdala” is not necessary. For example, in this scheme, the lateral amygdala and basal amygdala are viewed as nuclear extensions of the neocortex (rather than simply as amygdala regions related to the neocortex), the central and medial amygdala are ventral extensions of the striatum, and the cortical nucleus is part of the olfactory system. While this scheme has some merit, the present review focuses on the organization and function of nuclei and subnuclei that are traditionally said to be part of the amygdala, as these perform their functions regardless of whether the amygdala itself exists.

It is easy to be confused by the terminology that is used to describe the amygdala nuclei, as different sets of terms are used. This problem is especially acute with regards to the basolateral region of the amygdala. As was noted, the basolateral region consists of the lateral, basal, and accessory basal nuclei. However, in another terminological scheme, the basal and accessory basal nuclei are called the *basolateral* and *basomedial nuclei*, respectively. The use of the term *basolateral* to refer both to a specific nucleus (the basal or basolateral nucleus) and to the larger region that includes the lateral, basal, and accessory basal nuclei (the basolateral region) is the source of some difficulty, since authors do not always clearly identify whether they are referring to the nucleus or the region. Further, some studies use the term *basolateral complex* (BLA) to refer to the lateral and basal nuclei (and usually not the accessory basal).

Each of the nuclei of the amygdala can be further partitioned into subnuclei (Pitkänen, 2000; Pitkänen, Pikkarainen, Nurminen, & Ylinen, 1997). For example, the lateral nucleus has three major divisions: dorsal, ventrolateral, and medial (figure 61.4). Further division is also possible. The dorsal subdivision has a superior and an inferior region. The central nucleus, on the other hand, has lateral, capsular, and medial divisions. These subnuclear partitions of the lateral and central nuclei have turned out to have important functional significance.

STANDARD MODEL OF CONDITIONED FEAR REACTIONS: SERIAL PROCESSING WITHIN THE AMYGDALA Two areas of the amygdala are generally considered to be especially important for the acquisition and expression of Pavlovian fear conditioning (figure 61.5). The lateral nucleus (LA) receives and integrates the CS and US and later processes the CS in

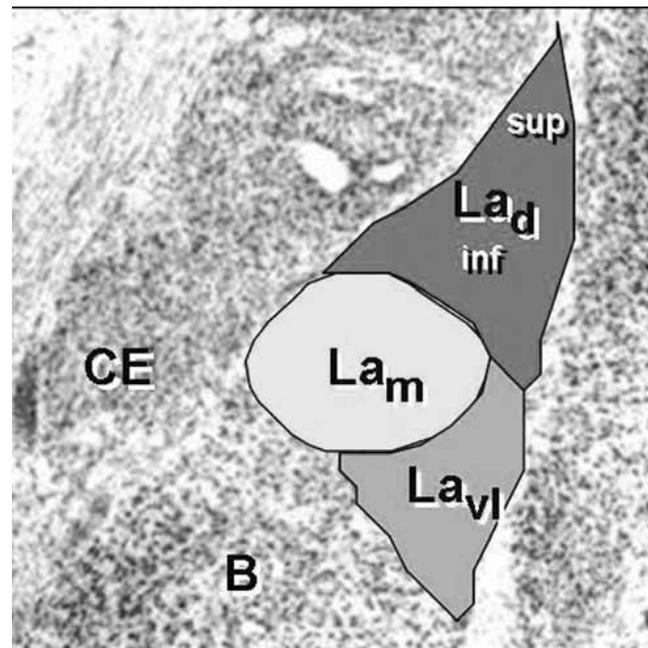

FIGURE 61.4 Subdivisions of the lateral nucleus of the amygdala. The lateral nucleus of the amygdala has three major subdivisions: dorsal (LA_d), ventrolateral (LA_{vl}), and medial (LA_m). Each of these has additional partitions. The dorsal subnucleus, for example, contains a superior (sup) and inferior (inf) region. Cells in the superior region have been implicated in the acquisition of fear conditioning, and cells have been implicated in the inferior region in long-term memory storage (see text). Abbreviations: B, basal nucleus; CE, central nucleus. (See color plate 77.)

the control of fear reactions. The central amygdala (CE), on the other hand, is especially involved in the expression of fear reactions. The basal nucleus (B) and the intercalated cell masses (ICT) also contribute.

The standard model evolved from a series of studies that first implicated the central amygdala (CE) starting in the late 1970s (Hitchcock & Davis, 1986; Kapp et al., 1979, 1984; LeDoux, Iwata, Cicchetti, & Reis, 1988). Given its connections to hypothalamic and brain stem areas that control species-typical behaviors and autonomic and endocrine responses related to fear, CE was viewed as important for the expression of fear-related CRs. Studies showing that the firing rate of cells in CE increased following CS-US pairing (Pascoe & Kapp, 1985) suggested that CE may also be a key site of plasticity in the formation of the CS-US association.

In the 1990s, emphasis began to shift to the lateral amygdala (LA) when it was shown that sensory inputs from the CS and US pathways mainly terminate in LA rather than in CE (Bordi & LeDoux, 1992; Clugnet & LeDoux, 1990; LeDoux, Sakaguchi, Iwata, & Reis, 1986; LeDoux et al., 1984), that damage to LA disrupts fear conditioning (LeDoux, Cicchetti, Xagoraris, & Romanski, 1990), and that CS and US inputs converge on single cells in LA

(Romanski, LeDoux, Clugnet, & Bordi, 1993). These studies suggested that CS-US convergence does not take place in the entire LA but only in its dorsal subnucleus (Romanski et al., 1993). Subsequent studies found that CS-US pairing during fear conditioning leads to the enhancement of short-latency neural responses elicited by a CS in the dorsal LA (Quirk, Armony, & LeDoux, 1995). Subsequent studies confirmed the importance of the dorsal LA (Collins & Pare, 2000; Hobin, Goosens, & Maren, 2003; Maren, 2000; Maren & Quirk, 2004; Repa et al., 2001) and further suggested that there may be different cell groups within the dorsal LA involved in the initial learning and long-term storage of plasticity (Repa et al., 2001).

Thus, CS-US convergence in LA came to be viewed as inducing synaptic plasticity. When the CS later occurs, it is transmitted to LA, where the potentiated synapses drive CE to express fear reactions via output connection to the brainstem (Davis, Walker, & Lee, 1997; Fanselow & LeDoux, 1999; LeDoux, 1996b, 2000; Maren, 2001; Maren & Fanselow, 1996). This standard model of fear conditioning is sometimes called the serial model because it assumes that inputs come into LA, that LA connects with CE, and that CE connects with regions that control CRs.

The idea that LA is a key site of plasticity was given additional weight by findings showing that long-term synaptic potentiation (LTP) could be induced in LA (Clugnet & LeDoux, 1990) or BLA (Chapman, Kairiss, Keenan, & Brown, 1990) by patterns of electrical stimulation. Particularly important was the fact that LTP could be induced in CS pathways to LA in vivo (Clugnet & LeDoux, 1990; Rogan & LeDoux, 1995) and in vitro (Weisskopf, Bauer, & LeDoux, 1999). Further, fear conditioning itself was shown to produce LTP-like changes in CS processing in LA in vivo (Rosenkranz & Grace, 2002; Rogan, Staubli, & LeDoux, 1997) and in vitro (McKernan & Shinnick-Gallagher, 1997).

Additional studies showed that fear conditioning and LTP in LA depend on similar molecular mechanisms. Initial studies focused on NMDA receptors, since these were known to be involved in synaptic plasticity in the hippocampus (Collingridge & Bliss, 1995; Cotman, Monaghan, & Ganong, 1988). Thus blockade of NMDA receptors in the LA disrupted fear conditioning (Fanselow & Kim, 1994; Maren, Aharonov, Stote, & Fanselow, 1996; Miserendino, Sananes, Melia, & Davis, 1990; Rodrigues, Schafe, & LeDoux, 2001), and similar manipulations also disrupted LTP in LA (Bauer, Schafe, & LeDoux, 2002). Alteration of gene expression related to AMPA receptors in LA also alters LTP and fear conditioning (Rumpel, LeDoux, Zador, & Malinow, 2005). Moreover, fear conditioning and LTP depend on similar second messenger and macromolecular events in LA (Dityatev & Bolshakov, 2005; Fanselow & Poulos, 2005; LeDoux, 2000; Maren, 2001; Pape & Stork, 2003; Rodrigues, Schafe, & LeDoux, 2004; Sah, Faber, Lopez De Armentia,

& Power, 2003; Walker & Davis, 2002). Studies of genetically altered mice also revealed parallels between fear conditioning and LTP (Matynia, Kushner, & Silva, 2002; Mayford, Abel, & Kandel, 1995; Wang, Hu, & Tsien, 2006), and some of the mechanisms overlap with findings from invertebrates (Bailey, Giustetto, Huang, Hawkins, & Kandel, 2000; Dubnau, Chiang, & Tully, 2003; Lechner & Byrne, 1998; Roberts & Glanzman, 2003; J. C. Yin & Tully, 1996).

Given that LA is the main sensory input region of the amygdala and CE is the output link to the brain stem, the standard model requires that connections exist between LA and CE. The LA connects with the CE via several direct and indirect routes within the amygdala (Pare, Quirk, & LeDoux, 2004; Pitkänen, Savander, & LeDoux, 1997; Royer, Martina, & Pare, 1999). Because it is generally assumed that the medial nucleus of CE (CEm) connects with brain stem areas that control CRs, a key issue is the extent to which LA connects with CEm (Pare et al., 2004). While direct connections to CEm seem weak at best, the LA connects with the lateral CE, which has connections to CEm (Petrovich & Swanson, 1997), though these latter connections are somewhat sparse. The LA also connects with the intercalate cell group (ITC), which form a chain of connections that lead to CEm (Royer et al., 1999). The LA also connects to the CEm via the B and accessory basal nuclei (Pitkänen et al., 1997). The multiplicity of connections between LA and CE suggest why lesions of a structure such as B may have effects on fear conditioning in some studies (Anglada-Figueroa & Quirk, 2005; Goosens & Maren, 2001) but not others (Amorapanth, LeDoux, & Nader, 2000), depending possibly on details of the training paradigm or possibly on the extent of damage in B. Regardless, paths of connectivity within the amygdala clearly link LA to CE, including CEm.

Recently, there has been a revival of interest in the possibility that the CE may be a site of plasticity as well as an output link between LA and areas that control CRs (Pare et al., 2004; Samson, Duvarci, & Pare, 2005; Wilensky, Schafe, Kristensen, & LeDoux, 2006). Several studies have thus shown that plasticity occurs in CE in vitro (Fu & Shinnick-Gallagher, 2005; Samson & Pare, 2005). Most germane is the fact that CE undergoes plasticity in vivo during aversive conditioning, as determined by single-unit recordings (Pascoe & Kapp, 1985; Rorick-Kehn & Steinmetz, 2005). Our recent findings showing that functional inactivation or protein synthesis inhibition in CE prevents memory formation during Pavlovian conditioning suggests that plasticity in CE plays a key and essential role (Wilensky et al., 2006). However, the earliest latency of unit CRs and the number of trials required to acquire unit CRs in CE (Pascoe & Kapp, 1985) are both greater than those in LA (Goosens, Hobin, & Maren, 2003; Maren, 2000; Maren & Quirk, 2004; Quirk, Armony, & LeDoux, 1997; Quirk et al., 1995; Repa et al.,

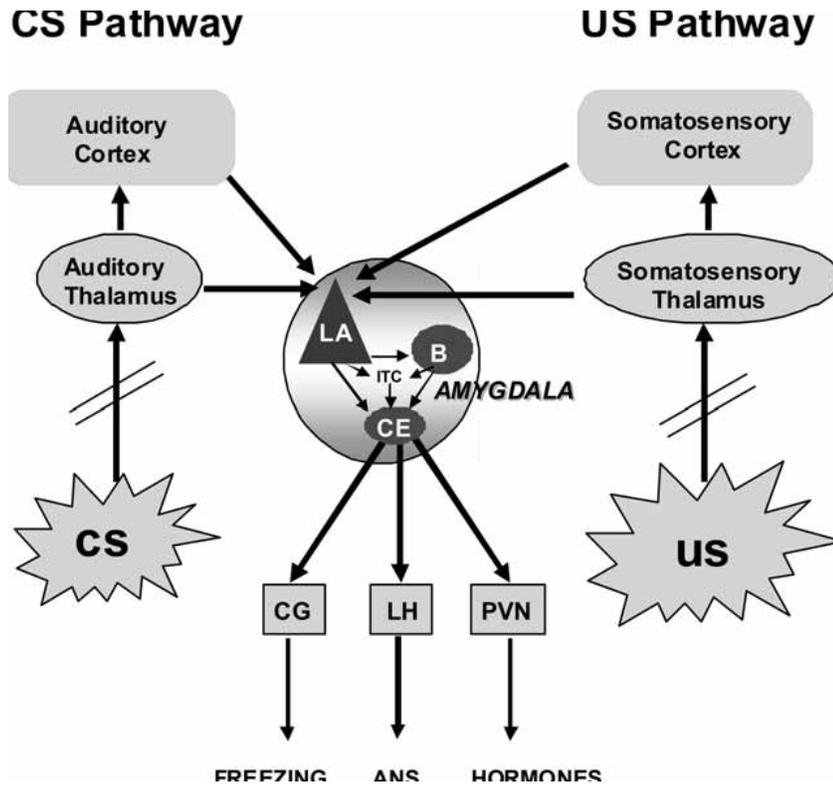

FIGURE 61.5 Auditory fear conditioning pathways. The auditory conditioned stimulus (CS) and somatosensory (pain) unconditioned stimulus (US) converge in the lateral amygdala (LA). The LA receives inputs from each system via both thalamic and cortical inputs. CS-US convergence induces synaptic plasticity in LA such that after conditioning the CS flows through the LA to activate the

central amygdala (CE) via intra-amygdala connections. CE in turn controls the expression of behavioral (e.g., freezing), autonomic (ANS), and endocrine responses that are components of the fear reaction. Abbreviations: B, basal amygdala; CG, central gray; LH, lateral hypothalamus; ITC, intercalated cells of the amygdala; PVN, paraventricular nucleus of the hypothalamus.

2001). These data are consistent with the notion that LA and CE are both sites of plasticity but that CE plasticity depends on LA plasticity.

The fact that LA is normally required for fear conditioning does not rule out the possibility that under some circumstances, fear conditioning can occur in animals with lesions of LA and B. Indeed, fear conditioning can occur in animals with lesions of LA and B when extensive training is given, especially in contextual conditioning but also in cued conditioning in some cases (Hall, Thomas, & Everitt, 2000; Killcross, Robbins, & Everitt, 1997; Lee, Dickinson, & Everitt, 2005; Maren, 1998, 1999).

A CHALLENGE TO THE STANDARD MODEL: PARALLEL PROCESSING WITHIN THE AMYGDALA In spite of the extensive evidence in support of the standard model, this view has been challenged. In these challenges, LA and B are usually considered together as an undifferentiated structure that is referred to as the BLA. It is argued that some aspects of fear conditioning can be mediated by the BLA independent of CE and that other aspects can be mediated by CE independent of BLA. Because BLA and CE are proposed to receive CS and US inputs separately and function

independently, this is called the *parallel model* (Balleine & Killcross, 2006; Cardinal et al., 2002; Killcross et al., 1997; Killcross & Blundell, 2002).

First of all, proponents of the parallel view argue that fear conditioning can occur when BLA is damaged (Balleine & Killcross, 2006). While this is true, essentially all of the evidence for this has come from studies in which overtraining is used (Hall, Parkinson, Connor, Dickinson, & Everitt, 2000; Killcross et al., 1997; Lee et al., 2005; Maren, 1998, 1999). Most studies that have contributed to the serial model have involved training with a small number of trials (fewer than 10). With overtraining, weak intra-amygdala pathways, weak direct sensory inputs to CE, or more complex circuitous pathways involving other brain regions may undergo synaptic plasticity, potentiation of which may allow the pathways to be utilized in ways that are not possible with few training trials. Indeed, recent studies show that CE is necessary for learning in overtrained animals (Zimmerman, Rabinak, McLachlan, & Maren, 2007). Thus, while findings from overtraining are important and interesting, they likely involve different circuits than those involved in the rapid form of fear conditioning that occurs in natural situations in which organisms do not always have the opportunity to

“practice” learning what to fear over many trials. BLA, and especially LA, is essential when standard, naturalistic training is involved.

Appetitive conditioning research is strongly influenced by the notion that CSs can enter into associations with different aspects of the US (sensory versus affective properties) and that these separate associations generate different response types (consummatory versus preparatory), an idea that was first formalized by Konorski (1967). These ideas were particularly important for the development of the parallel model of amygdala function, which is largely based on appetitive findings. Consummatory responses are those that are engaged when the subject is in direct contact with the US, such as chewing and licking in the case of food. Preparatory responses for food include approach and autonomic nervous system changes, responses that are appropriate when food is in the vicinity. Note that both consummatory and preparatory responses can include reactions and actions. Appetitive research on brain mechanisms of conditioning has therefore focused on identifying structures that mediate these separate associations and separate response classes. In the process, this research has evaluated both reactions and actions. This is in contrast to aversive research, which has primarily focused on fear reactions, at least in the last few decades. Aversive studies, less influenced by the Konorskian distinction between consummatory and preparatory responses, have generally assumed that there is one basic association between the CS and all aspects of the US. And this basic association can be used in different ways to generate different basic behaviors, including both reactions and actions. Thus, embedded within the serial versus parallel amygdala processing debate are fundamental questions regarding the nature of the CS-US association(s) and basic response classes.

In an abstract sense, it would be logical for the brain to process appetitive and aversive stimuli in similar ways. However, this might not be the case. Despite the superficial similarity of the behavioral designs that are used for appetitive and aversive conditioning, distinct kinds of stimuli serve as the US (food or water versus shock), the associations involved are fundamentally different (tone + food or water versus tone + shock), the conditioning procedures require many more training trials for appetitive conditioning relative to aversive conditioning, and the responses (approach versus freezing) likely involve different output circuits of the amygdala and possibly different intra-amygdala circuits.

The serial model of fear conditioning has been based on studies that measure conditioned reactions elicited by the CS. In contrast, the evidence for the parallel model has mostly been based on studies in which instrumental responses are used as an indirect measure of conditioned fear. In particular, much of the evidence for the parallel model has relied on the use of Pavlovian to instrumental transfer (PIT) tests in which a previously conditioned CS alters the perfor-

mance of a previously trained instrumental response. These studies are extremely important, as they have provided important clues about how to pursue the role of the amygdala in fear-related instrumental actions as an assessment of conditioned motivation. But their value in understanding how associations are acquired and stored during fear conditioning is less clear. Below, when we discuss the neural basis of PIT, we will discuss these findings and their applicability (or lack thereof) to fear conditioning.

In sum, the evidence that is being used to defend the parallel model does not justify the rejection of decades of research on fear conditioning. This will become more apparent later, after we discuss the neural basis of fear actions, especially the contribution of conditioned motivation, as studied by PIT tasks.

Neural basis of fear actions

Earlier, we mentioned two ways in which a Pavlovian fear-arousing CS influences instrumental responses: by serving as a conditioned reinforcer and by serving as a conditioned motivator (incentive). These are studied by using EFF and PIT tasks. In this section, we will therefore review research on the neural basis of EFF and PIT.

AMYGDALA CONTRIBUTIONS TO CONDITIONED REINFORCEMENT: STUDIES OF EFF A leading hypothesis about avoidance is that the instrumental response is reinforced by termination of stimuli (CSs) associated with the aversive US. That is, the avoidance response is learned and initially performed to remove the CS. Hence, CS termination serves as a conditioned negative reinforcer, a stimulus that increases the likelihood of responses that eliminates this same stimulus. This is usually studied by using EFF tasks. In spite of its potential to explain avoidance, little research has studied the role of the brain in EFF tasks.

The only study that explored the brain mechanisms of EFF was performed by our laboratory (Amorapanth et al., 2000) (figure 61.6). We found that pretraining lesions of LA disrupted both Pavlovian conditioning and EFF learning. CE lesions disrupted Pavlovian freezing responses but not instrumental EFF responses. And B lesions disrupted EFF learning but not freezing. Specifically, our results suggested that CS information flow through the amygdala begins in LA, where the Pavlovian CS-US association is stored, and then this association is used to generate a conditioned reinforcing signal (negative or positive) either in B or in its output targets. The double dissociation that was observed for CE and B led to the proposal that LA is critical for both aversive reaction and action learning because the Pavlovian CS-US association was learned and stored in LA, and this association is critical for both types of responses. Serial processing from LA to CE mediated aversive reaction learning, and serial processing

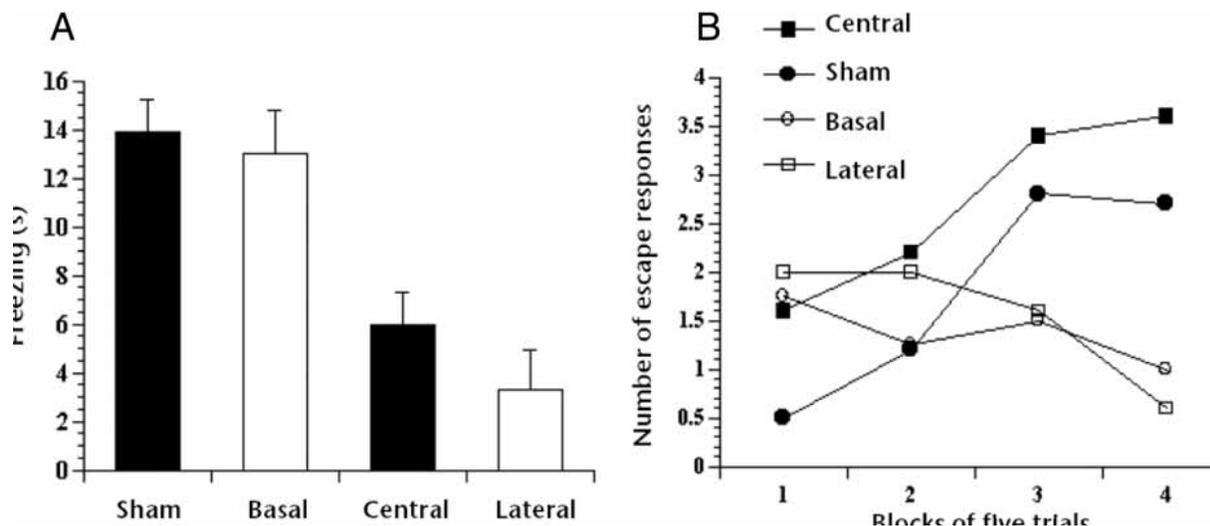

FIGURE 61.6 Escape from fear (EFF) learning depends on the lateral and basal, but not central, amygdala. Prior to behavioral training, rats received bilateral electrolytic lesions of LA, CE, or B. Rats were first subjected to Pavlovian fear conditioning and then to EFF training, using chamber crossing as the escape response. LA and CE lesions disrupted performance of a passive fear reaction to the CS (A, freezing). LA and B lesions disrupted performance of an

active EFF response (B, chamber crossing). These data suggest that LA is necessary for establishing the CS as a conditioned incentive. This information is then relayed to CE to initiate passive Pavlovian reactions and to B for active escape responding. Note that this study was done with an older EFF task prior to the development of the task illustrated in figure 61.1. (Reproduced from Amorapanth, LeDoux, & Nader (2000) with permission of *Nature Neuroscience*.)

from LA to B mediated aversive action learning (figure 61.7). Because the tasks that we and others before employed had several shortcomings, we developed a new task (Cain & LeDoux, 2007). This task will be especially useful in drawing firm conclusions about the role of amygdala areas in EFF learning and hence conditioned reinforcement.

negative reinforcement. Further, they did not distinguish between LA and B. Nevertheless, the general conclusion regarding fear-based action is the same as that from our study: LA and B are essential for this influence of Pavlovian CS on instrumental learning.

Another study that is relevant was performed by Killcross and colleagues (1997). They trained rats on a concurrent Pavlovian conditioning and conditioned punishment task and assessed the effects of CE versus BLA lesions. In this task, a previously conditioned CS punishes and thereby weakens a previously established, appetitively motivated instrumental response. In the same sessions, Pavlovian conditioning was assessed by conditioned suppression of appetitive bar pressing, using a separate bar from that used for the punishment assessment. Their results suggested that BLA lesions, but not CE lesions, interfered with conditioned punishment, which matches well with the results of Amorapanth and colleagues. But they also found that conditioned suppression, the Pavlovian measure, was impaired by CE lesions but not by BLA lesions. This second finding is at odds with many studies on conditioned reactions supporting the serial model. However, this was a complex task involving significant overtraining, and the relevance of the results to simpler tasks that do not involve overtraining should be viewed cautiously (Lee et al., 2005). Specifically, typical fear-conditioning studies use fewer than 10 training trials (as few as one in many studies), whereas Killcross and colleagues used approximately 120 trials. Also, the instrumental task involved conditioned punishment rather than conditioned

These conclusions from aversive conditioning are also consistent with appetitive conditioning results that indicate that the BLA but not the CE contributes to conditioned reinforcement (Burns, Everitt, & Robbins, 1999). The appetitive work suggests further that connections from the BLA to the ventral striatum allow the conditioned reinforcer, formed in the BLA, to mediate the acquisition of the instrumental action. Extra-amygdala circuits will be discussed below.

AMYGDALA CONTRIBUTIONS TO CONDITIONED MOTIVATION: STUDIES OF PIT Excluding conditioned suppression studies, research on brain mechanisms of PIT mainly involves appetitive conditioning tasks in which a previously conditioned CS is used as a conditioned incentive and its effects on instrumental behavior are assessed (Balleine & Killcross, 2006; Corbit & Balleine, 2005; Everitt et al., 2003; Hall et al., 2001; Holland & Gallagher, 2003; Talmi et al., 2008). This work indicates that the amygdala is critical for appetitive PIT. Further, as will be described below, different amygdala nuclei appear to make distinct contributions to different forms of appetitive PIT.

Prior to PIT studies, early appetitive conditioning research identified separate contributions of CE and BLA to general affective responses and US-specific responses. Damage to

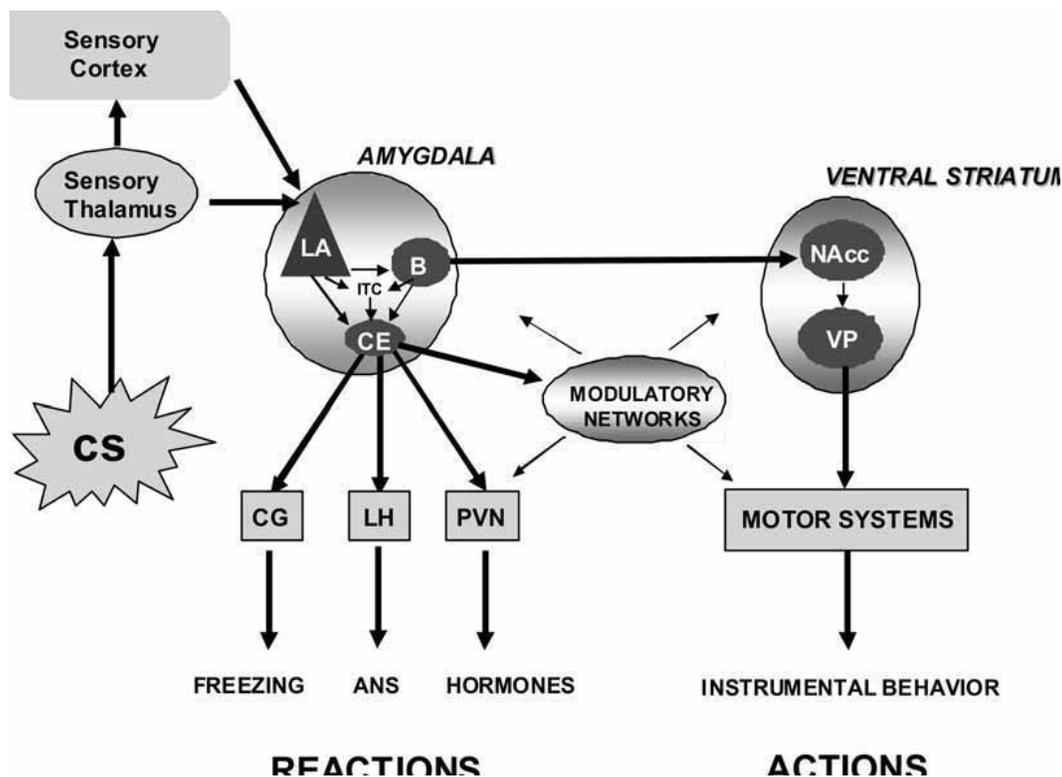

FIGURE 61.7 Schematic representation of circuits proposed to mediate fear-elicited emotional reactions and fear-motivated emotional actions. During fear conditioning the CS-US association is formed and stored in the lateral amygdala (LA) (see figure 61.5). After fear conditioning, the CS, processed in the sensory thalamus and cortex, drives activity in the LA and then CE. Activity in CE, in turn, leads to the expression of passive fear reactions (such as freezing behavior), activation of brain stem neuromodulatory systems that release amine neurotransmitters throughout the brain, and activation of autonomic nervous system (ANS) and neuroendocrine responses. The CS also functions as an incentive and a conditioned reinforcer by way of information flow from LA to B. Projections from B to nucleus accumbens (NAcc) may allow the use of CS information in the control of instrumental actions. Specific-

ally, the NAcc processing of incentive information is proposed to invigorate and guide active behavior via projections to the ventral pallidum (VP) and downstream motor systems, with the aid of neuromodulators (especially dopamine arriving from ventral tegmental area). Note that the amygdala aspects of the model are derived from work on amygdala-dependent fear conditioning and EFF learning (Amorapanth et al., 2000), while downstream portions of the model are borrowed from work in appetitive conditioning (e.g., Ikemoto & Panksepp, 1999; Kalivas & Nakamura, 1999; Cardinal et al., 2002). Once EFF is well-learned, there is a hypothetical inhibition of passive fear actions. Additional abbreviations: PAG, periaqueductal gray; LH, lateral hypothalamus; PVN, paraventricular nucleus; LA, lateral amygdala; B, basal amygdala; CE, central amygdala.

CE, but not to BLA, impaired the “preparatory” conditioned approach (Parkinson, Robbins, & Everitt, 2000) and orienting (Gallagher, Graham, & Holland, 1990). An opposite result was found with US-specific “consummatory” responses: Lesions of BLA, but not of CE, interfered with US devaluation effects (Hatfield, Han, Conley, Gallagher, & Holland, 1996) and potentiation of feeding by an appetitive CS (Gallagher & Holland, 1992; Holland & Petrovich, 2005; Holland, Petrovich, & Gallagher, 2002). Later studies pursued this dissociation, using appetitive PIT tasks (Balleine & Killcross, 2006; Corbit & Balleine, 2005; Everitt et al., 2003; Hall et al., 2001; Holland & Gallagher, 2003), in which Pavlovian CSs enhanced instrumental responding for food. Positive PIT (enhancement of responding) was observed when the USs in Pavlovian and instrumental conditioning matched (US-specific PIT) and when they were both appeti-

tive but distinct (general PIT). BLA lesions disrupted US-specific PIT but had no effect on US-general PIT, while CE lesions disrupted general but not specific PIT. Contradictory results in earlier studies (Everitt et al., 2003; Hall et al., 2001; Holland & Gallagher, 2003) have been attributed to the failure to distinguish between specific and general PIT (Balleine & Killcross, 2006).

Balleine and Killcross (2006) and others (Cardinal et al., 2002; Killcross & Blundell, 2002) argue that the model inspired by appetitive conditioning results should also apply to aversive motivation, based in large part on the effects of amygdala lesions on conditioned suppression. In conditioned suppression, an aversive CS decreases food-motivated lever pressing. This is viewed as a form of general PIT. The finding that suppression depends on CE and not on BLA (Killcross et al., 1997) is thus used to argue that aversive

general PIT depends on CE and not on BLA. Such data were the basis of the parallel model of amygdala processing in fear conditioning discussed above.

There are several reasons not to accept this conclusion without further study. First, conditioned suppression is not methodologically comparable to appetitive PIT. A comparable task would be one in which an aversive CS enhances an aversive instrumental response rather one in which an aversive CS suppresses an appetitive instrumental response. Second, the conclusion that conditioned suppression depends on CE but not on BLA is mainly supported by a study that used overtraining (Killcross et al., 1997), which, as already noted, is problematic. Further, a number of other studies have found that BLA lesions affect conditioned suppression, especially in the absence of overtraining (Cousens & Otto, 1998; Lee et al., 2005; Schiller & Weiner, 2004; Selden, Everitt, Jarrard, & Robbins, 1991). To account for this involvement of BLA in suppression when only a few training trials are used, it has been argued that suppression in such situations is due to freezing, which is deemed a US-specific response and not “true suppression,” which is considered a general affective response (Balleine & Killcross, 2006). This view is challenged by our finding that PAG-lesioned animals exhibit suppression but not freezing, even when only a few training trails are used (Amorapanth, Nader, & LeDoux, 1999). Since freezing is eliminated by the PAG lesion, the suppression that occurs must count as “true suppression” in spite of the fact that only a few training trials were used. Thus, freezing is not necessarily the explanation for why BLA lesions disrupt suppression. If suppression does reflect a form of general motivation based on emotional arousal, then it might be the case that CE is involved in general PIT but as an output of LA and B rather than a parallel and independent pathway.

To directly test the role of different amygdala areas in specific and general motivational functions, US-specific and US-general PIT tasks are needed. These have not been developed and used in aversive studies of brain function to date. However, it is likely that such tasks could be developed, since studies of avoidance conditioning have found that an aversive CS can enhance avoidance responding (Brackbill & Overmier, 1979; Ehrman & Overmier, 1976; Grossen & Bolles, 1968; LoLordo, 1967).

The PIT studies thus return us to the question of serial versus parallel processing in the amygdala. The appetitive studies point to BLA and CE as separately and independently mediating different forms of associative learning, leading to different responses. However, in aversive conditioning, the results suggest that LA and B are likely to be involved in both US-specific and general PIT. The CE may also be involved in aversive general PIT, but if so, this will occur via LA (and possibly B) rather than via the formation of a CS-US association that is independent of LA and B.

As has been noted already, we should not expect the brain to process appetitive and aversive stimuli in similar ways, given how different the USs and the responses involved are. Thus rather than overturning decades of research, the appetitive results provide hypotheses to be tested and methods for testing them in fear conditioning. Only after such work has been done should we draw the conclusion that amygdala circuits mediating fear conditioning are the ones that have been identified for appetitive conditioning rather than the ones that have been supported by decades of research.

EXTRA-AMYGDALA AREAS INVOLVED IN CONDITIONED REINFORCEMENT AND CONDITIONED MOTIVATION The evidence reviewed above suggests that the basal amygdala (B) is likely to play a key role in at least some aspects of aversive conditioned reinforcement and motivation. Anatomical output connections of B are thus probable target areas that might function as postamygdala processing links (Amaral & Insausti, 1992; Gabbott, Warner, & Busby, 2006; Johnson, Aylward, Hussain, & Totterdell, 1994; Kelley, Domesick, & Nauta, 1982; McDonald, 1998; Pitkanen et al., 2000). It is also possible that some aspects of conditioned motivation or reinforcement might involve connections from B to CE. This will not be considered further here. Instead, we will focus on four extra-amygdala targets of B: nucleus accumbens (NAcc), ventromedial prefrontal cortex (vmPFC), anterior cingulate cortex (ACC), and orbitofrontal cortex (OFC).

Nucleus accumbens NAcc is important for instrumental learning in response to environmental stimuli in appetitive tasks (Kelley, 2004) and may be required for expression of this memory, once it has been learned (Ikemoto & Panksepp, 1999; Nicola, 2007). Specifically, NAcc contributes to motivated action learning (Cardinal & Everitt, 2004; Ikemoto & Panksepp, 1999; Kelley, 2004; Koob, 1996; Salamone, Correa, Mingote, & Weber, 2003), including action learning about conditioned reinforcers (de Borchgrave, Rawlins, Dickinson, & Balleine, 2002; Kelley & Delfs, 1991; Robbins, Giardini, Jones, Reading, & Sahakian, 1990) (see figure 61.7).

Anatomically, NAcc is situated at the neural crossroads of emotion and movement (Graybiel, 1976; Mogenson, Jones, & Yim, 1980). Importantly, NAcc neuronal processing appears to contribute to the expression of aversively motivated instrumental learning as intra-NAcc dopamine receptor antagonists disrupt performance of signaled avoidance learning (Wadenberg, Ericson, Magnusson, & Ahlenius, 1990). In addition, performance of conditioned avoidance behavior is reduced by systemic catecholamine synthesis inhibition and rescued by intra-NAcc injections of dopamine (Jackson, Ahlenius, Anden, & Engel, 1977). Recent studies have also shown that NAcc dopamine is

elevated in response to aversive CS presentations (Salamone, Correa, Farrar, & Mingote, 2007). Thus we predict that pre-EFF lesions of the NAcc will impair EFF learning and performance. The above studies also suggest that NAcc may play a role in aversive conditioned motivation, and therefore we predict that posttraining lesions, or disconnections from B, may also impair aversive PIT. NAcc core and shell may make unique contributions, since NAcc core lesions seem to have a greater effect on appetitive conditioned motivation and conditioned reinforcement than shell lesions do (Hall et al., 2001; Parkinson, Olmstead, Burns, Robbins, & Everitt, 1999).

Ventromedial prefrontal cortex vmPFC consists of the infralimbic and prelimbic areas. Studies of interest have not always distinguished between the two regions. Although the literature on vmPFC contributions to conditioned reinforcement or conditioned motivation is sparse, some recent studies have implicated this region in expression of goal-directed actions (Balleine & Dickinson, 1998; Coutureau & Killcross, 2003). In addition, it has been suggested that the connection between B and vmPFC represents a functional link between incentive value and instrumental contingencies (Cardinal et al., 2002). Of particular relevance, however, is the well-documented role of the vmPFC in behavioral inhibition, especially inhibition of passive fear reactions such as freezing. The vmPFC, especially the infralimbic cortex, plays a prominent role in extinction (suppression) of Pavlovian fear reactions (Quirk, Garcia, & Gonzalez-Lima, 2006; Sotres-Bayon, Cain, & LeDoux, 2006). We hypothesize that vmPFC plays some role in enabling action learning like avoidance or EFF and predict that pretraining lesions, or disconnections from B, of infralimbic cortex will impair the acquisition of avoidance and EFF.

Anterior cingulate cortex (ACC) The ACC, which lies dorsal to vmPFC, has been the subject of a good deal of research in emotional learning tasks, both appetitive and aversive. The literature is a bit confusing, but several findings suggest that the ACC may be an interesting target, especially in EFF. For instance, ACC lesions impair signaled active avoidance learning in rabbits (Gabriel, Vogt, Kubota, Poremba, & Kang, 1991), and CS-evoked neural responses in ACC develop early in avoidance training (Gabriel, 1990). It has been suggested that BLA and ACC coordinate to add specificity to instrumental actions that depend on Pavlovian CSs (Everitt et al., 2003). Available data suggest that ACC may be particularly important for instrumental actions that depend on Pavlovian CSs (conditioned reinforcement; reviewed in Cardinal et al., 2002). Thus we predict that lesions of ACC or ACC disconnection from B will impair EFF learning. ACC might not be necessary for PIT, at least

in appetitive conditioning, since ACC lesions do not affect the enhancement of appetitive instrumental responding by a CS previously paired with food (Cardinal et al., 2003).

Orbitofrontal cortex OFC has been implicated in various behaviors involving the integration of incentive value with instrumental actions (Cardinal et al., 2002; Rolls, 2004; Schoenbaum, Gottfried, Murray, & Ramus, 2007). For instance, rats, monkeys, and humans with OFC damage show risk assessment impairments in instrumental choice tasks and an inability to flexibly alter behavior as contingencies change (Bechara, Damasio, & Damasio, 2000; Dias, Robbins, & Robbins, 1996; Gallagher & Schoenbaum, 1999). These deficits seem to be dependent on interactions between OFC and B, since disconnection lesions of these two structures create similar impairments in incentive processing. On the basis of these findings, we predict that OFC damage and OFC disconnection from B will impair both EFF learning and PIT performance.

Summary and conclusions

Animals, including humans, can respond in many ways to aversive stimulation. These responses can be broadly separated into four categories: reflexes, reactions, instrumental actions, and habits. Although fear research initially focused on instrumental avoidance behavior, this strategy was largely abandoned in favor of simple Pavlovian conditioned reactions. This switch in focus to a simpler procedure probably occurred because it facilitated investigations of brain mechanisms and because instrumental avoidance was believed to depend, at least partly, on prior Pavlovian conditioning. This new tack proved to be successful, and several decades' worth of intense research has led to a fairly comprehensive understanding of how the brain mediates the learning, storage, and performance of conditioned fear reactions. Briefly, the amygdala is critical for all three, LA being important for learning and storage and CE being important especially for expression of fear reactions. A recent modification of the standard serial model suggests that B is important for the reinforcement and motivation of instrumental actions, using the CS-US association stored in LA. Thus the standard serial model of fear conditioning assumes that LA is critical for generating the CS-US association, and CE and B mediate different consequences of this learning: reactions versus actions. However, much new research is needed to examine this hypothesis in more depth.

The switch in focus to basic fear reactions also had its costs, as our understanding of aversive action learning such as avoidance and EFF has lagged far behind. Such responses represent a large class of both normal and pathological fear behavior and should be studied in more detail to complete

our understanding of fear-related behavior. It should also be noted that fear actions likely depend on, or at least interact with, prior Pavlovian conditioning. Thus, the foundation provided by decades of intense Pavlovian conditioning research is likely to speed our understanding of aversive instrumental actions.

Research on appetitive conditioning has progressed along a slightly different trajectory. Most notably, appetitive research has benefitted from the Konorskian separation of responses into US-specific “consummatory” and general affective “preparatory” responses. Psychological assays have been honed to tap into these processes, and studies of neural mechanisms have focused on this distinction. The results of this research led to the development of the parallel model of amygdala function, in which CE mediates associations between the CS and general affective properties of the US, and generates responses appropriate for this association. BLA is said to mediate associations between the CS and sensory properties of the US and generates responses appropriate to this association. Note that each association type can generate both actions and reactions, so the distinction here is different from that emphasized by fear research. Importantly, CE and BLA processing are thought to function separately and independently, a concept that is also at odds with the standard fear model. And of course, the models differ in their conception of the association(s) that are formed. In contrast to the parallel model, the serial model assumes that one CS-US association type is formed in LA, between the CS and all properties of the US.

Appetitive conditioning research had progressed greatly in the past few decades and can inform new studies in the aversive field regarding conditioned reinforcement and conditioned motivation of instrumental actions. However, we argue that it is much too soon to abandon the serial model of amygdala-dependent fear conditioning, which is supported by a significant amount of past research. There are just too many methodological (and other) differences between aversive and appetitive studies that can explain the differences between the models. And there is the very real possibility that the amygdala functions one way for appetitive behaviors and another way for aversive behaviors. We argue that the appropriate path forward is to design new experiments to directly test the involvement of various amygdala regions in specific aspects of aversive instrumental action. More data are needed to resolve this apparent discrepancy. Appetitive studies will be invaluable in aiding the direction of this research.

In conclusion, much has been learned about how the brain acquires and controls reactions triggered by fear-arousing stimuli. However, much less is known about the neural mechanisms allowing the acquisition and control of fear-motivated actions. Given the importance of actions to

normal coping and pathological states, it is imperative that we begin to unravel these complex processes. Pathological fear states often involve instrumental responses that were adaptive but under certain conditions became maladaptive and inappropriate. Elucidating the neural mechanisms that underlie interactions between Pavlovian and instrumental aversive learning might enhance our understanding of what makes the shift from passive reactions to actions possible in the face of fear. This knowledge may aid our ability to break the vicious cycle of avoidance and lead to better coping strategies and therapeutic interventions.

62 Interactions of Emotion and Attention in Perception

PATRIK VUILLEUMIER AND TOBIAS BROSCHE

ABSTRACT Interactions between brain systems involved in emotion and attention have attracted a great deal of interest, as both may contribute to regulating behavior and awareness by enhancing the representation of sensory information relevant to the individual. This chapter reviews recent research derived from cognitive sciences and brain imaging that reveals a modulation of early perceptual pathways by emotional signals and suggests a crucial role for the amygdala in imposing direct feedback influences on sensory cortical areas that can boost perception and attention for emotionally relevant stimuli. While such emotional effects may arise in parallel to top-down influences mediated by attentional systems, a different task or context is likely to modulate the efficacy of such boosting, but such modulations still remain poorly known and debated. In addition, although emotional influences from the amygdala on perceptual processing have most often been studied with fear-related stimuli, similar effects might also arise for positive or arousing stimuli that are self-relevant.

To successfully move about in the world and respond to challenges, we have to rapidly detect unexpected changes and important information within our environment. But because of the brain's capacity limits, only a subset of all incoming stimuli can be selected for more in-depth processing, affording subsequent access to other systems such as memory, motor control, and conscious awareness. This competition for neural processing resources is influenced by several factors related to the observer and/or the stimulus. Top-down factors such as expectations and current goals can bias the competition and boost the neural representation of specific stimuli, for example, in searching for a given object in a scene. This voluntary control, termed *endogenous attention*, involves a modulation of sensory pathways by frontoparietal regions (Driver & Frackowiak, 2001). Conversely, physically intense or deviant properties of stimuli, such as their brightness or loudness, may elicit enhanced responses in the sensory stream and trigger reflexive orienting to these stimuli, corresponding to *exogenous attention*.

PATRIK VUILLEUMIER Department of Neuroscience, University Medical Center, Geneva; Swiss National Center for Affective Sciences, University of Geneva, Geneva, Switzerland
TOBIAS BROSCHE Department of Psychology, University of Geneva; Swiss National Center for Affective Sciences, University of Geneva, Geneva, Switzerland

Remarkably, the emotional relevance of a stimulus appears to play a similar and complementary role for controlling the allocation of processing resources for perception and awareness (Vuilleumier, 2005). A central function of emotions is to determine the relevance of a stimulus for well-being and survival and then coordinate an appropriate behavioral response (Scherer, 2001). Efficient processing of emotionally relevant stimuli is obviously highly adaptive, as unexpected events with emotional significance should be noticed more readily and, once detected, become the focus of attention, evaluation, and action. Compelling evidence indicates that this form of *emotional attention* is driven by specific neural mechanisms, including the amygdala. Hence both attention and emotion may contribute to regulate perception and access to conscious awareness, though via partly distinct neural mechanisms. Thus, emotion processing not only serves to imbue our experiences with affective flavors and feelings, but also directly shapes the content of awareness itself. In this chapter, we will provide a general overview of the reciprocal interplay between attention and emotion, considering both brain imaging and behavioral evidence, and will describe our current knowledge of underlying neural circuits.

Enhanced neural processing of emotional information

From everyday experience, we know that emotional stimuli have a special role in perception. Smiling people, attractive faces, one's own name or the name of a loved one overheard at a party, pictures of bloody mutilations, and screams all appear more salient and attention grabbing than neutral stimuli do. In line with these subjective impressions, brain imaging studies in humans have demonstrated increased neural responses to a great variety of emotional stimuli relative to comparable neutral stimuli, using different experimental paradigms and techniques such as functional magnetic resonance imaging (fMRI), positron emission tomography (PET), electroencephalography (EEG), or magnetoencephalography (MEG).

In the visual domain, an emotional "boosting" of neural responses to emotional compared to neutral stimuli has been observed in early visual areas, including primary visual

cortex, as well as in higher-level regions associated with object and face recognition. Pictures of scenes with emotional content produce greater activation in the lateral occipital cortex, faces with emotional expressions produce increases in the fusiform face area (FFA), and emotional body expressions activate both the fusiform and extrastriate body areas (FBA and EBA). Likewise, vocal and nonvocal sounds with emotional significance may evoke higher neural responses in auditory cortical areas than similar but more mundane sounds will. These findings suggest a selective modulation by emotion of brain regions involved in processing the specific stimulus category (see figure 62.1). Increased responses in visual or auditory cortex are also obtained for previously neutral stimuli after aversive conditioning. This suggests that such boosting is not (exclusively) due to intrinsic sensory features of the stimuli but directly relate to their emotional meaning.

Similarly, electrophysiological measures with EEG or MEG have shown enhanced cortical responses to emotional scenes, facial expressions, or fear-conditioned stimuli (for reviews, see Olofsson, Nordin, Sequeira, & Polich, 2008; Vuilleumier & Pourtois, 2007). Such effects may arise at several stages of perceptual processing, including early visual components (100–200 ms after stimulus onset) generated in striate and extrastriate cortex (such as C1, P1, or N1) as well as subsequent components such as the N170 or posterior negativities associated with object recognition processes in higher-level regions. Emotional increases also arise at longer latencies poststimulus onset, such as modulations of the P3 component and sustained late positive potentials (LPP), which may reflect more elaborate affective and cognitive evaluations of the stimuli, autonomic arousal, and/or memory formation. Source localization analyses suggest that these late ERP components reflect the activity of a widespread cortical network including prefrontal, cingulate, and parietal regions. LPP amplitude in EEG is also correlated with the magnitude of fMRI response in occipitotemporal cortex.

Several PET and fMRI studies have also reported that these cortical increases were significantly correlated with amygdala responses; that is, the more the amygdala was sensitive to the emotional meaning in a visual stimulus, the greater the responses of visual areas to this stimulus. Likewise, in conditioning studies, enhanced activation toward conditioned stimuli is usually accompanied by concomitant activation in the amygdala. This has led to the idea that the amygdala may play a critical role in driving such cortical increases, consistent with physiological and evolutionary considerations (Öhman, 2005) suggesting a key function of the amygdala for the rapid detection and response to potential dangers (see below). Furthermore, a vast majority of imaging studies demonstrating emotional influences on cortical perceptual responses used threat-

related cues such as fearful or angry faces as well as aversively conditioned stimuli, consistent with the central role of the amygdala in fear processing and fear learning (LeDoux, 1996). However, a similar enhancement of cortical responses has been observed in human visual and auditory cortex for positive visual scenes, erotica, pictures of babies, or joyful voices. These positive stimuli also increase amygdala activation, suggesting that the emotional processes underlying these effects might not be exclusively sensitive to fear but could more generally be sensitive to emotionally relevant or arousing information (Sander, Grafman, & Zalla, 2003).

Taken together, imaging and electrophysiology data show that emotion can boost perceptual processing at both early sensory and higher-level cortical stages, presumably affording a more robust representation and preferential access of these stimuli to further cognitive processing and awareness.

Behavioral effects of emotion on perceptual processing

In keeping with neuroimaging and electrophysiological evidence of enhanced neural responses, behavioral findings indicate that perception is facilitated and attention is prioritized for emotional information. Emotional stimuli may draw attention more quickly and impede attentional disengagement longer than neutral stimuli, which, depending on the task, can improve behavioral performance when targets are emotionally relevant but also lead to interference when an emotional stimulus competes with a nonemotional target.

Examples for behavioral facilitation by emotion come from visual search studies, in which the detection of a target among distractors is typically faster when the target is emotional rather than neutral (e.g., Öhman, Flykt, & Esteves, 2001). Although this has more often been shown with negative or threat-related stimuli such as angry faces, snakes, or guns, similar effects have sometimes been reported with positive or appetitive stimuli. Conversely, emotional distractors may impair search for a nonemotional target. More efficient searches do not imply that emotional stimuli are processed without attention or “pop out” like targets defined by salient feature differences (e.g., color), as was often interpreted in earlier studies. Instead, attention appears to be preferentially guided toward emotional information, reflecting biases in the allocation of attention rather than a shortcut to conscious perception. Thus, detection time slopes are typically shallower when targets are emotional rather than neutral but do not remain flat irrespective of the number of items in the search display.

Although these data suggest that emotion may drive attention, one cannot exclude the concept that the effects are due to associated stimulus or task characteristics and not direct

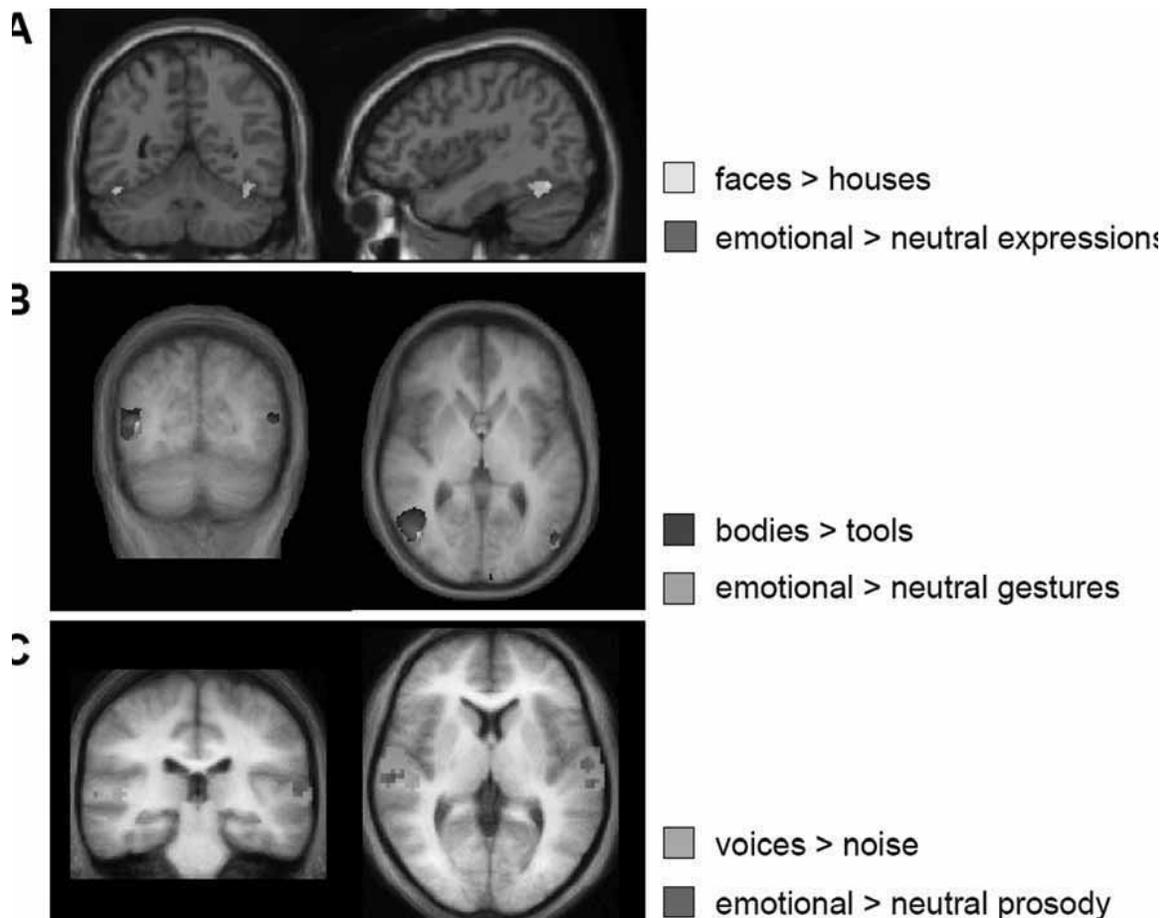

FIGURE 62.1 Emotional enhancement of neural responses in fMRI. (A) Faces with a fearful relative to neutral expression produce increased activation in fusiform cortex, overlapping with the fusiform area selectively activated by faces as compared with houses. (From Vuilleumier et al., 2001.) (B) Bodies with dynamic gestures expressing various emotions (fear, anger, happiness, or disgust) produce increased activation in lateral occipital area cortex,

effects of emotional appraisal. For example, the degree of attentional capture by an emotional stimulus does not always correspond to the strength of affective evaluations for the same stimulus when measured by implicit tests such as affective priming (Purkis & Lipp, 2007). However, in other tasks, ratings of emotional intensity correlate with degree of response facilitation (Brosch, Sander, & Scherer, 2007). A role of emotional processes is also supported by the findings that attentional biases in search (and other) tasks can be modulated by individual state and trait differences related to emotion. For example, attentional bias toward relevant threatening information is often enhanced in people with specific phobia: Attention is directed faster to pictures of snakes than to pictures of spiders in snake phobics but vice versa in spider phobics (Öhman et al., 2001). Furthermore, depressive individuals show an increased bias toward negative information, whereas high levels of optimism are associated with stronger attentional bias toward positive

overlapping with the extrastriate area selectively activated by bodies as compared with tools. (From Peelen, Atkinson, Andersson, & Vuilleumier, 2007.) (C) Voices with angry prosody produce increased activation in temporal cortex, overlapping with an area in superior temporal gyrus selectively activated by human voices as compared with noises with similar acoustic energy. (From Grandjean et al., 2005.) (See color plate 78.)

information. State differences related to current mood may also influence attentional biases toward positive or negative information (Smith et al., 2006). These individual differences strongly suggest that prioritized attention is determined by an appraisal of the emotional meaning and personal relevance of a stimulus rather than just salient sensory features. However, it is still possible that such effects reflect a greater sensitivity or tuning of perceptual systems to some critical features, perhaps subsequent to emotional experience and learning (Weinberger, 1998).

Enhanced performance induced by emotional meaning has been observed in other visual tasks, such as the attentional blink. In the latter, the detection of a target word in a rapid serial visual stream (items appearing successively at fixation at about 10 Hz) is impaired when it occurs shortly after another target. However, this deficit is greatly attenuated for emotional stimuli (e.g., Anderson & Phelps, 2001). Conversely, it may increase for a second neutral target

following an emotional one, suggesting that the emotional meaning of items tend to either grab or divert attention in situations in which resources cannot be equally deployed for every successive stimulus.

Examples of disruption of performance by emotion come from variants of the Stroop interference task, in which participants name the color of a word that can be emotional or neutral. Slower response times to emotional items are generally interpreted to reflect enhanced attentional capture by their emotional meaning. Although a negativity bias has commonly been reported, in the form of more interference by negative than by positive or neutral words, particularly in clinical populations with anxiety disorders, there is also a larger interference for words that are related to individually relevant topics. This has been demonstrated, for example, for spider phobics, social phobics, rape victims, and posttraumatic stress disorder (PTSD) patients (J. M. G. Williams, Mathews, & MacLeod, 1996).

Once attention has been drawn to and engaged by emotional stimuli, it may also dwell longer at their location and facilitate the processing of subsequent stimuli. Such orienting effects have been demonstrated by using the dot probe task, in which participants have to respond to a target (e.g., a dot) that replaces one of two simultaneously presented cues, one cue being emotionally significant (e.g., a fearful or angry face) and the other being neutral. Typical results show faster responses to targets that replace the emotional cue (valid trial) rather than the neutral cue (invalid trial). These effects may reflect either a facilitation of orienting attention toward the emotional stimulus or a greater difficulty in disengaging attention from it (Koster, Crombez, Verschuere, & De Houwer, 2004). In addition to faster response times, emotional cueing may also increase contrast sensitivity for the subsequent target (Phelps, Ling, & Carrasco, 2006). These effects are essentially exogenous and reflexive, since they occur despite the fact that the cue is not predictive of the target location. They may arise with both negative and positive emotional cues (Brosch, Sander, Pourtois, & Scherer, 2008) and operate even across sensory modalities (i.e., for visual targets following auditory cues) (Brosch, Grandjean, Sander, & Scherer, 2008), suggesting that the prioritization of emotionally relevant stimuli is organized supramodally across multiple sensory channels.

Thus, both behavioral and imaging data converge to indicate that perceptual processing is enhanced for emotionally relevant information. Such enhancement may affect performance under conditions of limited resources, in which stimuli in a cluttered scene or in rapid succession must compete for attention, allowing better detection or faster responses to emotional stimuli. Whereas attentional control is generally thought to depend on top-down signals from frontal and parietal areas boosting the neural processing of task-relevant stimuli, the influence of emotion appears

to produce a similar boosting on perceptual pathways to increase the representation of affectively relevant stimuli and bias attention toward them, but the neural mechanisms may implicate partly distinct brain circuits, as will be described below.

Neural circuits underlying emotional attention

The amygdala is thought to be critically involved in processing the emotional relevance of stimuli but also in mediating the influence of emotion on perception. Its dense reciprocal connections with widespread regions in the cortex, including all stages along the perceptual pathways as well as prefrontal regions (Amaral, Behnia, & Kelly, 2003), enable it to receive rich sensory information and to exert both direct and indirect feedback on sensory pathways to boost the processing of emotional stimuli (see figure 62.2). Anatomical studies in the macaque show that direct feedback projections from the amygdala on visual cortex are topographically organized, with denser projections to rostral, high-level areas than to caudal, low-level areas. Most of these projections arise from the basal nucleus of the amygdala but with a progressive gradient, such that its dorsal part (magnocellular, Bmc) predominantly targets earlier areas (such as V1) and its more

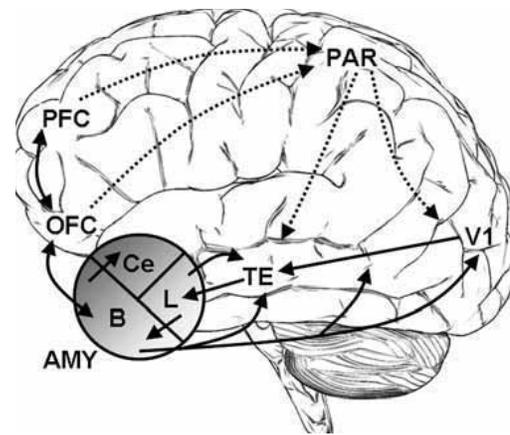

FIGURE 62.2 Reciprocal pathways between emotional and attentional control. Feedback from lateral (L) and basal (B) nuclei from amygdala (AMY) can amplify neural representations of emotionally relevant information at different stages along sensory cortical areas (as illustrated here for the visual system, with early primary visual cortex, V1, and later visual areas in inferotemporal cortex, TE.). While the lateral nucleus receives and projects mainly to higher-level areas, the basal nucleus projects to all stages of sensory processing. Top-down signals from parietal cortex (PAR) on sensory areas may focus attentional resources on the location of emotional events. Amygdala feedback loops may be modulated by influences from orbitofrontal cortex (OFC), as well as by interconnections with prefrontal areas (PFC). Amygdala output via the central nucleus (Ce) can also activate other brain systems, including cholinergic projections from forebrain to parietal, as well as frontal and sensory cortical regions. These projections are not shown here.

ventral part (intermediate, Bi) predominantly reaches later areas (such as TEO and TE). By contrast, most visual inputs to the amygdala project to the lateral nucleus, which then projects to the basal nucleus and back to higher-level areas only (such as TE). A similar topographical organization probably exists in the auditory domain.

Direct evidence for a modulatory influence of this amygdala feedback loop on cortical responses in humans is provided by fMRI results showing that amygdala lesions may impair functional activation of intact visual areas to emotional faces. In a visual discrimination task comparing responses to fearful and neutral faces (presented at either attended or ignored locations), healthy controls typically show increased activation in fusiform cortex to fearful faces relative to neutral faces, irrespective of whether attention is focused on the faces or concurrent house pictures instead (Vuilleumier, Armony, Driver, & Dolan, 2001). However, this increase is not observed in patients with amygdala damage due to medial temporal lobe sclerosis, in contrast with patients whose sclerosis is restricted to the hippocampus and does not affect the amygdala (Vuilleumier, Richardson, Armony, Driver, & Dolan, 2004). These findings indicate that the amygdala plays a causal role in the enhanced processing of emotional stimuli within distant cortical sites. Preliminary ERP results have also pointed to functional anomalies in visual responses to emotional faces in patients with amygdala lesions, affecting both the early P1 component and later components that arise at 500 ms after stimulus onset.

Furthermore, an impact of amygdala lesion on visual performance has also been demonstrated behaviorally in patients with temporal lobe resection (Anderson & Phelps, 2001). Those with left or bilateral damage to the amygdala did not show the normal facilitation of detection for emotional relative to neutral words in an attentional blink paradigm, even though the patients still understood normally the affective meaning. This deficit provides further evidence that affective influences on attentional processes depend on amygdala function.

Amygdala outputs also project to cholinergic basal forebrain nuclei, which in turn can modulate perception through their widespread connections with many cortical areas. However, imaging results have shown that cholinergic stimulation may modulate orbitofrontal and parietal regions, without significant changes in the normal emotional boosting of sensory (e.g., visual) areas (Bentley, Vuilleumier, Thiel, Driver, & Dolan, 2003).

In addition, emotional stimuli can produce indirect effects by modulating activity within the frontoparietal attention network. This was observed, for example, in the reflexive spatial orienting induced by peripheral emotional stimuli in a dot probe task (Pourtois, Schwartz, Seghier, Lazeyras, & Vuilleumier, 2006), in which a neutral visual target (e.g., a dot) is presented following a pair of faces (e.g., one fearful

and one neutral), replacing either the emotional or the neutral face (valid or invalid trials, respectively; see above). Greater fMRI activation is observed in the intraparietal sulcus (IPS) when targets are preceded by a fearful face than a neutral face, consistent with enhanced attentional orienting and faster detection of targets on valid trials. This increased activation of IPS on valid trials contrasted with strongly reduced activation on invalid trials in which targets are presented in the ipsilateral visual field after an emotional face on the contralateral side, suggesting that IPS may become unresponsive to stimuli in the ipsilateral hemifield subsequent to the enhanced focusing of attention on the contralateral side. These neural effects corroborate behavioral findings that emotional stimuli may not only draw but also hold attention to their location (Fox, Russo, & Dutton, 2002).

In keeping with these fMRI results, ERP recordings during the dot probe paradigm (Brosch, Sander, et al., 2008; Pourtois, Grandjean, Sander, & Vuilleumier, 2004) show higher amplitude of the P1 visual potential to targets that replace an emotional rather than a neutral face. As the P1 is generated in extrastriate occipital cortex and modulated by spatial attention, these data further demonstrate that emotional cues may bias spatial attention and enhance visual processing for subsequent stimuli at the same location. Detailed spatiotemporal analysis of the ERPs suggests that this enhancement of P1 is preceded by a modulation of parietal activity that correlates with the magnitude of P1 increases (Pourtois, Thut, Grave de Peralta, Michel, & Vuilleumier, 2005), suggesting that this earlier parietal activity may be responsible for generating top-down influences on visual cortex following the presentation of the emotional cue.

Taken together, these data show that emotional signals may not only activate the amygdala and related emotional brain systems, but also directly affect sensory cortices to modulate the neural representation of a stimulus and additionally influence frontoparietal mechanisms responsible for orienting and shifting attention in space. Thus, subsequent information arising at the same location as emotional cues will also benefit from enhanced processing resources.

The automaticity of emotional attention

Most of the emotional influences on behavioral and neural processes described above arise in conditions in which emotional meaning itself is not directly relevant to the task and therefore appears to be processed automatically without intention or even without awareness. For instance, the emotional Stroop interference demonstrates that word meaning is extracted involuntarily, although this is not required and in fact is counterproductive with respect to the task goal. Likewise, in the dot probe task or visual search (see above),

attention seems reflexively oriented toward emotional cues even when these are not predictive of target location.

However, there are still debates about the exact degree of “automaticity” of emotional processing and emotional attention (Pessoa, 2005; Vuilleumier & Driver, 2007). Automaticity implies several different functional features (related to intentionality, controllability, rapidity, and awareness) that do not necessarily co-occur (Moors & De Houwer, 2006), but much remains to be done to disentangle these different aspects in relation to emotional processing. Three main questions that are often subsumed under this issue concern (1) whether emotional responses in the amygdala require cortical processing or can be triggered by a subcortical shortcut, (2) whether emotional processing has to compete for general attentional resources or takes place irrespective of task demands, and (3) whether attentional effects induced by emotion are totally independent from attentional processes mediated by frontoparietal networks.

The first question concerning the route of emotional inputs to the amygdala derives from fear-conditioning experiments in rats (LeDoux, 1996), showing that auditory information may reach the amygdala via a short latency pathway from the thalamus, the so-called low road, even after interruption of cortical pathways. By analogy, a visual shortcut (via collicular-pulvinar pathways) has been proposed in humans (Morris, Öhman, & Dolan, 1999) to account for the findings that healthy subjects may show amygdala activation to masked fearful faces that are not perceived consciously and that patients who are blind after destruction of visual cortex may still discriminate emotional stimuli and show increased amygdala activation to emotional facial expressions (Pegna, Khateb, Lazeyras, & Seghier, 2005). Subcortical inputs might also reach the amygdala via direct pulvinar projection to extrastriate areas. Although there is no direct evidence in humans that a subcortical route would be truly faster than the cortical route, collicular-pulvinar pathways are known to carry only magnocellular visual inputs (not parvocellular), which convey fast but coarse, low-spatial frequency information throughout the visual system (Vuilleumier, Armony, Driver, & Dolan, 2003).

Alternatively to this two-pathway mechanism, a two-stage mechanism might also allow rapid inputs to reach the amygdala through a first feedforward sweep of cortical activation (Bullier, 2001). Amygdala responses could be triggered by a limited amount of information, such as low spatial frequency cues conveyed by magnocellular visual inputs to the cortex, or simple “diagnostic” features of emotional stimuli (e.g., wide-open eyes in fearful faces). This initial emotional appraisal could then provide subsequent feedback signals to cortical areas, where further processing may take place over longer periods on the basis of more complex sensory information (e.g., high-spatial frequency, parvocellular inputs).

Both the two-pathway or two-stage mechanisms would account for ERP data demonstrating that the emotional value of some stimuli (e.g., facial expressions) can be encoded after short latencies (e.g., 100–140 ms), prior to higher-level processes associated with perceptual or categorical encoding (e.g., 170–200 ms). Recent research using MEG and dynamic causal modeling (Rudrauf et al., 2008) has provided support to the two-pathway hypothesis, by showing that a network including a fast subcortical pathway could better explain patterns of activation to emotional information. However, more direct neurophysiological evidence is still needed to disentangle the differences between these two hypotheses.

A second question on automaticity is whether limitation in attentional resources or awareness may reduce processing of emotional stimuli, like other classes of stimuli, or whether emotional stimuli are privileged or immune to general attention control. On the one hand, several imaging studies have demonstrated parallel influences of emotion and attention on brain responses. By manipulating attention and emotion separately in fMRI studies, it was found that the response to faces in visual cortex (Vuilleumier et al., 2001) or to voices in auditory cortex (Grandjean et al., 2005) could be modulated by each factor independently. In the former study, participants were presented with pairs of faces and pairs of houses and had to focus attention on one pair only (either faces or houses) while ignoring the other (to make a difficult same/different identity judgment). Faces were either both fearful or both neutral. As was expected, face-sensitive regions in fusiform cortex showed increased activation when attention was directed to pairs of faces rather than to houses; more important, fusiform activity was also greater for fearful faces than for neutral faces, both when faces were task-relevant and when they were ignored. In other words, fear expression could boost fusiform activity in a parallel and additive manner to the modulation by spatial attention on the same region. Similar results have been obtained by using an auditory dichotic task, in which voice-selective regions in superior temporal sulcus were not only modulated by voluntary attention (with greater responses when focusing on the contralateral than ipsilateral ear), but also modulated by emotional prosody (with greater responses to angry than neutral voices), irrespective of the side of the angry voices (i.e., in the attended or unattended ear). Furthermore, in the face-house task, amygdala lesions can abolish the modulation by emotion while preserving modulation by attention (Vuilleumier et al., 2004). These data demonstrate that emotional enhancement of face or voice processing may arise over and above a concomitant influence of endogenously driven attention and that such emotional response may still persist when attention is diverted and cortical processing is reduced. Moreover, in both studies, amygdala activation was unaffected by spatial attention, consistent with its presumed role in driving emotional enhancement. A similar additive

pattern has been found with ERPs to complex emotional scenes presented at attended or unattended locations in visual hemifields (Keil, Moratti, Sabatinelli, Bradley, & Lang, 2005).

Nevertheless, it is possible that attentional and emotional effects may interact in some other brain areas (e.g., STS or V1) and that further diversion of attentional resources is necessary to suppress emotional processes. For instance, directing attention away from emotional stimuli may reduce amygdala responses in tasks in which attentional load is particularly high (Pessoa, Padmala, & Morland, 2005) and thus possibly also reduce the impact of emotion on perceptual processing. Although many studies have reported amygdala responses to emotional stimuli without attention or even without awareness (e.g., Anderson, Christoff, Panitz, De Rosa, & Gabrieli, 2003; Jiang & He, 2006; Whalen et al., 1998), several others have reported reduced responses in such conditions (e.g., Pessoa, Kastner, & Ungerleider, 2002; Pessoa et al., 2005). However, in some cases, inattention or unawareness may reduce the differential response to emotional stimuli, owing to concomitant increases to neutral or positive stimuli (Anderson et al., 2003; Silvert et al., 2007; M. A. Williams, McGlone, Abbott, & Mattingley, 2005) rather than just decreases to emotional stimuli. In addition, individual differences may also influence the pattern of responses. In a study using the same face-house task as above, individuals with low state anxiety actually showed reduced amygdala activation to unattended fearful faces, possibly driven by prefrontal attentional control mechanisms (Bishop, Duncan, Brett, & Lawrence, 2004). Greater amygdala activity in high-state anxiety might reflect weaker attentional control and/or amplification of feedback loops within the amygdala subnuclei under the influence of prefrontal regions (Kim et al., 2004).

The third issue concerning the independence of attentional and emotional influences on perception is supported not only by evidence of additive modulations in imaging studies (Keil et al., 2005; Vuilleumier et al., 2001) but also by neuropsychological observations indicating that emotional biases may still arise after brain lesions producing selective attentional deficits. Patients with right parietal or frontal damage may present with hemispatial neglect, characterized by failures in orienting attention to the contralateral/left space (Driver, Vuilleumier, & Husain, 2004); but the severity of neglect has been shown to be reduced for emotional stimuli relative to neutral stimuli, such as faces with angry or happy expressions, bodies with emotional gestures, pictures of spiders, or voices with various emotional prosodies (Grandjean, Sander, Lucas, Scherer, & Vuilleumier, 2008; Vuilleumier & Schwartz, 2001). Furthermore, a systematic analysis of brain lesions in these patients revealed that those with the largest gains in detection for emotional relative to neutral stimuli have lesions centered

on lateral frontal and parietal regions, whereas those with weaker emotional biases have more frequent lesions in basal ganglia and orbitofrontal regions (for both emotional faces and emotional voices). Imaging results have also shown that fearful faces can still produce enhanced activation in intact visual cortex despite parietal damage and neglect and despite unawareness of such faces (Vuilleumier et al., 2002). These neuropsychological data add to the evidence that emotional influences on perception are not mediated by frontoparietal networks controlling spatial attention and further suggest that orbitofrontal regions might be implicated in mediating interactions between emotion and attention.

To sum up, although emotional stimuli may evoke reflexive and involuntary processing under many conditions, this does not preclude that such effects can be amplified or attenuated by cognitive or affective factors such as task load, anxiety, phobic traits, expectations, or prior experience. Involuntary monitoring of emotional stimuli and reflexive boosting of perceptual processes may reflect some “default” settings or intrinsic preparedness within neural pathways yet be adaptively shaped by various regulatory mechanisms that themselves can operate potentially with or without conscious control. However, the brain circuits that are responsible for such modulations remain to be determined, and their relationship to specific facets of automaticity still needs to be clarified.

Personality differences and cultural factors

The notion that interindividual differences influence attention and perception is not a new discovery. Bartlett (1932) noted that “temperament, interests and attitudes often direct the course and determine the content of perceiving.” A number of behavioral results demonstrate that attentional biases to emotional information may depend on individual factors such as anxiety, optimism, positive or negative mood states, depression, or current goal states. Even cultural differences have been found to modulate attentional capture in the emotional Stroop task, with greater interference by the emotional semantics of words in American participants but greater interference by emotional prosody in Japanese participants (Ishii, Reyes, & Kitayama, 2003).

Although the neural substrates of these effects are unresolved, recent imaging studies have revealed different amygdala responses to emotional stimuli in relation to various personality traits, including anxiety, harm avoidance, extraversion, phobic fears, or attachment style (e.g., Bishop, Duncan, & Lawrence, 2004; Canli, Sivers, Whitfield, Gotlib, & Gabrieli, 2002; Sabatinelli, Bradley, Fitzsimmons, & Lang, 2005). A stronger “automatic” amygdala activation in anxious people may arise specifically under conditions of low cognitive or attentional load, together with reduced activation in areas associated with conflict monitoring and

executive control such as ACC and lateral PFC. Whereas state anxiety correlates with amygdala activation, trait anxiety correlates with relative deactivations in PFC and ACC, suggesting different effects of different aspects of anxiety (Bishop, Jenkins, & Lawrence, 2007). However, it remains to be determined whether the attentional biases that are described behaviorally in these conditions exert similar or different neural modulations, possibly implicating not only perceptual processing but also semantic processing, as well as memory retrieval, decision making, or thought.

Interactions between emotional attention and current behavioral goals

Rapid and reflexive processing of emotional stimuli without intention is adaptive to detect relevant information in the environment; however, it can also be distracting and detrimental to performance. For example, emotional distractors may impair working memory, accompanied by activation of amygdala and ventrolateral prefrontal cortex (VLPFC) but concurrent deactivation of task-related regions in dorsolateral prefrontal cortex (DLPFC) and lateral parietal cortex (Dolcos & McCarthy, 2006). A similar pattern has been observed during an attentional oddball task, with rare emotional and nonemotional pictures embedded in a stream of standard shapes. Amygdala and ventral frontal regions were activated by emotional stimuli, whether participants had to respond to them or not, while dorsal frontoparietal regions responded to target stimuli, irrespective of their emotionality. Anterior cingulate gyrus showed additive effects, responding to all emotional stimuli but responding more strongly when they were target (Fichtenholtz et al., 2004). Behavioral interference in the emotional Stroop task is also accompanied by activation of amygdala and rostral anterior cingulate cortex. ACC activation might reflect a processing conflict due to attention capture by emotional stimuli, which might then trigger activation in the lateral PFC to adjust and maintain top-down goal-related control.

Other studies have demonstrated a modulation of amygdala activity by behavioral goals, expectations, or emotion regulation efforts, which can perhaps determine the degree of emotional influences on sensory processing. However, amygdala activation toward negative information seems less amenable to attenuation by voluntary goals than does activation toward positive information (Cunningham, Van Bavel, & Johnsen, 2008). Different expectations can also produce different effects on amygdala responses to relevant stimuli. Single-cell recordings in monkeys suggest that some neuronal populations within the amygdala may be modulated by expectations of reward or punishment selectively, whereas others respond to any unexpected reinforcer independent of valence (Belova, Paton, Morrison, & Salzman, 2007). The effects of emotion regulation and

expectations are presumably mediated by connections from orbitofrontal cortex (OFC), which may act as a gateway between emotional processes in the amygdala and representational memory systems in the prefrontal cortex (Roesch & Schoenbaum, 2006). OFC might thus strengthen or inhibit amygdala responses based on current context and internal state.

In summary, interactions between attention and emotion involve a large network that not only is centered on the amygdala, but also has many reciprocal connections with several prefrontal areas, including orbitofrontal and cingulate cortex as well as DLPFC (Cavada, Company, Tejedor, Cruz-Rizzolo, & Reinoso-Suarez, 2000). This network is well positioned to appraise the emotional relevance of stimuli by integrating representations of affective value with complex situational factors related to goals, expectations, experience, or personality and might serve to modulate both perceptual processes within sensory cortices and other cognitive processes within dorsal and lateral prefrontal areas. Through these interactions, by analogy with the notion of attentional sets (Folk, Remington, & Johnston, 1992), *emotional attentional sets* might sensitize neural pathways to stimuli that are emotionally relevant, given both their intrinsic meaning and the current state of the individual.

Conclusions

Recent research has provided us with a remarkable amount of new knowledge concerning the mechanisms by which perception and attention may be influenced by emotional processing. Such influences are implemented by a dynamic interplay between the amygdala and other brain regions, including sensory cortices as well as parietal and prefrontal areas. These emotional mechanisms complement *endogenous* and *exogenous* attentional systems that are known to select and organize sensory inputs based on voluntary behavioral goals and low-level physical salience and thus constitute a specialized neural system for *emotional* attention in the service of fast and adaptive response to highly relevant events.

63 Context Effects and the Amygdala

PAUL J. WHALEN AND F. CAROLINE DAVIS

ABSTRACT The amygdala is a critical component of the brain network responsible for learning about cues that predict biologically relevant outcomes. But these cues are always encountered within a particular context, and this contextual information can modulate amygdala responses. Here, we review neuroimaging studies examining human amygdala responses to specific predictive cues and the modulation of these responses by contextual information. Specifically, we focus on human neuroimaging studies of facial expressions as an example of predictive environmental cues. These studies suggest that regions of the prefrontal cortex and hippocampus are responsive to contextual information and that these responses presumably influence amygdala responses to faces when they are encountered within a given context. These data are interpreted as consistent with the nonhuman animal conditioning literature that supports a role for these regions in facilitating context conditioning.

All environmental events eventually derive their meaning from their context. For example, a person crying at a funeral means something quite different from the very same person crying on a gold medal podium (see Russell & Fernandez-Dols, 1997). Thus, a particular environmental event will give rise to a differential of potential meanings; the context then allows for the selection of the most appropriate meaning of this event within a given circumstance. In this chapter, we will focus on human neuroimaging studies of the amygdala and its interest in events that predict biologically relevant outcomes (e.g., the facial expressions of others). We will see that through its reciprocal connections with the prefrontal cortex, the amygdala can show great flexibility in its responses to predictive cues when informed about contextual considerations. We will then connect this information with the nonhuman animal conditioning literature depicting the known role of the amygdala in facilitating context conditioning.

Using facial expressions to study the human amygdala

Facial expressions mediate a critical portion of our nonverbal communication. From the expressions of others, we can glean information about their internal emotional state, their intentions, and/or their reaction to contextual events in our immediate environment. Facial expressions of emotion have

predicted important events for us in the past, and we can use this previous experience to respond appropriately to expressions as we perceive them. In this way, facial expressions can be considered conditioned stimuli.

HUMAN AMYGDALA RESPONSES TO FEARFUL FACIAL EXPRESSIONS ARE RELATED TO THEIR GREATER CONTEXT DEPENDENCE On the basis of animal research showing the importance of the amygdala in fear conditioning (Davis, 1992; Kapp, Whalen, Supple, & Pascoe, 1992; LeDoux, 2000), and studies of bilateral amygdala lesion patients showing deficits in processing the facial expression of fear (Adolphs, Tranel, Damasio, & Damasio, 1994; Broks et al., 1998), early human neuroimaging investigations of amygdala responses to facial expressions focused on fearful expressions (Breiter et al., 1996; Morris et al., 1996; M. L. Phillips et al., 1997; Whalen et al., 1998). Subsequent studies have replicated robust amygdala activations to fearful faces (Pessoa, Japee, Sturman, & Ungerleider, 2004; Whalen et al., 1998; Whalen, Shin, McInerney, & Fischer, 2001). These findings have been presented as consistent with the traditional role of the amygdala in processing threat-related information exclusively.

But additional data from these same amygdala lesion patients suggest that the amygdala is not responding to fearful faces solely because of their threatening nature. (Adolphs et al., 1994). We took this finding as a clue and speculated that perhaps the amygdala is particularly important for processing expressions that predict uncertain (fear) vs. certain (anger) threat. To elaborate, though angry and fearful faces can be equated in terms of the subjective arousal and valence ratings that subjects ascribe to them, they offer very different predictive information value. While both expressions suggest to a viewer that the probability of threat in the immediate context has increased, fearful faces provide no information about the source of that threat, while angry faces embody the very threat that is to be dealt with. Said another way, fearful faces are much more *context dependent* than angry faces are. Fearful faces call for diffuse attention to be directed toward the immediate context (“What is she afraid of?” and “Should I be afraid too?”), while angry faces call for direct attention aimed at the face (“What will he do next?” and “How will I respond?”).

In partial support of this hypothesis, studies have shown that fearful expressions are related to greater contextual

PAUL J. WHALEN and F. CAROLINE DAVIS Department of Psychological and Brain Sciences, Dartmouth College, Hanover, New Hampshire

monitoring. For example, subjects are better at a perceptual discrimination task on trials that are contextually bound to fearful faces (Phelps, Ling, & Carrasco, 2006). Interestingly, it is known that we, to some degree, mimic the expressions of others (Hess, Blairy, & Philpott, 1999; Dimberg, 1990). It follows then that another person's fearful expression would lead to mimicry of a similar expression on our part. If the detection of fearful expressions leads to facilitated environmental monitoring, then this mimicry could be an important component of this process. Consistent with this notion, recent data show that when subjects make fearful expressions, they show facilitated monitoring of the context (Susskind et al., 2008).

Human neuroimaging data show that amygdala responses may be a critical component of the process that instigates greater environmental monitoring in response to fearful expressions. We have published one study showing that while one portion of the amygdaloid complex appears to track the valence of presented facial expressions, another shows responses that appear to be sensitive to the uncertainty associated with their predicted outcomes (Whalen et al., 2001). Specifically, a ventral portion of the amygdala showed responses of equal magnitude to fearful and angry faces when compared to neutral faces, consistent with the notion that this region of the amygdala may have been responding to the equal negative valence of these expressions. In parallel, a more dorsal portion of the human amygdaloid complex extending into the ventral basal forebrain showed greater responses to fearful faces when directly compared to angry faces. We hypothesized that these dorsal amygdala/ventral forebrain responses may be in reaction to the uncertain information value and greater contextual dependence associated with fearful expressions compared to angry expressions (Whalen et al., 2001).

These data suggest that in addition to threat detection, the amygdala is also recruited when the nature of predicted threat is unclear. Thus the amygdala will be the most indispensable in situations when the organism has the most to learn. If some portion of signal changes within the amygdaloid complex in response to fearful expressions are truly related to the ambiguity of the contextual event that elicited the expression, rather than the negative valence of the face itself, then a compelling demonstration would involve showing a similar amygdala activation to a facial expression that has a similar ambiguity of contextual source but that is not necessarily negatively valenced.

THE FACIAL EXPRESSION OF SURPRISE Surprised expressions provide an important comparison for fear. Though neither expression (fear nor surprise) indicates the exact nature of its eliciting event, fearful expressions do provide additional information concerning predicted negative valence. Surprise, on the other hand, can be interpreted either positively

or negatively (Tomkins & McCarter, 1964). For example, when asked to provide a story about what is happening to the person pictured showing a surprised expression, some people describe an oncoming car (negative), while others describe an unexpected birthday party (positive) (Davis & Whalen, unpublished observations). Thus surprised facial expressions can be used to (1) reveal important individual differences in the propensity to subjectively ascribe positive or negative valence to an ambiguous facial expression and (2) determine the relationship between these subjective ratings and fMRI signal changes in the amygdala. Further, given their potential dual valence representation, we expected these expressions to be particularly sensitive to context manipulations.

For our first study, we simply had subjects passively view repeated presentations of individuals displaying surprised facial expressions and then had subjects rate the expressions on a scale from 1 (very positive) to 9 (very negative) following the fMRI scanning session. Figure 63.1A shows that a lateral ventral region of the amygdala tracked individual differences in valence interpretations of surprised faces. Subjects who interpreted the surprised faces negatively showed higher signal values that correlated with the intensity of these ratings, while subjects who interpreted the faces positively showed lower correlated signal values. Consistent with the assertion made above that the amygdala is also responsive to the ambiguity of contextual source (which exists whether the face is interpreted negatively or positively), figure 63.1B shows homogeneous signal increases across all subjects within more dorsal as well as medial portions of the amygdala, despite these differences of opinion related to the valence of the faces. Thus different portions of the amygdaloid complex appear to work on different parts of the problem: predictive aspects of an expression that appear clear to the viewer (e.g., valence—"that face looks negative to me") and, simultaneously, other aspects that remain unclear (e.g., context—"I wonder what she is reacting to").

It might seem a bit surprising that the ventral amygdala did not respond to the surprised faces in some individuals (i.e., those who interpreted the faces positively). Given that one function of the amygdala is to monitor the environment for potential threat, one would have thought that the ventral amygdala would have responded to the potential negativity of the surprised faces similarly in all subjects. Individual differences of this type suggested to us that another region of the brain might be exerting a regulatory influence over the amygdala. Accordingly, we looked to the medial prefrontal cortex (mPFC), given the known reciprocal connections of this region with the amygdala in both the rat and non-human primate (e.g., Ghashghaei, Hilgetag, & Barbas, 2006; Stefanacci & Amaral, 2002).

We identified two regions of the mPFC that were correlated with subjects' valence interpretations of surprised faces

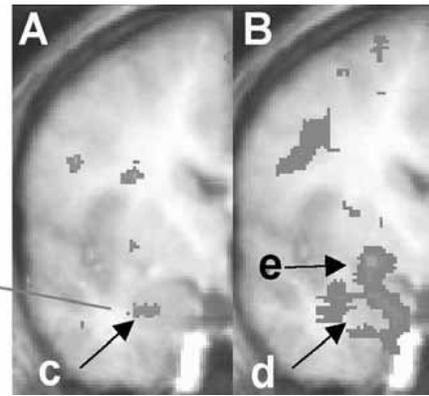

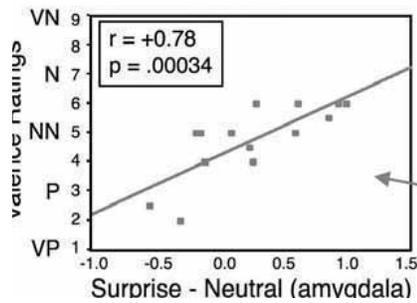

FIGURE 63.1 (A) The activated voxels depict the location within the ventral amygdala where a positive correlation with ratings of surprise was observed (arrow c) from the results of H. Kim and colleagues (2003). Scatterplot to the left presents these data. The *x*-axis presents fMRI responses to surprised versus neutral faces, while the *y*-axis presents the valence scale from 1 to 9. Labels on the *y*-axis: VN, very negative; N, negative; NN, neither negative nor positive; P, positive; VP, very positive. (B) Voxels at this same anterior-posterior level ($y = -3$) showing a significant main

effect for surprised versus neutral faces across all subjects. The maximally activated voxel for this main effect is located in the dorsal amygdala/SI (arrow e). Note that these voxels do not include the voxels in which we observed the significant correlation based upon individual differences (arrow d). Image B is thresholded liberally ($p < .05$, uncorrected) to make the points that (1) no trend toward a main effect for surprise existed in the voxels presented in A, and (2) we have signal coverage across the entirety of the amygdaloid complex.

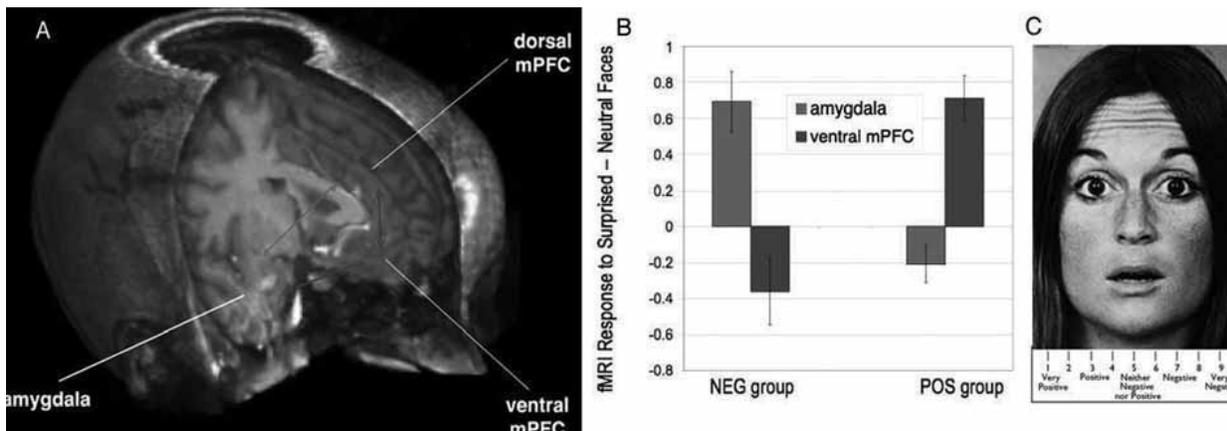

FIGURE 63.2 (A) A three-dimensional depiction of the correlational results of H. Kim and colleagues (2003). Amygdala and dorsal mPFC loci that showed a positive correlation with valence ratings of surprise (colored in orange) are also positively correlated with one another (red arrow, $r = +.66$). The ventral mPFC locus that showed a negative correlation with valence ratings of surprise (colored in blue) is also negatively correlated with amyg-

dala (blue arrow; $r = -.69$) and the dorsal mPFC (blue arrow; $r = -.62$). (B) Bar graph focusing on the inverse relationship between the amygdala and ventral mPFC in subjects who interpreted the surprised faces either positively (POS) or negatively (NEG). (C) An example of the surprised faces and valence scale used to rate them. (See color plate 79.)

(see figure 63.2). Like the amygdala, a dorsal region of the mPFC (specifically the rostral ACC; see H. Kim et al., 2003) displayed a positive relationship with negative valence ratings (i.e., higher activity with more negative ratings). A ventral region of the mPFC (ventral ACC; see H. Kim, Somerville, Johnstone, Alexander, & Whalen, 2003) showed an opposite relationship with valence ratings of surprised faces compared to the amygdala and dorsal mPFC (i.e., higher activity with more positive ratings). That this ventral mPFC activity was inversely correlated with the ventral amygdala, is consistent

with the location of known prefrontal-amygdala connections in nonhuman primates (Ghashghaei et al., 2006).

Figure 63.2A presents a three-dimensional representation of these regions where activity in the ventral mPFC is inversely related to activity in the amygdala and dorsal mPFC. Figure 63.2B presents a bar graph that focuses on the inverse relationship between the ventral mPFC and the amygdala, showing that subjects who interpreted these faces negatively showed high amygdala responses and correlated low ventral mPFC responses, while the subjects who

interpreted them positively showed high ventral mPFC responses and correlated low amygdala responses. Note that this inversely correlated ventral mPFC-amygdala fMRI activity was observed during passive viewing. That is, activity measured while subjects viewed repeating surprised faces predicted the valence ratings the subjects assigned to these faces following the scanning session. These data suggest that these brain activations related to valence calculations were relatively automatic/implicit while subjects passively viewed the faces (H. Kim et al., 2003).

One interpretation of these data is that in response to ambiguous surprised expressions, a regulatory override message from the ventral region of the mPFC is required to interpret these faces as positively valenced. Inherent in this assertion is the presumption that the amygdala is involved in an initial default negative interpretation of surprised faces in all subjects, after which some subjects are able to regulate this amygdala response and respond more positively. More generally, these data suggest that surprised faces constitute a simple means for tapping into a purported medial prefrontal-amygdala regulatory circuit, a circuit that mediates a similar override function during the extinction of conditioned fear responses (Milad & Quirk, 2002; Morgan, Romanski, & LeDoux, 1993; Phelps, Delgado, Nearing, & LeDoux, 2004; see Oler, Quirk, & Whalen, in press, for further discussion).

MODULATING AMYGDALA RESPONSES TO SURPRISED FACES BY MODULATING THE CONTEXT IN WHICH THEY ARE PRESENTED If the hypothesis that greater amygdala activity is observed to fearful and surprised faces because they are more context-dependent is sound, then manipulation of

contextual information during presentations of surprised faces should differentially affect amygdala activation. Figure 63.3A shows the design of an experiment in which participants were explicitly told whether the presented surprised face was in reaction to a negative event or a positive event. Instead of letting subjects decide for themselves whether a particular surprised face was negative or positive, each surprised face was preceded by a contextual sentence describing either a negative or a positive event (e.g., “He just lost \$500” or “He just found \$500”). Subjects were told that the expression that followed the sentence was in direct reaction to the described event. Figure 63.3B shows that the ventral amygdala did not show differential responses to the sentences themselves but did show differential responses to the faces that were primed by the contextual sentences. Specifically, although the presented contextual sentences were carefully matched for ratings of subjective arousal and intensity of valence, amygdala responses were greater to the surprised faces that were presented in a negative context compared to a positive context (H. Kim et al., 2004). Note the lack of activation across more dorsal portions of the amygdaloid complex (see figure 63.1); we suggest that this is due to the fact that the sentences disambiguated the eliciting source of the surprised faces; thus only the activation based upon valence, not the main effect for surprise, is observed. Also, consistent with the findings of H. Kim and colleagues (2003), a region of the mPFC (dorsal ACC) showed activation to negative and positive contextual sentences (see figure 63.4).

We speculate that across the two studies, the mPFC exerted an influence over amygdala activity leading to lower amygdala signal intensities when surprised faces were interpreted positively. In the latter study (H. Kim et al., 2004),

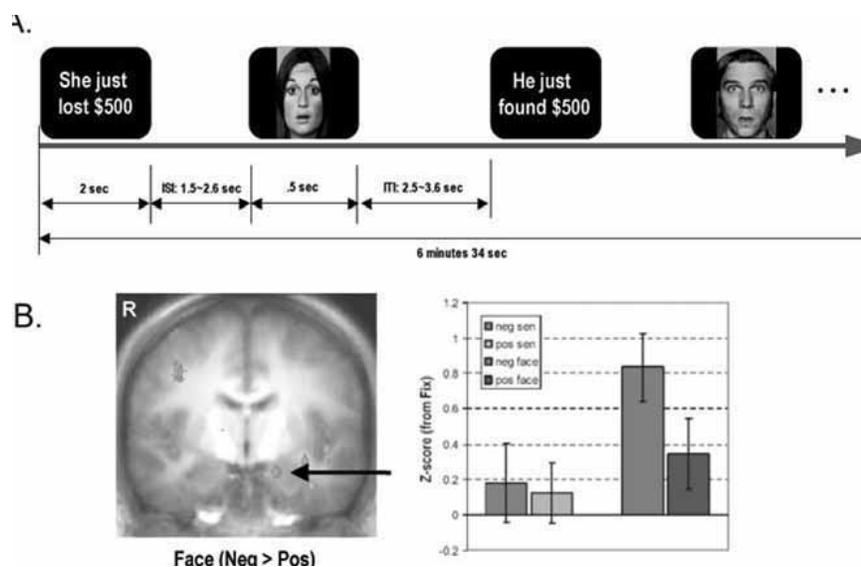

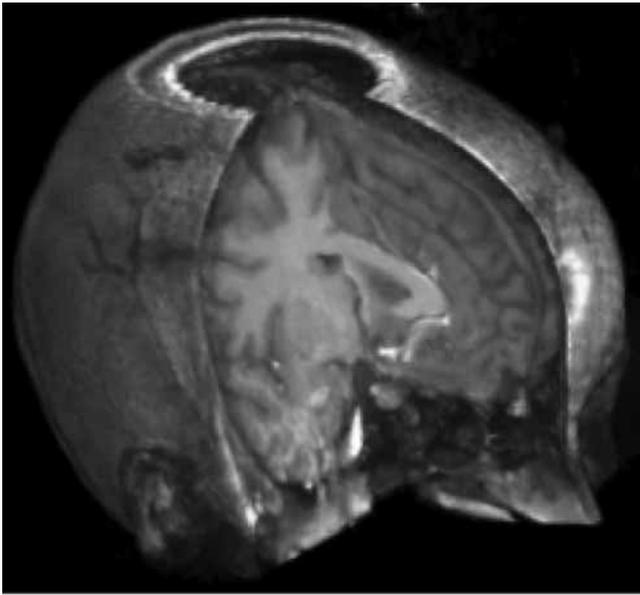

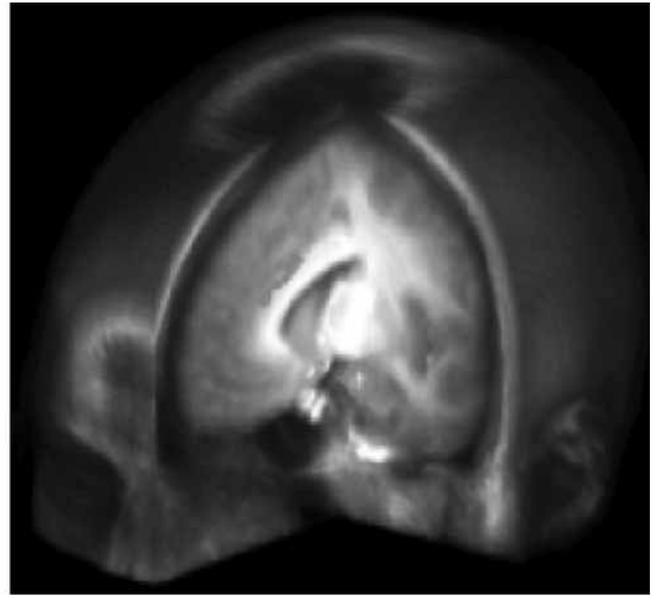

FIGURE 63.3 Paradigm from H. Kim and colleagues (2004).

Undetermined valence

Kim et al. *Neuroreport* 2003

Determined valence

Kim et al. *J Cogn Neurosci* 2004

FIGURE 63.4 Comparison of results of H. Kim and colleagues (2003) with those of H. Kim and colleagues (2004). (See color plate 80.)

the basis of this regulation was derived from the contextual sentences, while in the former study (H. Kim et al., 2003), this information was likely derived from past experience/reinforcement history with these expressions. Note the striking laterality difference observed between these two studies where a right-sided prefrontal-amygdala network processed surprised faces whose valence was left undetermined (H. Kim et al., 2003), while a left-sided network processed surprised faces whose valence was determined (see H. Kim et al., 2004, for discussion). Note also the lack of involvement of the vmPFC when the sentences disambiguated the faces. Perhaps a regulatory input from the vmPFC is only necessary when subjects have to discern the potential valence of the expressions for themselves (see H. Kim et al., 2004, for discussion). Alternatively, numerous studies have implicated the vmPFC in self-relevant processing (e.g., Moran, Macrae, Heatherton, Wyland, & Kelley, 2006). In H. Kim and colleagues' (2004) study, the sentences provided information about the person pictured. One possibility is that when no such contextual information is available, we default to a more self-relevant hypothesis testing mode ("I wonder what that expression means for me"), a mode that involves the vmPFC. Future studies will be necessary to sort out these possibilities. For now, these initial studies have delineated other brain structures with which the amygdala interacts to help disambiguate the valence of ambiguous facial expressions of emotion.

To summarize, facial expressions that are ambiguous are highly susceptible to contextual manipulation. The amygdala in concert with the prefrontal cortex uses contextual information to resolve this ambiguity (H. Kim et al., 2004). These neuroimaging data in humans using facial expressions as the predictive cues of interest are consistent with the conditioning literature largely carried out by using nonhuman animal subjects. These studies in nonhuman animals suggest that the amygdala is involved in processing contextual information through interactions with other brain regions, such as the hippocampus and prefrontal cortex. Below, we describe recent human neuroimaging studies of context conditioning that support a similar role for the amygdala, hippocampus, and prefrontal cortex, while drawing parallels with the facial expression work we have just described.

Context conditioning

Similar to the above discussion of the contextual modulation of facial expressions, the vast Pavlovian conditioning literature demonstrates the critical role that context plays in determining the meaning of conditioned "cues." The amygdala is consistently implicated in "cue conditioning," in which an animal learns that a distinct cue such as a light or tone (conditioned stimulus, CS) predicts a biologically relevant event such as a food reward or painful shock (unconditioned stimulus, US; see, e.g., LeDoux, 1996; Kapp et al., 1992).

However, the animal always learns such associations in a particular context. Though the processing of contextual configurations associated with the presentation of specific conditioned cues is known to be dependent on the dorsal hippocampus (J. J. Kim & Fanselow, 1992), the amygdala has been shown to be a critical facilitator of such learning (R. G. Phillips & LeDoux, 1992). This contextual information is likely conveyed to the amygdala via multiple neural pathways such as through the hippocampus (Maren, 2001), the orbitofrontal cortex (Stefanacci & Amaral, 2002), and the ventral medial prefrontal cortex (Milad & Quirk, 2002).

Grillon and colleagues recently provided evidence in the human that the amygdala, hippocampus, and prefrontal cortex are recruited during a contextual conditioning task (Alvarez, Biggs, Chen, Pine, & Grillon, 2008). In this neuroimaging experiment (see figure 63.5), subjects learned that a certain virtual reality context predicted shock (CX+) while another context predicted safety (CX-). Brain areas showing greater activity during the CX+ compared to the CX- included the amygdala, prefrontal cortex, and hippocampus. Importantly, the authors also employed structural equation modeling to infer directional relationships between activity in these structures and concluded that the prefrontal cortex and hippocampus might be providing contextual information to the amygdala that then initiates conditioned responding appropriate to a particular context.

When a cue has clear predictive value (i.e., a tone *always* predicts a shock), then it is less dependent upon contextual cues to retrieve the appropriate meaning of that cue. However, there are many situations in which the predictive meaning of a cue is more ambiguous, and in these situations, contextual information becomes very important (similar to the arguments presented above in relation to surprised faces; see Oler et al., in press). A classic illustration of this is extinc-

tion. During extinction, an animal learns that a cue that previously had very clear predictive value (a tone always predicts a shock) now has multiple meanings (Bouton, 1994). That is, in some contexts, the tone predicts a shock, whereas in others, it predicts no shock. In this scenario, context plays an important role in influencing the animal's response to a CS, but it is not the direct relationship between the context and the occurrence (or nonoccurrence) of the US that is important. Rather, the context helps to activate the appropriate representation of the CS (Bouton, 1994; Bouton, Westbrook, Corcoran, & Maren, 2006).

In the human, a circuitry involving interactions between the amygdala and the hippocampus, OFC, and vmPFC during contextually dependent extinction learning has been documented. During neuroimaging, Milad and colleagues (2007) trained subjects to expect shocks following the presentation of a light in one context (context A) and extinguished this relationship in the same context. They found increases in activity in both the amygdala and vmPFC during extinction learning. Interestingly, the authors brought subjects back the next day and exposed them to the extinguished CS in either the extinguished context (context A) or a new context (context B). During this session, they observed increases in vmPFC and hippocampal activity to the extinguished context compared to the new context. Critically, functional connectivity analyses suggested that activity in the vmPFC on day 2 was positively correlated with activity in both the hippocampus and the amygdala. Taken together, these studies provide strong support that a neurocircuitry involving the amygdala, hippocampus, and prefrontal cortex supports the ability to learn about the relationship between environmental events that have biologically relevant predictive value and the contexts in which they occur.

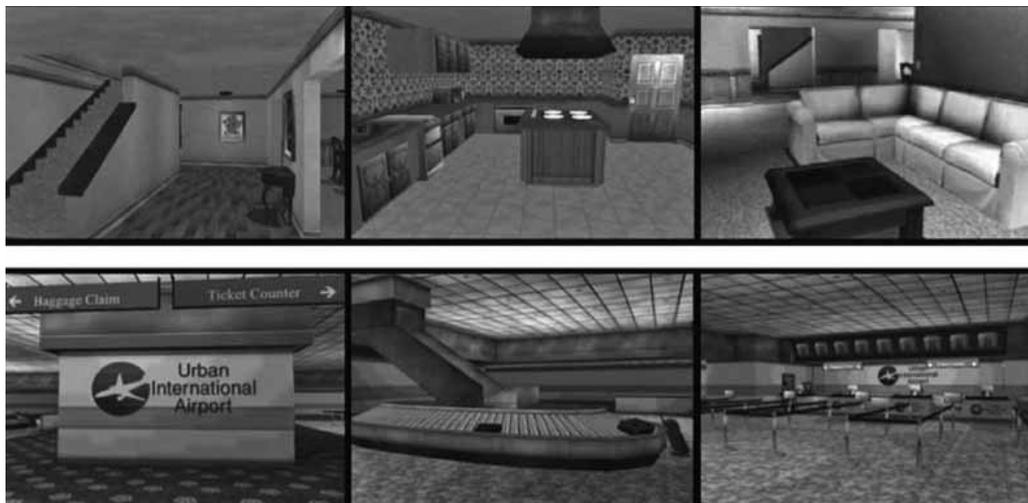

FIGURE 63.5 Examples of the virtual reality environments used by Alvarez and colleagues (2008) that served as conditioned contexts. (Reproduced with permission.)

Experimental context as a determinant of fMRI activations to specific stimuli

Often, we expect that there will be hard rules by which neural systems operate, for example, “The amygdala responds to negative more than positive stimuli” or “The amygdala is influenced by arousal, not valence.” But it would be strange if a neural system that functioned to support biologically relevant learning was so inflexible. It would make more sense if there were some basic operating principles guiding amygdala activity across all species that interact with the more flexible cortical circuitry.

This idea is best kept in mind when one considers that in experimental designs, the stimuli that are included as other conditions of interest, control conditions, or foil conditions effectively comprise the context in which the main stimuli of interest will be considered. These stimuli will not necessarily be independent of the main stimuli but will instead shade the very light in which these stimuli are perceived. Here we offer four examples.

IS NEUTRAL EVER NEUTRAL? Neutral faces often constitute the baseline condition for neuroimaging studies assessing amygdala responses to fearful faces. This is a sound strategy, as any responses observed to fearful faces when directly contrasted with neutral faces are soundly interpreted as in response to the fearful expression itself. But such a design will necessarily ignore any interest the amygdala might have in neutral faces in their own right. An older psychology literature suggests that the interpretation of neutral faces is strongly influenced by the clearer valence of other categorical expressions in the immediate context. That is, neutral expressions are rated as more positive when negative expressions such as fear are in the immediate context, while they are rated as more negative when positive expressions are in the context (Russell & Fehr, 1987). With this in mind, Somerville, Kim, Johnstone, Alexander, and Whalen (2004) presented neutral expressions accompanied only by happy expressions in the experimental context. They observed bilateral amygdala activation in response to the neutral expressions that correlated with individual differences in subjects’ level of anxiety, greater levels of anxiety being associated with greater amygdala responses to neutral faces. The implication of this finding for the present discussion is that it might well have been this particular experimental context that created a situation in which the amygdala tracked neutral faces more than it would have otherwise. Future studies that modify the valence of the expressions that make up the context for neutral faces can directly test this hypothesis.

STATIC VERSUS DYNAMIC Another example of the influence of experimental context is derived by comparing

results from two separate studies. The amygdala has clearly been shown to respond to static photographs of facial expressions across numerous neuroimaging studies. While interesting, it is obvious that these stimuli lack a degree of ecological validity, since the expressions that we encounter on a daily basis are always dynamic. One study using only static images showed that the amygdala responds to both fearful and angry faces (compared to neutral faces) and that a greater spatial proportion of the amygdala responded to fearful faces (Whalen et al., 2001). A subsequent study also included these static image conditions but did not replicate this effect (LaBar, Crupain, Voyvodic, & McCarthy, 2003). Critically, this study also included dynamic displays of these stimuli within the experimental context. It is probable, then, that in such an experimental context, the amygdala tracked the more salient and interesting dynamic displays to the exclusion of the static displays (LaBar et al., 2003). In the experimental context that was devoid of dynamic displays, the amygdala tracked the best available predictive information (i.e., static displays) (Whalen et al., 2001). Thus, a more flexible rule might be that in any given situation, the amygdala will track the best potential source of information from which to learn. This notion is consistent with other data showing that while the amygdala is responsive to facial expressions of emotion, it responds even more to facial expressions embedded within an associative learning context (Hooker, Germine, Knight, & D’Esposito, 2006). A more recent study demonstrated that amygdala activation is observed when subjects are asked to match a given facial expression to an appropriate context (Sommer, Dohnel, Meinhardt, & Hajak, 2008). Taken together, these data are consistent with the idea that the amygdala is particularly interested in facial expressions because of their predictive value, which will ultimately be gleaned from their current environmental context.

INSTRUCTIONS Task instructions are another example of contextual information that can influence neural processing of presented stimuli. That is, the very same stimuli will be processed in very different ways depending on how subjects are instructed to interpret these stimuli. For example, Anderson, Christoff, Panitz, De Rosa, and Gabrieli (2003) compared amygdala responses to fearful and disgusted faces. Earlier studies had suggested that the amygdala is interested in fearful expressions but not disgusted expressions (e.g., M. L. Phillips et al., 1997). Anderson and colleagues (2003) presented these facial expressions on a screen superimposed with pictures of houses. During some time periods, subjects were instructed to pay attention to the faces, while during others they attended to the houses. Replicating the earlier work, Anderson and colleagues (2003) showed that the amygdala responded to fearful faces whether or not subjects were instructed to pay attention to these expressions. But

the amygdala responded to disgusted faces only when they were not attended to. Thus the amygdala tracked the presence of disgusted faces to a greater degree when they were being implicitly processed. The authors interpreted their data to suggest that the amygdala widens its focus from fear-specific to more generalized threat-specific as attention to faces moves from explicit to implicit. For the purposes of this discussion, we see that task instructions constitute a powerful context that will influence patterns of neural responsivity.

FACE AS CONTEXT Since we have focused on facial expressions of emotion as predictive cues, it is interesting to consider the possibility that the face itself actually constitutes a context, and the muscle movements can be considered the predictive cues. We have enough experience with faces to know where to look within this context to discern predictive information. Numerous studies have shown that the eye and mouth regions are the first place we look for such information. What neural systems support this ability? One hint comes from studies showing that subjects with amygdala damage fail to properly monitor the eye region of the face (Adolphs et al., 2005). Similarly, rats with amygdala damage fail to turn their head to the region of the cage where a predictive light is located (see Gallagher & Holland, 1992). These data support the notion that the amygdala is part of an orienting system that initiates behaviors (e.g., eye scanning, head turning) that facilitate the search for predictive information in locations within the context where the organism has last encountered predictive cues (see Whalen et al., 2009, for discussion). Such behaviors could be initiated by recognizing that one has encountered a “face context” or a “cage context,” respectively. These observations may effectively summarize why lesions of the amygdala affect context conditioning. While areas of the brain such as the hippocampus and the prefrontal cortex are assessing the context as a configuration, the amygdala, like a prosopagnosic, might be surveying the individual elements that ultimately constitute that context.

Conclusions

Here, we have presented studies that assess amygdala activation to predictive facial expressions that are particularly context dependent (fear and surprise). We have seen that amygdala responses to fearful and surprised faces can be as much about what these faces clearly tell you (“I predict something negative”) as they are about what they do not yet tell you (“I offer no information about what exactly that might be”). For this information, the amygdala interacts with other brain regions such as the hippocampus and prefrontal cortex to access contextual information that might serve to disambiguate the predictive nature of these expressions. The

fact that surprised faces are ambiguous with respect to valence (i.e., have predicted both positive and negative events in the past) means that contextual information will be even more important in determining their meaning compared to fear. More generally, we have seen that data in human subjects in response to facial expressions of emotion complement data from nonhuman animals showing a clear role for the amygdala in facilitating contextual processing (R. G. Phillips & LeDoux, 1992). Further, recent neuroimaging studies have delineated a similar neurocircuitry supporting context conditioning in the human.

Finally, we reviewed studies demonstrating that the experimental context (e.g., instructions, other stimuli present) of a given study constitute a powerful context that will influence fMRI activations to individual events within that context. Thus the amygdala will track fearful faces one moment and disgusted faces the next (Anderson et al., 2003). It will track static displays of expressions in one study (Whalen et al., 2001) but ignore them in another experimental context that includes dynamic displays (LaBar et al., 2003). And it can track neutral faces depending upon the nature of adjacent expressions (Somerville et al., 2004). Thus the amygdala will be bit of a chameleon, eluding categorization based upon responses that follow a single rule. Instead, in collaboration with other brain regions, it will be an integral part of a circuit that tracks the predictive meaning of stimuli in light of their contextual implications.

64 Neurogenetic Studies of Variability in Human Emotion

AHMAD R. HARIRI

ABSTRACT As research in cognitive neuroscience has progressed in the last decades, there have been many important technological and methodological advances in the increasingly complimentary fields of molecular genetics and neuroimaging. These advances have facilitated fruitful collaboration across once disparate disciplines, with early results shedding new light on the mechanisms that give rise to individual differences in complex behaviors and related psychiatric disorders. At the leading edge of such efforts is imaging genetics, an experimental strategy for the effective integration of molecular genetics and neuroimaging technologies for the study of biological mechanisms that mediate individual differences in behavior and related risk for psychiatric disorders. Imaging genetics studies have provided a more complex and nuanced understanding of the pathways and mechanisms through which the dynamic interplay of genes, brain, and environment shapes variability in behavior. This chapter provides a brief overview of these studies and discusses the broader potential of imaging genetics, through its orchestrated application with studies of environmental effects and its continued integration with basic animal research, to inform risk and resiliency.

Conceptual basis

Individual differences in trait affect, personality, and temperament are important predictors of vulnerability to neuropsychiatric disorders including depression, anxiety, and addiction. Accordingly, identifying the biological mechanisms that give rise to trait individual differences affords unique opportunity to develop both predictive markers of disease liability and identify novel targets for individualized treatment. In the past five years, human neuroimaging studies, especially those employing blood oxygen level dependent functional magnetic resonance imaging (BOLD fMRI), have begun to reveal the neural substrates of interindividual variability in these and related constructs (Bertolino et al., 2005; Brown, Manuck, Flory, & Hariri, 2006; Haas, Omura, Constable, & Canli, 2007; Hariri et al., 2006; Pezawas et al., 2005; Somerville, Kim, Johnstone, Alexander, & Whalen, 2004). Moreover, recent studies have established that BOLD fMRI measures represent temporally

stable and reliable indices of brain function (Johnstone et al., 2005; Manuck, Brown, Forbes, & Hariri, 2007). Thus, much like their behavioral counterparts, patterns of brain activation represent enduring, traitlike phenomena, which in and of themselves may serve as important markers of liability and pathophysiology.

As neuroimaging studies continue to illustrate the predictive relationship between regional brain activation and traitlike behaviors (e.g., increased amygdala reactivity predicts core features of anxious temperament), an important next step is to systematically identify the underlying mechanisms that drive variability in brain circuit function. In this regard, recent neuroimaging studies employing pharmacological challenge paradigms, principally targeting monoamine neurotransmission, have revealed that even subtle alterations in dopaminergic, noradrenergic, and serotonergic signaling can have a profound impact on the functional response of brain circuitries that support affect, personality, and temperament (Bigos et al., 2008; De Martino, Strange, & Dolan, 2008; Hariri, Mattay, Tessitore, Fera, et al., 2002; Harmer, Mackay, Reid, Cowen, & Goodwin, 2006). Similarly, multimodal neuroimaging approaches have provided evidence for directionally specific relationships between key components of monoaminergic signaling cascades, assessed with radiotracer position emission tomography (PET), and brain function, assessed with BOLD fMRI (Fisher, Meltzer, Ziolk, Price, & Hariri, 2006; Rhodes et al., 2007). Collectively, pharmacological challenge neuroimaging and multimodal PET/fMRI are revealing how variability in behaviorally relevant brain activation emerges as a function of underlying variability in key brain neurotransmission systems (e.g., increased serotonin signaling predicting increased amygdala reactivity).

The next logical step is to identify the sources of interindividual variability in these key neurochemical signaling mechanisms. In the modern era of human molecular genetics, this step is firmly planted in the direction of identifying the relationships between common variation in the genes encoding components of these signaling cascades, their protein products, and, subsequently, brain circuit function. As sequence variation across individuals represents the ultimate wellspring of variability in emergent neurobiological

AHMAD R. HARIRI Department of Psychology and Neuroscience, Institute for Genome Sciences and Policy, Duke University, Durham, North Carolina

and related behavioral processes, understanding the relationships between genes, brain, and behavior is critical for establishing the etiology and pathophysiology of psychiatric disease. The emerging field of imaging genetics seeks to establish a principled framework for the integration of modern molecular genetics and neuroimaging technologies toward the ultimate goal of identifying truly predictive makers of disease vulnerability (Hariri & Weinberger, 2003a).

Why study genes?

Genes have an unparalleled potential impact on all levels of biology. In the context of disease states, particularly behavioral disorders, genes are fundamental to our understanding of the mechanisms involved in the development of disease. Whereas most human behaviors cannot be explained by genes alone, and certainly much of the variance in aspects of brain information processing will not be genetically determined directly, variations in a genetic sequence that affect gene function will contribute a substantial amount of variance to these more complex phenomena. This conclusion is implicit in results garnered from twin studies that have demonstrated a strong genetic contribution to variability (~40–70%) in aspects of cognition, temperament, and personality (Plomin, Owen, & McGuffin, 1994). Similarly, many psychiatric illnesses, which often cluster within families, have a significant genetic basis (Kendler, Prescott, Myers, & Neale, 2003). Genes, therefore, have the potential to identify underlying mechanisms of variability in behavior and disease risk. Within this context, imaging genetics represents the specific ability to understand the neurobiological mechanisms through which genes may impact variability in these emergent phenomena.

The classic approach used in genetic association analyses involves the use of candidate genes. A candidate gene is a gene that is implicated in the manifestation of a particular behavioral or clinical (i.e., disease-related) phenotype through its effects on a biological process implicated in the same phenotype. With this approach, a genetic variation (or polymorphism) that potentially affects the function of a behaviorally or clinically relevant biological process is identified, and then deviations in the frequency of one variant (or allele) in populations expressing the phenotype are determined. Ideally, the genetic variation should have an impact on molecular or cellular function of the gene or protein (i.e., be a functional variation), and the target phenotype should be stable, robust, and quantifiable. Within the imaging genetics framework, the target phenotype is usually a physiological response of the brain during specific behavioral processes (e.g., amygdala reactivity when viewing threatening facial expressions).

Why neuroimaging?

Previous investigations of candidate genes have attempted to associate functional polymorphisms directly with a behavior; however, such findings have been weak and inconsistent, as there are considerable interindividual differences in the dimensions of observed behavior as well as subjectivity in behavioral measures, often requiring daunting sample sizes to detect even small gene effects (Burmeister, McInnis, & Zollner, 2008). More important, gene effects are not expressed directly at the level of behavior but rather are mediated by effects on molecular and cellular cascades biasing information processing in brain circuitries that mediate behavioral responses to environmental challenge. Neuroimaging, therefore, provides an efficient and effective tool with which to explore the functional impact of brain-relevant genetic polymorphisms and identify neural pathways through which these variants contribute to the emergence of variability in behavior and disease risk.

Basic principles of imaging genetics

Three basic principles have been articulated for imaging genetics (Hariri & Weinberger, 2003b): (1) selection of candidate genes, (2) control for nongenotype factors, and (3) task selection. Well-defined functional polymorphisms (single nucleotide polymorphisms (SNPs) or other structural variants) in coding or promoter regions previously linked with specific physiological effects at the cellular level whose impact has been described in distinct brain regions are an ideal starting point. Selecting variants that have known neurobiological consequences (e.g., increases in serotonin signaling) is important because of an emphasis in imaging genetics on specifying mechanisms through which genes affect brain and related behavior. Because potential genetic effects are still relatively small in comparison to typically large effects of age, sex, and IQ, as well as environmental influences (e.g., illness, injury, substance abuse), controlling for these potential confounds is necessary. Furthermore, since imaging genetics studies focus on a single or relatively few polymorphisms against a background of millions, these studies must carefully control for occult differences in genetic background (i.e., ancestry or population stratification) of the genotype groups. Because of small genetic effects, the choice of a probe of functional brain circuitry is imperative; therefore, a well-characterized behavioral paradigm should be employed to maximize sensitivity and inferential value. The ideal tasks for these investigations are thus ones that have been established to engage specific brain systems robustly in all individuals as well as displaying variance across individuals.

Imaging genetics studies of amygdala reactivity and human emotion

The following sections provide introductory examples of how imaging genetics can lead to insights about the biological mechanisms that underlie individual differences in complex behavioral traits. In many cases, the genetically driven variability in behavior represents an intermediate phenotype that confers risk for neuropsychiatric disease in the context of specific environmental influences. In each group of studies, neuroimaging was employed as a complementary approach to identify effects of genetic polymorphisms, often resulting in molecular and cellular alterations, as well as being associated with specific behaviors and/or disease states, of discrete neural circuitries that support the associated behavioral or clinical phenomena. In addition, each study incorporated the basic principles of imaging genetics described above, such as the implementation of rigorous controls for nongenetic factors such as age, sex, population stratification, and performance on the experimental task. All of the studies also capitalized on existing functional paradigms designed to explore physiological aspects of distinct neural systems.

SEROTONIN TRANSPORTER (5-HTT) The vast potential of imaging genetics has been most dramatically highlighted in recent studies whose collective results demonstrate that common sequence variation in the human serotonin transporter gene is associated with downstream alterations in serotonin signaling cascades that result in relatively increased serotonin signaling and, eventually, increased amygdala reactivity to environmental threat (Hariri & Holmes, 2006). Abnormal 5-HT neurotransmission has been implicated in the pathophysiology of mood and anxiety disorders and has been a target of pharmacological intervention (e.g., SSRIs). In comparison to the 5-HTTLPR long (L) allele, the short (S) allele has been associated with alterations conferring relatively increased 5-HT signaling (Hariri & Holmes, 2006). At the behavioral level, possession of either one or two copies of the S allele has been associated with increased levels of temperamental anxiety (Munafo, Clark, & Flint, 2005; Schinka, Busch, & Robichaux-Keene, 2004; Sen, Burmeister, & Ghosh, 2004), conditioned fear responses (Garpenstrand, Annas, Ekblom, Orelund, & Fredrikson, 2001), and development of depression, particularly in the context of environmental stress (Caspi et al., 2003; Kendler, Kuhn, Vittum, Prescott, & Riley, 2005).

Against this background, imaging genetics has revealed that threat-related reactivity of the amygdala, a brain region that is critical in mediating behavioral and physiological arousal, is significantly increased in S allele carriers in com-

parison to L allele homozygotes (Hariri, Mattay, Tessitore, Kolachana, et al., 2002). This pattern already represents one of the most positively replicated findings not only in the nascent field of imaging genetics but also in behavioral and psychiatric genetics (Munafo, Brown, & Hariri, 2008). In addition, the 5-HTTLPR S allele has been further linked with reduced gray matter volume in and functional coupling between the amygdala and medial prefrontal cortex (Pezawas et al., 2005). As the magnitude of threat-related amygdala reactivity (as well as its functional coupling with medial prefrontal cortex) is associated with temperamental anxiety, these imaging genetics findings suggest that the 5-HTTLPR S allele may be associated with increased risk for depression upon exposure to environmental stressors because of the polymorphisms influence on the reactivity of this corticolimbic circuitry. The imaging genetics research with the 5-HTTLPR highlights the effectiveness of this strategy in illuminating specific mechanisms that mediate individual variability in behavior and risk for disease.

MONOAMINE OXIDASE-A To the extent to which the effects of the 5-HTTLPR variant on corticolimbic development and function related to emotion processing are serotonin mediated, it would be expected that other genes related to serotonin function would show similar effects on the function of this circuitry. 5-HT neurotransmission is also regulated through intracellular degradation via the metabolic enzyme monoamine oxidase-A (MAO-A). A common polymorphism in the MAO-A gene, resulting in a relatively low-activity enzyme, has been associated with increased risk for violent or antisocial behavior as well as for depression and anxiety (Caspi et al., 2002; Kim-Cohen et al., 2006).

A recent fMRI study reported that the low-activity MAO-A allele is associated with relatively exaggerated amygdala reactivity and diminished prefrontal regulation of the amygdala (Meyer-Lindenberg et al., 2006). The magnitude of functional coupling between these regions predicted levels of temperamental anxiety, suggesting that the genetic association between the MAO-A low-activity variant and abnormal behavior might be mediated through this circuit. Interestingly, both the 5-HTTLPR S and MAO-A low-activity alleles presumably result in relatively increased 5-HT signaling and exaggerated amygdala reactivity. As the directionality of these effects are consistent with animal studies documenting anxiogenic effects of 5-HT (Burghardt, Bush, McEwen, & LeDoux, 2007; Burghardt, Sullivan, McEwen, Gorman, & LeDoux, 2004; Forster et al., 2006), as well as pharmacological neuroimaging studies demonstrating a potentiation of amygdala reactivity subsequent to acute 5-HT reuptake blockade (Bigos et al., 2008), the imaging genetics data provide important insight regarding the neurobiological and behavioral effects of 5-HT.

TRYPTOPHAN HYDROXYLASE-2 Recent imaging genetics studies that have examined the impact of variation in 5-HT subsystems highlight the potential reciprocal nature by which functional imaging and molecular genetics approaches can be mutually informative in advancing our understanding of the biological mechanism of behavior. Tryptophan hydroxylase-2 (TPH2) is the rate-limiting enzyme in the synthesis of neuronal 5-HT and thus plays a key role in regulating 5-HT neurotransmission (Walther & Bader, 2003; Zhang, Beaulieu, Sotnikova, Gainetdinov, & Caron, 2004). A recent study found that a SNP in the regulatory region of the human TPH2 gene affects amygdala function. Specifically, in comparison with the G allele of this polymorphism, the T allele was associated with relatively exaggerated amygdala reactivity (Brown et al., 2005). This report provides further insight into the biological significance of TPH2 in the human central nervous system and provides a critical next step in our understanding of the importance of this newly identified second tryptophan hydroxylase isoform for human brain function. Moreover, it marks an important advance in the application of functional neuroimaging to the study of genes, brain, and behavior. In contrast to previous studies of genetic effects on brain function, in which the molecular and cellular effects of the candidate variants had been previously demonstrated (e.g., 5-HTTLPR, MAO-A, COMT, and BDNF), these fMRI data provide the first evidence for potential functionality of a novel candidate polymorphism. In this way, the initial identification of a systems-level effect of a specific polymorphism provides impetus for the subsequent characterization of its functional effects at the molecular and cellular level. Converging with this initial imaging genetics finding (and a subsequent replication (Canli, Congdon, Gutknecht, Constable, & Lesch, 2005)), a recent molecular study has demonstrated that this SNP and another promoter SNP impact transcriptional regulation of TPH2 that may affect enzyme availability and 5-HT biosynthesis (Chen, Vallender, & Miller, 2008). Such scientific reciprocity between imaging and molecular genetics illustrates how the contributions of abnormalities in candidate neural systems to complex behaviors and emergent phenomena, possibly including psychiatric illnesses, can be understood from the perspective of their neurobiological origins.

NEUROPEPTIDE Y In addition to the above candidate genes, imaging genetics studies have recently explored the impact of genetic variation beyond 5-HT. For example, neuropeptide Y (NPY), a 36-amino-acid peptide neurotransmitter, is an evolutionarily highly conserved molecular component involved in the regulation of brain systems processing stress and emotion (Heilig et al., 1993; Holmes, Heilig, Rupniak, Steckler, & Griebel, 2003). Anxiolytic-like effects of NPY have been reported in a wide range of pharmacologically validated animal models (Broqua, Wettstein, Rocher,

Gauthier-Martin, & Junien, 1995; Heilig, Soderpalm, Engel, & Widerlov, 1989; Heilig & Widerlov, 1990; Sajdyk, Vandergriff, & Gehlert, 1999), and NPY release is profoundly induced by stress (Thorsell, Carlsson, Ekman, & Heilig, 1999). In humans, both cerebrospinal fluid and plasma NPY levels correlate with anxiety and stress levels (Boulenger et al., 1996; Irwin et al., 1991; Widerlov, Lindstrom, Wahlestedt, & Ekman, 1988).

A relatively common NPY diplotype consistently predicts NPY mRNA in postmortem brain and lymphoblasts as well as plasma concentrations of NPY (Zhou et al., 2008). Diplotype expression is also inversely proportional to temperamental anxiety (Zhou et al., 2008). Similar to the effect on trait anxiety, NPY haplotype predicts amygdala reactivity in gene-dosage (stepwise) fashion, with heterozygous individuals intermediate in activation (Zhou et al., 2008). Importantly, the magnitude of amygdala activation predicts measures of temperamental anxiety in this sample. Together, the results suggest that NPY effects on temperamental anxiety are mediated in part through biased amygdala reactivity. In addition to these effects, task-related hippocampal activation was predicted by NPY haplotype. This finding is of interest because the functional interactions of the amygdala and hippocampus are critical for emotional memories, and long-lasting changes in hippocampal architecture are induced by stress.

Summary and future directions

Imaging genetics is in its infancy, as the number of genes that have been explored is very few and the strategies for looking at genetically driven variability in brain function are relatively simplistic. Nevertheless, the results above underscore the power and utility of this integrated approach for the identification of biological mechanisms and pathways that mediate individual differences in complex behaviors and related vulnerability to disease. While current imaging genetics studies highlight a powerful new approach to the study of genes, brain, and behavior, the true potential of this approach will be realized only by aggressively expanding the scope and scale of the experimental protocols.

Although single-gene effects on brain function can be readily documented in small samples ($N < 20$), the contributions of multiple genes acting in response to variable environmental pressures is ultimately necessary for the development of truly predictive markers that account for the majority of variance in any given phenotype, such as stress resiliency. For example, the interactive effect of the BDNF Val66Met and 5-HTTLPR on corticolimbic circuitry has been examined recently in an imaging genetics sample of over 100 subjects (Pezawas et al., 2008). An epistatic mechanism between these molecules is suggested by pharmacological and animal models linking 5-HTT and BDNF in cell

signaling related to stress-mediated neuroplasticity (Luellen, Bianco, Schneider, & Andrews, 2006; Ren-Patterson et al., 2006). Surprisingly, the BDNF Met66 allele, which is associated with abnormal regulated BDNF release and reduced hippocampal activity, appears to block the effects of the 5-HTTLPR S allele on reduced amygdala volume. Presumably, the reduced responsivity of the Met66 allele protects against the exaggerated 5-HT signaling associated with the 5-HTTLPR S allele. Such studies provide an example of the biologic epistasis that likely underlies the pathogenesis of a complex disease in the human brain.

Combining existing neuroimaging modalities is another important future direction for imaging genetics. Implementation of multimodal strategies is critical for identifying intermediate mechanisms that mediate the effects of genetic polymorphisms on neural circuit function and related behaviors. The potential of multimodal neuroimaging was recently demonstrated in a study that employed both PET and fMRI to identify the impact of 5-HT_{1A} autoreceptor regulation of 5-HT release on amygdala reactivity (Fisher et al., 2006). In the study, adult volunteers underwent [¹¹C] WAY100635 PET to determine 5-HT_{1A} autoreceptor binding potential, an in vivo index of receptor density. During the same day, all subjects also underwent fMRI to determine the functional reactivity of the amygdala. Remarkably, the density of 5-HT_{1A} autoreceptors accounted for 30–44% of the variability in amygdala reactivity. Downstream effects on 5-HT_{1A} autoreceptors—notably, reduced receptor density—have been hypothesized to mediate neural and behavioral changes associated with the 5-HTTLPR S allele (David et al., 2005). Thus these findings suggest that 5-HT_{1A} autoreceptor regulation of corticolimbic circuitry represents a key molecular mechanism mediating the effects of the 5-HTTLPR.

Ultimately, we anticipate that such mechanistic understanding will allow for the early identification of individuals who are at greater risk for behavioral problems that can have long-term health-related implications. Continued imaging genetics research at the interface of genes, brain, and behavior holds great promise in further explicating the neurobiological mechanisms through which risk for psychiatric disease emerges in the context of environmental adversity (Caspi & Moffitt, 2006; Hariri & Holmes, 2006). Such knowledge will, in turn, facilitate the development of therapeutic interventions, tailored to individual neurobiologies, which will be more effective in combating the enormous personal and public health burden associated with common psychiatric disorders.

65 Components of a Social Brain

JASON P. MITCHELL AND TODD F. HEATHERTON

ABSTRACT Human ecology is radically different from that of other animals, despite the relatively short period of time that separates us phylogenetically from other primates. Recent commentators have suggested that the unique cognitive skills possessed by humans may, in fact, reduce to a small number of primary adaptations for one specialized ability: social cognition, the ability to interact effectively and safely with conspecifics. Emerging research from the neurosciences has begun to elucidate the component parts of these broad social skills. Here, we review evidence that suggests that human social cognition comprises four specialized abilities: a coherent sense of self, the ability to keep track of the mental states of others, control over socially inappropriate emotions and impulses, and sensitivity to threats of exclusion or aggression from other people. We conclude with a review of recent neuroimaging findings that support the view that social cognition has a privileged status in the human cognitive repertoire.

Compared with the ecology of other animals, the lifestyle of *Homo sapiens* is certainly a strange and glamorous affair. Among the world's fauna, humans are the only species that routinely communicates through language, develops reusable tools, designs and constructs architectural structures, tailors its own clothing, engages in economic exchange, composes music, organizes governments, or worships the divine. The sheer range of differences between the species-typical behavior of humans and that of other animals has prompted some theorists to wonder whether sufficient time separates us from our primate cousins for the evolution of distinct cognitive mechanisms to subserve each of these uniquely human pursuits (Tomasello, 1999; Tomasello, Carpenter, Call, Behne, & Moll, 2005). That is, given the relatively small amount of time since the divergence of the human and chimpanzee lineages (between four million and six million years), could separate cognitive adaptations have evolved to support human language and tool use, our insistence on building domestic structures and wearing clothes, and our strange penchant for music, politics, and religion? Or is the divergence between humans and other animals the result of a small number of more primary adaptations, which in turn allowed the development of secondary traits that piggyback on these more fundamental species-unique skills?

JASON P. MITCHELL Department of Psychology, Harvard University, Cambridge, Massachusetts

TODD F. HEATHERTON Department of Psychological and Brain Sciences, Center for Cognitive Neuroscience, Dartmouth College, Hanover, New Hampshire

Surveying the problem posed by the enormous ecological gap between humans and chimpanzees, Tomasello (1999; Tomasello et al., 2005) has argued that many of the unique cognitive skills possessed by humans may, in fact, reduce to a small number of primary adaptations centered on one particularly specialized feature of the mind: the processes that give rise to social cognition. Critical for the development of many of our species-unique behavior—such as language, the use of handheld tools, the assembling of complex social systems—are the ability to learn from and the motivation to teach others. Unlike other primate species, which do not regularly engage in direct instruction, humans actively seek to impart their own knowledge to other humans, especially to young members of the species. Conversely, humans also seem to have a particular motivation to unlock the thoughts and knowledge of others around them, as evidenced by the never-ending “why?” questions asked by two-year-olds. In contrast, whereas apes may acquire new skills from others through imitation, they neither seek out pedagogic contexts nor appear inspired to aid the acquisition of knowledge by others, for example, by explicitly demonstrating a behavior, by repeating it for others to see more clearly, or by taking active steps to shape another's attempts at acquiring a new motor skill.

This species-unique proclivity for learning and teaching imbues humans with enormous behavioral advantages over other animals. Rather than each of us being required to discover facts about the world for ourselves, humans routinely capitalize on the accumulated knowledge of all the other people to whom they have some access. That is, whereas other apes can learn about only those objects and events with which they come into immediate contact, humans can avail themselves of what others, both past and present, have uncovered about the world. As such, we tend to add complexity to already existing knowledge rather than generating it from scratch—such as improving on the workings of already-existing tools and behaviors instead of creating them *de novo*. Unlike the knowledge of apes, which effectively remains trapped inside the mind of its possessor, human know-how spreads quickly through any population of humans who are in contact with each other, so if one person acquires a new bit of knowledge, all other humans in her group can generally make use of it as well.

What grants humans the ability to traffic so readily in the knowledge and beliefs of others? That is, starting with

the basic primate mental algorithm, what additional cognitive software is needed to create a social animal of the human variety? Here, we expand on a model that attempts to identify the necessary basic components of the social brain (Heatherton, in press; Krendl & Heatherton, in press). From this perspective, building a social brain requires at least four distinct cognitive abilities. The first of these is a stable and coherent sense of self, the knowledge that one has mental states that are both idiosyncratic and private but that are in principle capable of being shared with others. The motivation to engage in teaching behavior is predicated on the assumption that one's knowledge is idiosyncratic and not immediately apparent to others, that is, that one has knowledge that is unique to a self. In addition, teachers must assume that their learners are sufficiently similar to them that the teachers can impart their knowledge, that is, that learners are capable of thinking the same thoughts as oneself; the reason we do not routinely teach calculus to first-graders or lecture our pets about quantum physics is that we do not assume that their minds are sufficiently similar to our own to allow them to think the thoughts that we do.

Second, if one adaptive goal of the social brain is to foster the spread of knowledge from one mind to the next, humans require a mechanism for keeping track of the mental states of others. This skill, variously known as *mentalizing* or *theory of mind*, allows one person to intuit the beliefs, thoughts, feelings, goals, and desires of other people for the purposes of both predicting and influencing their behavior.

Third, human knowledge spreads only among individuals who are in contact with one another. As such, one requirement for human social life is the ability to live in close proximity with large numbers of other people. Although other primates may form groups as large as a few hundred individuals (Marc Hauser, personal communication, May 21, 2008), humans have developed the ability to live in close contact with a number of conspecifics that exceeds this by several orders of magnitude (witness New York City and Tokyo as examples). Living in large social groups, even relatively small human groups on the order of a rural village, poses cognitive challenges of considerable difficulty. Among the most substantial of these is the need to regulate one's own desires and emotions to maintain social harmony. That is, maintaining cooperative relationships among large numbers of unrelated individuals requires a cognitive system with special abilities to inhibit potentially destructive emotional expression, a skill with which other primates (with the possible exception of bonobos) struggle.

Finally, the centrality of group living to human ecology generates two sources of special dangers that the social brain must have evolved to handle: threats from one's own group and threats from other groups. Threats from one's own group generally take the form of the potential for social

exclusion, a fate that at many times in human history was equivalent to a death sentence. Conversely, because humans naturally form groups, one always faces the possibility of intergroup competition for resources or explicit conflict (group raids, war, etc.). Accordingly, the social brain should be expected to have developed mechanisms for anticipating and dealing with both sources of intraspecies threat.

In this chapter, we explore the functional neuroanatomy associated with these four components of social cognition brain: self-awareness, theory of mind, self-regulation, and threat detection. Unlike many other aspects of cognition, almost everything we know about the social brain has been uncovered in the last decade and a half. Fortunately, the emergence of social neuroscience has been both rapid and far-reaching; therefore, despite its infancy, this approach has netted a substantial number of reliable and surprising empirical findings about how the brain gives rise to human sociality. To this end, we conclude the chapter with a brief speculative review of some unexpected observations of the peculiar "specialness" of social thought within the human cognitive repertoire.

Components of the social brain

SELF-AWARENESS Survival in human social groups requires that people monitor their behavior and thoughts and evaluate them against prevailing group (social) norms. Discussions of the importance of such introspective awareness have a long history in psychology. For example, William James (1890) devoted a chapter of his *Principles of Psychology* to issues of one's own knowledge of self. More recently, Neisser (1988) has described a number of distinct ways in which one can think of selfhood, such as a "conceptual self" that represents our understanding of our own personality traits and dispositions, an "ecological self" that represents our sense of authoring our own actions in the environment, and a "narrative self" that maintains our sense of personal history and autobiographical memory (also see Boyer, Robbins, & Jack, 2005; S. Gallagher, 2000). Sedikides and Skowronski (1997) argue that this last sense of self is a widely shared human trait that leads to more efficient mental processing of personal and contextual information, thereby increasing the likelihood of survival and reproduction.

Cognitive neuroscience has made considerable progress in identifying the functional neuroanatomy underlying several of these different aspects of self-awareness. Of these, most is known about the brain regions subserving introspective knowledge of one's own stable personality traits and dispositions. Specifically, both neuroimaging research and studies with neuropsychological patients have implicated ventral aspects of the medial prefrontal cortex (vmPFC) as contributing importantly to conceptual aspects of selfhood. For example, a considerable number of neuroimaging studies

have implicated this region in tasks that require participants to judge their own personality traits (Craik et al., 1999; Heatherton et al., 2006; Johnson et al., 2002; Kelley et al., 2002; Macrae, Moran, Heatherton, Banfield, & Kelley, 2004; Moran, Macrae, Heatherton, Wyland, & Kelley, 2006; Ochsner et al., 2004; Schmitz, Kawahara-Baccus, & Johnson, 2004; Zysset, Huber, Ferstl, & von Cramon, 2002) or report on their preferences and opinions (Ames, Jenkins, Banaji, & Mitchell, 2008; Jenkins, Macrae, & Mitchell, 2008; Mitchell, Macrae, & Banaji, 2006), compared to judging these characteristics in others.

The more an item is believed to be reflective of the self, the greater the activity in this area (Moran et al., 2006), and items that are inherently self-relevant (such as personal information) lead to vMPFC activity even during passive viewing when people are not asked to engage in self-referential processing (Moran, Heatherton, & Kelley, in press). Interestingly, damage to this region can lead to deficits in the organization of knowledge about one's preferences. Fellows and Farah (2007) have reported that, when asked to indicate how much they like/dislike various stimuli, patients with vMPFC lesions show unusually large discrepancies between testing sessions, suggesting that damage to this region leads either to failure to retrieve knowledge of one's preferences or to instability in otherwise stable aspects of selfhood.

In addition to knowledge about one's own personality and preferences, humans require a system for keeping track of the actions they perform (what Neisser referred to as an "ecological self"). In recent behavioral work, researchers have demonstrated enhanced memory performance for stimuli that a participant freely selects, compared to those that are selected by someone else (Cloutier & Macrae, 2007). Extending these results, Powell, Macrae, Cloutier, Metcalfe, and Mitchell (submitted) demonstrated that the sense of agentic free selection was associated with greater activity in the intraparietal sulcus (IPS), a region that was previously implicated in maintaining representations of one's goals and computing the motor commands needed to bring them about (Grafton & Hamilton, 2007; Hamilton & Grafton, 2006; Tunik, Rice, Hamilton, & Grafton, 2007). Moreover, activity in IPS correlated with the mnemonic fate of items—showing greater activity for items that were later remembered than for those that were later forgotten—but only for items that were freely chosen by the participant. In other words, much as the conceptual sense of who one is relative to others—that is, one's stable traits and preferences—relies on vMPFC, the agentic sense of what one has done relative to others draws on the activity of IPS.

Theorists have also pointed out the importance to the self of feeling continuity between one's present and past experiences, that is, of possessing a consistent autobiography. Studies of autobiographical memory have implicated a wide range of brain areas, including retrosplenial cortex,

parahippocampal gyrus, temporoparietal junction (TPJ), medial frontal cortex, temporal pole, cerebellum, and the hippocampus (for review, see Maguire, 2001). Of these, perhaps the most consistent finding is that of the MPFC, which has regularly been observed during tasks in which participants are asked to remember events from their own personal past.

Although there exists no specific "self" spot in the brain, this brief review of the cognitive neuroscience of self-awareness suggests that specific regions, such as MPFC and IPS, play an important role in distinguishing between self and other, a critical feature of the adaptive social brain. An important current goal in social neuroscience is further description of the precise cognitive processes that are subserved by these regions. For example, how exactly does the MPFC compute one's preferences or retrieve knowledge about one's stable personality traits? How does the IPS "tag" actions as having been performed by self rather than by another person? Elucidating the computations carried out by these regions and how they combine to give rise to our sense of self promises significant advances to our understanding of how the self contributes to social cognition.

MENTALIZING One of the most critical components of social cognition is the ability to infer the mental states of other people, a skill that is alternately referred to as *mentalizing*, *having a theory of mind*, or *adopting the intentional stance* (Dennett, 1987). Mentalizing enables the ability to empathize and cooperate with others, accurately interpret other people's behavior, and even deceive others when necessary. A rapidly emerging neuroimaging literature on mentalizing has consistently implicated a small number of regions in making inferences about the mental characteristics of other people: MPFC, (TPJ), and medial parietal cortex (Amodio & Frith, 2006; Frith & Frith, 1999, 2001; H. L. Gallagher & Frith, 2003; Mitchell, 2006).

But how exactly does one make sense of the thoughts and feelings of other people, given that perceivers never have direct access to the inner workings of another person? Some cognitive scientists and philosophers have argued that one solution to this problem of mentalizing is suggested by the fact that, although one cannot directly perceive the mental states of another person, one does typically have immediate access to a decent proxy system: oneself. Simulationist (or projectionist) accounts of mentalizing posit that one way in which perceivers may infer others' goals, feelings, or preferences is to put themselves in the same situation as the target person, read off the feelings and thoughts that accompany that simulation, and then attribute (roughly) the same mental states to the target individual. However, this strategy for using oneself as a proxy for others works only when one can reasonably assume that another person will have similar responses to a situation; if a perceiver believes himself or

herself to be highly dissimilar from a target individual, the use of self-referential mentalizing can be inappropriate.

Interestingly, a series of neuroimaging studies has provided evidence in favor of this view by capitalizing on the well-characterized role of vMPFC in self-referential thought, as reviewed above (Jenkins et al., 2008; Mitchell, Banaji, & Macrae, 2005; Mitchell et al., 2006). Specifically, when perceivers mentalized about the preferences and opinions of a similar other (e.g., someone who shared the same social and political attitudes), a region of vMPFC was engaged; the same region was highly engaged when perceivers considered their own preferences. In contrast, a more dorsal region of MPFC was preferentially engaged when perceivers mentalized about dissimilar others. These results suggest that perceivers might indeed draw on their own knowledge about self in understanding the mental states of others, at least those others who are believed to be relevantly similar.

How does one go about inferring the mental states of those perceived to be dissimilar from self, that is, when simulation may be inappropriate? Although the exact mechanisms that support nonsimulationist mentalizing have yet to be detailed, the TPJ appears to augment the role of the MPFC in social cognition and may play an important role in non-self-referential theory of mind. Specifically, the TPJ is preferentially engaged during inferences about particular kinds of mental states, namely, others' beliefs or knowledge about the world (Saxe, Carey, & Kanwisher, 2003; Saxe & Kanwisher, 2003; Saxe & Wexler, 2005), which may be inferred without reference to one's own beliefs or knowledge. For example, many studies of inferences about others' knowledge have used the classic false belief task, in which a character in a story believes that X is true, although the perceiver knows that X is false (e.g., the location of a hidden object). Here, perceivers cannot use their own self-referential knowledge (X is false) to make inferences about the target's beliefs, and the TPJ may subserve some of the ancillary social-cognitive processes that allow this decoupling of one's own knowledge of self from knowledge of others, perhaps by using a more rule-based approach to mentalizing.

SELF-REGULATION People who defy group norms—such as by cheating, lying, or being incompetent—often experience social emotions that indicate that something is wrong. We feel embarrassed when we goof, guilty when we harm, and ashamed when we get caught. Such social emotions serve as important guides for subsequent behavior (Baumeister, Stillwell, & Heatherton, 1994); for example, feeling embarrassed or ashamed motivates behavior to repair social relationships, and feeling guilty about considering cheating on one's partner helps to rein in one's response to temptation. In other words, social emotions promote self-regulation, which allows us to alter our behavior, make plans, choose from alternatives, focus attention on pursuit of goals, inhibit

competing thoughts, and regulate social behavior (Baumeister, Heatherton, & Tice, 1994). Self-regulation refers not only to executive processes such as working memory, attention, memory, choice, and decision making, but also to the control of emotion (covering issues of affect, drive, and motivation). Although humans have the capacity to delay gratification, control appetites and impulses, and persevere to attain goals, failures of self-regulation are among the most important and perplexing problems facing society (e.g., drug abuse, domestic violence, binge eating).

The importance of self-regulation is that it helps people to control their behaviors and actions so that they remain in good standing within their groups. Throughout evolutionary history, people have faced the continuing struggle between satisfying personal desires and being a good member of the group. From a selfish hedonistic perspective, people should eat as much as they want, freeload on group resources, ignore restrictions on sexual conduct, use substances that induce euphoria, and so on. Essentially, strictly on the grounds of individual enjoyment, people should engage in activities that engage the mesolimbic dopamine system and produce rich feelings of reward. If it feels good, do it. But those who eat all the food, fail to be productive because they are incapacitated, or poach mates are bad group members; therefore most groups have shared norms and standards of conduct that discourage or place constraints on selfish, hedonistic activities. Religious doctrine, common to most cultural groups, places explicit rules on such behavior. Subcortical reward motives, then, are in constant battle with higher-level cognitive beliefs and values.

Neuroscience research indicates that various regions of PFC are responsible for the human capacity for self-regulation (see the review by Banfield, Wyland, Macrae, Munte, & Heatherton, 2004). For instance, functional neuroimaging studies have implicated the ACC in decision monitoring, initiating the selection of an appropriate novel response from several alternatives, performance monitoring, action monitoring, detection or processing of response conflict, and internal cognitive control (Wyland, Kelley, Macrae, Gordon, & Heatherton, 2003). More recently, we found an important role for the ACC in efforts to suppress unwanted thoughts (Mitchell et al., 2007), such that ACC was transiently engaged following the occurrence of unwanted thoughts, whereas dorsolateral PFC was most active during tonic efforts to suppress those thoughts. This finding is in keeping with the important role of prefrontal regions in executive functions more generally, all of which are necessary for successful self-regulation (Miller & Cohen, 2001). Since the case of Phineas Gage (Damasio, Grabowski, Frank, Galaburda, & Damasio, 1994; Macmillan, 2002), we have known that damage to certain prefrontal regions is associated with a lack of impulse control and self-regulatory difficulties more generally. The role of lateral PFC regions in

regulating social emotions appears to be among the most robust findings in social neuroscience.

How is brain activity related to self-regulatory behavior? Failures of self-regulation are commonplace, as can be confirmed by asking chronic dieters who are usually on a diet but seem to sabotage their diets with occasional, or not so occasional, bouts of overeating. In a series of classic studies, Herman and Polivy (1975) demonstrated that chronic dieters are prone to excessive eating in certain situations. In one of their first studies, chronic dieters (called *restrained eaters*) and nondieters were invited to the laboratory to engage in a supposed taste test, which was described as a test of perception (because the researchers did not want the subjects to know that eating was being monitored). Prior to the taste test, some of the participants were asked to drink one or two flavorful but obviously fattening milkshakes. The participants then were asked to taste and rate flavors of ice cream and were invited to help themselves to as much of the ice cream as they wanted. Nondieters ate sensibly; those who did not receive a preload ate a lot of the good-tasting (and free) ice cream, whereas those who had drunk one or two milkshakes ate much less of the ice cream. Restrained eaters, however, did just the opposite, eating much more if they had received a preload. This has been called the “what the hell effect,” the mindset of the dieter being “I’ve blown my diet, so I might as well just keep eating.” This finding of disinhibited eating has since been confirmed repeatedly (Heatherton & Baumeister, 1991) and serves as an excellent example of self-regulatory collapse.

In a recent imaging study, Demos, Kelley, and Heatherton (submitted) told dieters ($N = 50$) and nondieters ($N = 50$) that they were investigating the effect of nasal cavity temperature on BOLD signal artifact in orbitofrontal cortex. This cover story provided a rationale for requiring participants to drink either a large glass of cold water or a large glass of a high-calorie chocolate milkshake that would be forbidden in most diets and that had been associated with disinhibited eating by dieters. During scanning, subjects viewed images of animals, environmental scenes, people, and attractive food and made simple person perception judgments (i.e., “Is there a person present in the image?”). The person perception judgment was included to ensure that subjects attended to all images and to further disguise the primary goal of the study in examining cue reactivity to food images. A voxel-wise whole-brain ANOVA revealed that bilateral regions of the nucleus accumbens (NAcc) demonstrated a dietary status \times preload interaction that mimicked the well-established behavioral pattern of disinhibited eating. Specifically, when participants received water prior to scanning, nondieters showed greater NAcc activity to food images than did dieters. This pattern was reversed in individuals who received the milkshake preload, such that dieters produced much greater NAcc activity than nondieters did.

Activity in the left amygdala revealed the reverse interaction: activity in the left amygdala was greater for dieters than for nondieters following the water and was greater for nondieters than for dieters following the milkshake preload. Importantly, the interactions in NAcc and amygdala were unique to food images; these patterns were not present when subjects viewed any of the nonfood images. This study demonstrates two important points. First, somehow dieters are able to view attractive food cues without activating reward circuitry while their diets are intact (although how they do this is currently unknown). In sharp contrast, following a large milkshake that should have induced satiety (and that eliminated a reward response among nondieters), dieters showed much greater reward-related food cue reactivity.

Studies such as these described begin to provide information relevant to people’s efforts to regulate their thoughts and actions. Coupled with research identifying brain regions involved in emotional regulation (Ochsner et al., 2004), social neuroscientists are tackling longstanding questions regarding the human capacity to control itself in order to obtain long term goals and be effective group members.

DETECTION OF THREAT Over the course of human evolution, a major adaptive challenge to survival was other people, both ingroup members and members of other groups. However, the nature of these threats is distinctly different. As was discussed above, the fundamental human need to belong makes social exclusion a potentially fatal sentence. In contrast, members of other groups pose a threat because they represent physical danger or competition for limited resources. As such, the social brain requires mechanisms not only to detect threats posed by both ingroup and outgroup members, but also to differentiate between the specific nature of each kind of social threat. A variety of brain regions have been identified as relevant to the detection of threat, including the amygdala and the anterior cingulate cortex (ACC), both of which have also been implicated in specifically social aspects of threat detection.

If humans have a fundamental need to belong, our system for social cognition must necessarily include mechanisms for detecting inclusionary status (Leary, Tambor, Terdal, & Downs, 1995; Macdonald & Leary, 2005). That is, given the dangers posed by exclusion from one’s group, humans must be capable of benchmarking their interpersonal relationships with others. A recent set of neuroimaging studies has examined the concomitants of a particular form of ingroup threat detection: social rejection. In the first of these studies, Eisenberger, Lieberman, and Williams (2003) engineered an experimental situation in which participants were unexpectedly excluded from a computer game by a virtual interaction partner, who simply started ignoring the participant. Participants reported experiencing social rejection under these circumstances, and the authors found that the depth of such

rejection feelings was positively correlated with activity in the dorsal ACC. Since this initial study, other studies have also implicated the ACC, although some of them find a more ventral rather than dorsal region (Somerville, Heatherton, & Kelley, 2006). Another recent study (Burklund, Eisenberger, & Lieberman, 2007) found a relationship between rejection sensitivity and activity in both dorsal ACC and the ventral ACC during emotional processing. The somewhat disparate findings of these studies indicate the need for further research to more clearly identify the neural correlates of states of social distress, especially in terms of the functional roles of ACC in processing and responding to threat cues.

Of course, social threats also come from outside one's own group. The cognitive neuroscience of such external threats has burgeoned in recent years, the amygdala being the area most commonly identified as relevant to outgroup threat. For example, studies have associated amygdala activity with white perceivers' negative responses to African-Americans (Cunningham et al., 2004; Phelps et al., 2000; Richeson et al., 2003). People who possess stigmatizing conditions that make them seem less than human, such as the homeless, also activate regions of the amygdala (Harris & Fiske, 2006). Krendl, Macrae, Kelley, Fugelsang, and Heatherton (2006) have found amygdala responses to physically unattractive individuals or people who are otherwise stigmatized by their appearance.

Considered together, these data strongly suggest that evaluations of outgroup members engage the amygdala. But what precisely does the amygdala do in the context of social cognition? One possibility derives from the longstanding notion that the amygdala may play a special role in responding to stimuli that elicit fear (Blanchard & Blanchard, 1972; Feldman-Barrett & Wager, 2006; LeDoux, 1996), suggesting that the amygdala may contribute to hard-wired circuits that have developed over the course of evolution to protect animals from danger. For example, the amygdala is robustly activated in response to primary biologically relevant stimuli (e.g., faces, odors, tastes), even when these stimuli remain below the subjects' level of reported awareness (Morris, Ohman, & Dolan, 1998; Whalen et al., 1998).

However, many recent imaging studies have also observed amygdala activity in response to stimuli of positive valence, indicating that the amygdala is not solely concerned with fear. Indeed, some have argued that the amygdala is important for drawing attention to novel stimuli that have biological relevance. For instance, Stephan Hamann and colleagues (Hamann, Herman, Nolan, & Wallen, 2004) found that activity within the amygdala increased when both men and women viewed sexually arousing stimuli, such as short film clips of sexual activity or pictures of opposite-sex nudes. As such, the amygdala may play a role in processing social emotions more generally, because such affective states

have direct relevance in maintaining long-term social relationships. Along these lines, Paul Whalen has argued that the amygdala is especially concerned with ambiguous stimuli that provide insufficient information to discern the nature of the threat (Whalen, 1998, 2007); since fear faces indicate an unspecified threat, they may engage the amygdala more than less ambiguous facial displays, such as anger (Whalen et al., 2001).

The "special" nature of social cognition

As was discussed above, a particular set of social-cognitive processes supporting our understanding of other minds has consistently been linked to a fairly small number of brain regions: specifically, the MPFC, TPJ, and medial parietal cortex. Interestingly, this set of brain regions is marked by an unusually high rate of resting metabolic activity. That is, different brain areas have overall higher or lower rates of metabolism when individuals rest passively without performing a specified task (Gusnard & Raichle, 2001), suggesting that some regions may chronically carry out cognitive processing even in the absence of explicit task demands. This observation suggests that, when allowed to relax to baseline, the human brain seems to persist in some kinds of social-cognitive processing, subserved by regions such as the MPFC and TPJ that have particularly high resting metabolic rates.

Perhaps even more speculatively, these brain regions demonstrate an unusual tendency to "deactivate" when perceivers engage in tasks that do not rely on social thought. When performing tasks that instead require consideration of nonsocial aspects of the world (e.g., visual search or semantic decision tasks), the human brain seems to suspend the otherwise high resting activity in the MPFC, TPJ, and medial parietal cortex. Suggestively, the tendency to deactivate during nonsocial tasks suggests that the processing in these regions may be in some way incompatible with nonsocial cognition; the brain regions that subservise other aspects of cognition (e.g., language or vision) do not share this feature of active inhibition when one performs a task that does not require those processes. Together, these observations suggest, albeit speculatively, that the human cognitive system may be in a state of continuous readiness to encounter other minds (hence the high resting metabolic rate evinced by these regions) and that this social default must be actively suspended to engage appropriately with nonsocial entities, such as inanimate objects.

Conclusion

Over the past two decades, the integration of cognitive neuroscience and social psychology has led to a spate of insights into the neural basis of human social cognition. In beginning to examine the neural underpinnings of social behavior,

researchers have begun the process of carving social cognition “at its joints,” using the brain to identify the cognitive processes that allow humans to tap into the minds of others. We have learned that social thought relies on a suite of different mechanisms, some of which are quite distinct from the processes that subserve nonsocial aspects of human cognitive abilities, whereas others make use of more general-purpose computations. Here, we have specifically suggested that the social brain comprises at least four distinct mechanisms: awareness of self, understanding other minds, regulation of one’s own behavior and emotions, and the detection and avoidance of social threat. But the field of social neuroscience is still very much in its infancy, and much remains to be added to this list. We look forward to such future insights with excitement.

66 The Neural Basis of Emotion Regulation: Making Emotion Work for You and Not Against You

JENNIFER S. BEER

ABSTRACT Too much emotion can get you into trouble. However, the maxim “Everything in moderation” applies to our emotional lives because a life without any emotion is not desirable either. We certainly need to experience some emotions in order to recognize when good *and* bad things happen. Luckily, the body’s campaign for homeostasis extends to emotional processes; therefore we do have some mechanisms in place to regulate our emotions so that we can maximize their benefit and minimize their costs. What neural circuitry is involved in the control of emotion? Does it depend on the psychological manner in which we strive to regulate our emotions? Is it different from the neural basis of regulatory processes used to control nonemotional processes? This chapter addresses these questions by reviewing the human neuroscience research on three broad categories of emotional regulation: processes of distraction, reappraisal, and controlling emotional influences on decision making.

Too much emotion can get you into trouble. There are certainly extreme examples such as “crimes of passion,” in which people may commit acts of violence that would be inconceivable to them in a nonemotional state, or the pursuit of drug-induced euphoria, which cannibalizes resources needed to maintain employment and relationships. In addition to problems of intensity, emotions can often butt heads with societal norms. For example, the gloomy face of the groom’s mother at a wedding might reflect her internal emotional state but bode poorly for her relationship with the future daughter-in-law. However, the maxim “Everything in moderation” applies to our emotional lives because a life without any emotion is not desirable either. We certainly need to experience some emotions in order to recognize when good *and* bad things happen. In fact, Eric Wilson argues in his book *Against Happiness: In Praise of Melancholy* that American culture has placed too much emphasis on suppressing negative emotions and boosting positive emotions, which is costing people the motivational and creative lessons that can be learned only from negative experience. Luckily, the body’s campaign for homeostasis extends to emotional

processes; therefore we do have some mechanisms in place to regulate our emotions so that we can maximize their benefit and minimize their costs. What neural circuitry is involved in the control of emotion? Does it depend on the psychological manner in which we strive to regulate our emotions? Is it different from the neural basis of regulatory processes used to control nonemotional processes? This chapter addresses these questions by reviewing the human neuroscience research on three broad categories of emotional regulation: processes of distraction, reappraisal, and controlling emotional influences on decision making.

Definitions and methodological issues for the study of emotion regulation

Emotion regulation is a diverse set of processes aimed at modifying emotional experience and expression. A common definition of emotion regulation encompasses any control processes that are executed to manipulate when, where, how, and which emotions we experience and express (Gross, 1998). Although the term *regulation* may connote an effortful, conscious process, emotion regulation is considered to occur at both automatic and conscious levels of processing. Emotion regulation has both interindividual and intraindividual goals. Most people prefer to feel good and avoid feeling bad and therefore exert control over their emotions to boost positive feelings and minimize negative feelings (e.g., Taylor, 1991). Additionally, when emotions clash with societal norms, people regulate the expression of their emotion in order to avoid negative social consequences. Although emotion regulation most often includes suppressing emotion, it is important to note that emotion regulation may involve the suppression, reduction, or inflation of emotion.

Perhaps the most challenging aspect of studying emotion regulation is measuring whether regulation occurred. If people automatically regulate their emotion, then any emotion response (or lack thereof) may reflect an emotion regulation process. In other words, even if emotion is

JENNIFER S. BEER University of Texas at Austin, Austin, Texas

expressed, it could reflect an automatic regulation of its magnitude. Most researchers avoid this issue by instructing participants to regulate their emotions through one of two strategies: (1) distracting one's self away from emotional stimuli and (2) reappraising the meaning of emotional stimuli. These studies have provided important information but cannot completely rule out the possibility that the neural regions that support emotion regulation in these studies reflect participants' efforts to follow the experimental instructions and not emotion regulation per se. Therefore it is important to examine naturally occurring emotion regulation processes. But how can researchers do this? Although the topic is not often included in discussions of the neural basis of emotion regulation, research on the spontaneous regulation of the influence of emotion on decision making provides a valuable complement to the studies that explicitly instruct participants to regulate their emotional experience. An examination across these literatures provides an answer to whether different types of emotion regulation strategies (e.g., distraction versus reappraisal, instructed versus spontaneous, regulation of emotional experience versus its influence on subsequent cognition) engage different neural systems. Additionally, these studies provide insight into whether the executive function systems associated with the control of nonemotional stimuli also extend to the control of emotional stimuli.

“Sticking your head in the sand”: Distracting attention away from emotional stimuli

One way in which people can control their emotional reactions is to inhibit their attention to events that elicit emotion in the first place. For example, if you are trying to enjoy a nice meal at a restaurant, you might find it annoying when someone at the next table is carrying on a loud conversation on a cell phone. To get rid of your annoyance, you might decide to block out the conversation and ignore it all together. Neuroscientists have examined the neural systems that support the ability to inhibit attention to events that elicit emotion in two ways: distracting attention away from

an *anticipated* emotional event and inhibiting attention when distracting emotional information *interferes* with the task at hand.

ANTICIPATION Studies examining the process of distraction when someone is anticipating an emotional event have found the most consistent evidence for the role of the lateral prefrontal cortex (see figure 66.1). These studies typically forewarn participants that emotional events will occur and require the participants to distract their attention away from these events. Participants are explicitly instructed to suppress any thoughts about the emotional events. For example, participants were forewarned that they would be presented with either a negative picture or a neutral picture and were instructed to distract their attention away from these upcoming events by focusing on the experimental context (e.g., “I am lying in a scanner”). Participants who engaged in this distraction process when anticipating a negative emotional picture compared to a neutral picture recruited greater activity in the lateral prefrontal cortex activity (BA 9) and medial prefrontal cortex (BA 8) and exhibited amygdala deactivation (Herwig et al., 2007). In addition to negative pictures, researchers have examined the neural systems that support distraction in the face of upcoming pain. For example, distraction was also associated with lateral prefrontal cortex activation (BA 9/46) when participants anticipated an electric shock, but this activation was generally associated with anticipating an upcoming event regardless of whether it was an electric shock or the absence of shock (Kalisch, Wiech, Hermann, & Dolan, 2006). Together, these studies suggest that frontal regions support the ability to distract attention away from an upcoming emotional event, but it is important to note that the lateral prefrontal cortex has generally been implicated in suppression of nonemotional thoughts (e.g., Mitchell et al., 2007).

INTERFERENCE Other studies require participants to perform a cognitive task while they simultaneously regulate interference from emotional distractors. To successfully

FIGURE 66.1 Regions associated with distraction: lateral prefrontal cortex (A), anterior cingulate cortex (B), and amygdala (C).

perform the tasks, participants must inhibit their attention to the emotionally distracting information. These studies have found that inhibiting attention to emotional distractors is most consistently associated with (1) increased activation in the anterior cingulate and (2) decreased activation in the amygdala (see figure 66.1). A number of studies have examined participants' ability to distract themselves while receiving pain in the form of a cold pressor task or the application of heat. These studies have found that distracting oneself from physical pain most consistently recruits anterior cingulate cortex (ACC) activity and some other frontal regions (Bantick et al., 2002; Frankenstein, Richter, McIntyre, & Remy, 2001; Wiech et al., 2006). For example, participants' self-reports of negative affect correlated negatively with activation in the ACC (BA 32, BA 24), dorsolateral prefrontal cortex (BA 46), ventrolateral prefrontal cortex (BA 45), and medial prefrontal cortex (BA 10, BA 32) during heat stimulation (Wiech et al., 2006). However, it is unclear whether the activation in the ACC occurs in a consistent subregion. In one study, participants who performed a verbal attention task to distract themselves from a cold pressor on their foot reported less pain and significantly activated the caudal portion of the ACC (BA 32) (Frankenstein et al., 2001). In contrast, another study found that participants who distracted themselves from painful heat reported less pain and significantly activated a rostral portion of the ACC and the orbitofrontal cortex (Bantick et al., 2002).

In addition to studies of regulating interference from pain, researchers have investigated participants' ability to regulate their response to threat cues while performing another task. For example, participants were presented with pairs of house pictures and had to decide whether the same house was depicted across the pictures. The house pictures were flanked by pictures of emotional facial expressions that were either neutral or fearful. The study compared conditions in which the fearful faces were presented either infrequently or frequently. The infrequent condition reflected more interference because participants did not have time to habituate to the fearful cues through satiation. Rostral ACC (BA 32) activated in relation to infrequent fearful distractors. Furthermore, participants' state ratings of anxiety predicted reduced ACC activity and less recruitment of dorsolateral prefrontal cortex (DLPFC) and ventral lateral prefrontal cortex (VLPFC). In other words, regulating away interference from threat cues engaged the ACC, and people who were less successful at regulating their anxiety were the least likely to recruit the ACC, DLPFC, and VLPFC (Bishop, Duncan, Brett, & Lawrence, 2004).

Additionally, several studies have examined the regulation of emotional interference through variations of the Stroop paradigm. For example, participants might be presented with pictures of emotional facial expressions that have

emotion words written across the middle. Their task is to identify the emotional content of the facial expression; emotion words that are different from the content of the facial expression represent a condition in which participants have to inhibit their attention to the interfering emotional information. Participants do not tend to make as many errors on this task as they do on the traditional color Stroop task. Instead, emotional interference is indicated by slower reaction times for the interference trials. Research has shown that the presence of emotionally interfering words (as compared to words that match the context of the facial expression) activate dorsomedial prefrontal cortex (BA 8/32), DLPFC, and amygdala (Compton et al., 2003; Etkin, Egner, Peraza, Kandel, & Hirsch, 2006; Egner, Etkin, Gale, & Hirsch, 2008). Participants who successfully regulate the emotional interference significantly activate rostral anterior cingulate (BA 24/32), and activity in this area predicts decreased activation in the amygdala (Etkin et al., 2006; Egner et al., 2008). Modulation of the rostral anterior cingulate was also found in a study that employed an Emotional Counting Stroop paradigm (Whalen et al., 1998). In this study, participants had to count the number of negative or neutral words on the screen. Increased anterior cingulate activation was initially associated with presentation of negative words compared to neutral words. Although no differences in reaction times were found between the negative and neutral conditions in this study, there may have still been emotional interference. Participants may have habituated to the emotional interference, and therefore the effect was diminished after the initial trials (Compton et al., 2003).

Just as there was inconsistency in the subregion of anterior cingulate activation associated with regulating interference from pain, mixed evidence has been found for the selectivity of the subregion of the ACC associated with regulating interference from information that is specifically emotional (rather than any distracting information). On the one hand, one study compared the interference of emotional information with the interference of nonemotional information (e.g., when the gender of a face conflicts with a gender label written across the face) and found that rostral anterior cingulate activation was specific to the interference of emotional information rather than all kinds of information (Egner et al., 2008). However, a functional magnetic resonance imaging (fMRI) study found that the Emotional Stroop task was associated with activation in the caudal portion of the ACC typically found in relation to a traditional Stroop interference effect (Haas, Omura, Constable, & Canli, 2006), and a single-cell recording study found that several cells in this caudal region of the anterior cingulate were specific to the counting Emotional Stroop task (Davis et al., 2005). Although there is no clear explanation for the differences in findings across the studies, one possible difference between the two

studies that found caudal activation and the rest of the research reviewed here is that these studies used positively or negative valenced words that were not descriptions of emotional states; many of the other studies did use emotional state terms. Additionally, one of the studies did not involve the presentation of pictures of emotional facial expressions (Davis et al., 2005).

Reappraisal: “Making lemonade out of lemons”

Another way in which people regulate their emotion is by reappraising events that give rise to emotion. The meaning of the event is changed so that it becomes nonemotional or elicits a different emotion. An important distinction between distraction and reappraisal paradigms is that reappraisal paradigms require participants to decrease or increase their emotions while still attending to the emotional stimuli rather than distracting themselves by looking away or focusing on irrelevant thoughts. In a typical reappraisal experiment, participants receive a fair amount of training on how to reappraise emotional stimuli before they even enter the scanner (e.g., Ochsner, Bunge, Gross, & Gabrieli, 2002; Phan et al., 2005; Urry et al., 2006). Participants are presented with emotional stimuli and instructed to generate an alternative interpretation of the stimuli so that the salient emotional meaning is changed. For example, a negative scenario such as a baby covered in electrodes while receiving medical treatment can be reappraised as a positive event because the treatment is necessary for a healthy recovery. Researchers can then compare neural activity associated with reappraising the emotional meaning of stimuli to neural activity associated with reacting to the most salient emotional meaning of stimuli.

In contrast to the research on distraction, studies of reappraisal use less varied paradigms. These studies mostly focus on reappraisal as a means of suppressing a negative emotional experience. The bulk of these studies focus on reducing negative emotion through the reappraisal of negative

pictures from the International Affective Picture Set (IAPS) (Lang, Bradley, & Cuthbert, 1995) in young healthy adults (e.g., Banks, Eddy, Angstadt, Nathan, & Phan, 2007; Eippert et al., 2007; Kim & Hamann, 2007; Ochsner et al., 2002; Ohira et al., 2006; Phan et al., 2005; Schaefer et al., 2002) or older adults (Urry et al., 2006), and some have examined reappraisal of negative IAPS that represent moral violations (e.g., Harenski & Hamann, 2006). A few studies have examined the neural basis of reducing negative emotion through the reappraisal of sad films in adults (e.g., Lévesque et al., 2003) and children (e.g., Lévesque et al., 2004). However, there are some exceptions to the focus on the reduction of negative emotion. Some studies have examined the reduction of positive emotion through reappraisal of positive stimuli (e.g., Beauregard, Lévesque, & Bourgouin, 2001; Kim & Hamann, 2007) or the inflation of emotion (e.g., Kim & Hamann, 2007; Ochsner et al., 2004).

ERP research suggests that reappraisal happens as early as 200 ms after the onset of the emotional stimulus and is sustained for at least 2 s (Hajcak & Nieuwenhuis, 2006). Whereas the distraction research most consistently found activation in the ACC and deactivation in the amygdala, fMRI and PET research suggests that the reappraisal process is governed by (1) *increased* activation in frontal regions such as lateral prefrontal cortex, medial and lateral orbitofrontal cortex, and anterior cingulate/dorsomedial prefrontal cortex and (2) *decreased* activation in the amygdala (see figure 66.2).

LATERAL PREFRONTAL CORTEX A number of studies have found that reappraising stimuli to reduce emotional experience is associated with activity in the ventrolateral and lateral prefrontal cortex. For example, studies of healthy, young adult participants as they reappraise negative pictures or films have found significant increases in activation in the ventrolateral prefrontal cortex (BA 46/10: Ochsner et al. 2002; BA 44/46: Kim & Hamann, 2007; Phan et al., 2005) and the lateral prefrontal cortex (Banks et al., 2007; Eippert et al., 2007; Kim & Hamann, 2007; Lévesque et al., 2003;

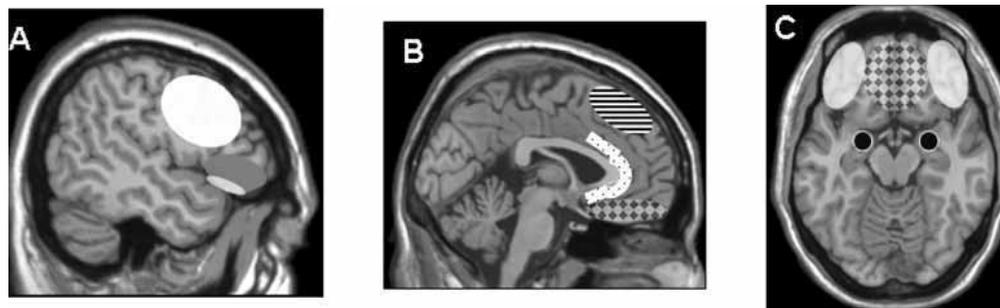

FIGURE 66.2 Regions associated with reappraisal. Dorsolateral (white in *A*) and ventrolateral (dark gray in *A*) prefrontal cortex. Medial (checkerboard in *B*, *C*) and lateral (light gray in *A*, *C*) orbi-

tofrontal cortex, dorsomedial prefrontal cortex (striped in *B*), anterior cingulate (dotted in *B*), and amygdala (black with white outline in *C*).

Ohira et al., 2006). Similar regions of activation have been associated with the reappraisal of negative stimuli in older adult populations (BA 9, BA 44: Urry et al., 2006) and in children (BA 47, BA 9: Lévesque et al., 2004). Additionally, a study of individual differences in rumination suggests that participants who are likely to have poor ability to regulate their emotion (i.e., report high levels of dispositional rumination) do not strongly recruit the lateral prefrontal cortex when instructed to reappraise negative stimuli (Ray et al., 2005). Together, these studies suggest a consistent role of the lateral prefrontal cortex, a region that is associated with control of nonemotional responses, in the process of reappraisal. Furthermore, activation in lateral prefrontal cortex is reduced for individuals who struggle to reappraise emotional stimuli (e.g., ruminators).

Although many of the reappraisal studies explicitly instruct participants to reappraise stimuli, two studies suggest that regions of lateral prefrontal cortex may also be associated with the automatic regulation of negative emotion (Cheng et al., 2007; Haas et al., 2006). In one study, participants were presented with pictures of facial expressions that were fearful, happy, sad, or neutral. Participants were instructed to rate the gender of the person in each picture. On the basis of previous research suggesting that individuals who are high in agreeableness are automatically motivated to regulate away threat signals (Tobin, Graziano, Vanman, & Tassinari, 2000), the authors of this fMRI study reasoned that highly agreeable individuals would be likely to automatically regulate their response to fearful faces but not happy or sad faces. The results were consistent with this hypothesis: self-reported ratings of agreeableness were positively correlated with lateral prefrontal activation (BA 9) in relation to the fearful face trials but not related to the happy or sad face trials (Haas et al., 2006). In a second study, physicians who practice acupuncture and acupuncture novices were presented with short film clips of patients receiving acupuncture (Cheng et al., 2007). In comparison to novices, who activated neural regions associated with empathic pain, the physicians activated lateral prefrontal cortex. The authors of the study suggest that the lateral prefrontal cortex activity reflects the physicians' spontaneous tendency to regulate away any empathic pain by focusing on how the treatment will help the patient (Cheng et al., 2007).

Although the bulk of studies examine the reappraisal of negative emotion, a few studies have found lateral prefrontal activity in relation to reappraisal in other kinds of paradigms and, in some cases, more complex emotions. For example, bilateral ventrolateral prefrontal cortex (BA 47) activity is associated with reappraising moral emotion pictorial stimuli (Harenski & Hamann, 2006), and lateral prefrontal cortex (BA 44) is associated with reappraising erotic emotional stimuli (Beauregard et al., 2001). The relationship between lateral prefrontal cortex activity and reappraisal also extends

to reappraisals aimed at intensifying emotional experience. Lateral prefrontal cortex activity (BA 9 and BA 44) has been found in association with increasing negative emotional experience in young adults (Ochsner et al., 2004) and elderly adults (Urry et al., 2006) as well as increasing positive emotional experience in young adults (Kim & Hamann, 2007).

MEDIAL AND LATERAL ORBITOFRONTAL CORTEX A number of reappraisal studies have also found significant medial and lateral orbitofrontal cortex activation. For example, the reappraisal of negative pictures or sad films is associated with medial orbitofrontal activity (BA 11) in children (Lévesque et al., 2004) and adults (Banks et al., 2007; Eippert et al., 2007; Kim & Hamann, 2007; Lévesque et al., 2003; Ochsner et al., 2004; Phan et al., 2005). The reappraisal of positive IAPS is also associated with bilateral orbitofrontal cortex activity (Kim & Hamann, 2007). Furthermore, not only is medial orbitofrontal cortex activity associated with the reappraisal condition in neuroimaging studies, but there is also some evidence that this activity correlates with peripheral nervous system indicators of emotional suppression. One neuroimaging study found increased medial orbitofrontal activity (BA 11) in relation to the reappraisal of negative emotional stimuli and that this activity correlates with increased skin conductance response (SCR) (Ohira et al., 2006). Increased skin conductance has been associated with emotional suppression (e.g., Gross & Levenson, 1993).

ANTERIOR CINGULATE AND MEDIAL PREFRONTAL CORTEX A number of studies have also found that reappraisal is associated with anterior cingulate activity. For example, anterior cingulate activity (BA 24/32) is associated with the reappraisal of negative IAPS (Banks et al., 2007; Eippert et al., 2007; Kim & Hamann, 2007; Ochsner et al., 2002; Phan et al., 2005) and moral emotional pictures (Harenski & Hamann, 2006) in adults and the reappraisal of sad films in children (Lévesque et al., 2004). Anterior cingulate (BA 32) activity is also involved in reducing positive emotion through the reappraisal of positive stimuli (Beauregard et al., 2001). In addition to reducing emotion, the ACC has been implicated in increasing emotion through reappraisal of both negative and positive pictures (Kim & Hamann, 2007).

A number of reappraisal studies have also found significant activation in regions of the dorsomedial prefrontal cortex that are broadly adjacent to the anterior cingulate activation. For example, regions of BA 8/9 show significant activation in relation to the reappraisal of negative IAPS (Banks et al., 2007; Kim & Hamann, 2007; Ochsner et al., 2002; Phan et al., 2005). Additionally, BA 9/10 activity has been associated with the reappraisal of sad films (Lévesque et al., 2003) and moral emotional stimuli

(Harenski & Hamann, 2006). Finally, the left medial prefrontal cortex (BA 9) has been associated with increasing negative emotion through reappraisal of negative IAPS (Ochsner et al., 2004).

AMYGDALA Reappraising emotional stimuli modulates amygdala activity. For example, a decrease in amygdala activity is associated with reappraising negative IAPS in young (Banks et al., 2007; Eippert et al., 2007; Ochsner et al., 2004; Phan et al., 2005) and elderly adults (Urry et al., 2006) and the reappraisal of positive erotic stimuli (Beauregard et al., 2001). Similarly, amygdala activity increases in relation to reappraisal aimed at (1) inflating *negative* emotional experience in young (Eippert et al., 2007; Ochsner et al., 2004; Schaefer et al., 2002) and elderly adults (Urry et al., 2006) and (2) inflating *positive* emotional experience in young adults (Kim & Hamann, 2007).

RELATION OF FRONTAL REGIONS AND AMYGDALA Some studies suggest that the relative activation of frontal regions and relative decrease amygdala activity may be related. One fMRI study required female participants to reappraise negative pictures and found that reappraisal was associated with left ventrolateral prefrontal cortex (BA 46/10) activation correlated with decreased right amygdala activation (Ochsner et al., 2002). Another fMRI study that included both male and female participants and involved reappraisal of negative pictures found that reappraisal was associated with a negative correlation between right ventrolateral prefrontal cortex activation (BA 47) and left amygdala activation (Phan et al., 2005). Although these studies found a general relationship between the frontal lobes and amygdala, other studies have found individual differences in the frontal-amygdala coupling when participants are reappraising negative IAPS (Urry et al., 2006) and the strength of the frontal-amygdala coupling predicts individual differences in self-reported regulation success (i.e., a reduction in negative emotion) (Banks et al., 2007). In contrast to the studies reviewed above, numerous studies examining reappraisal of negative IAPS or films do not report a significant correlation between frontal activity and amygdala deactivation. It is possible that this relationship was not tested and, therefore, the failure to report the negative correlation might not indicate a nonreplication.

Regulating the influence of emotional expression on decision making

Distraction and reappraisal studies often explicitly instruct participants to regulate their emotional experiences in relation to anticipated or present emotional stimuli. A remaining question is whether the neural regions associated with emotional regulation in these studies extend to spontaneous emotion regulation. Additionally, these studies focus on the

regulation of emotional experience and do not address the regulation of emotion's expression on complex cognition such as decision making. To address these questions, it is necessary to explore research literatures that may not always be included in reviews of the neural basis of emotion regulation. In particular, an important avenue for addressing these questions is research examining situations in which participants spontaneously regulate the influence of emotion on their decision making.

Much of the research that examines the spontaneous regulation of emotional influences on decision making are designed from the perspective of economic models of decision making. Economic models of decision making assume that people should make self-interested decisions, that is, decisions that maximize their financial gains and minimize their financial losses (e.g., Kahneman & Tversky, 2000). However, people may sometimes react emotionally to some aspect of a financial decision that is irrelevant, and if they follow these emotions, they make decisions that sacrifice monetary gain. Therefore, it is possible to examine the spontaneous regulation of emotional expression on decision making by creating situations in which participants' self-interest competes with their emotional reactions. Studies adopting this approach have most often found that spontaneous regulation of emotional expression on decision making is associated with dorsolateral prefrontal cortex, medial and lateral orbitofrontal cortex, and anterior cingulate activity (see figure 66.3).

The Ultimatum Game is one paradigm that measures differences in gambling decisions that reflect the influence of an initial but irrelevant emotional reaction or the regulation of that emotional reaction. As a responder in the Ultimatum Game, participants must decide whether to accept or reject another player's suggestion about how to split a sum of money provided by the experimenters. Some offers are fair (e.g., very close to 50% for each person), but others are unfair (e.g., 80% for the player and 20% for the participant). If the responder accepts the offer, the participants receive the money according to the terms of the offer. If the responder rejects the offer, then neither player receives any money. Participants tend to have a negative emotional reaction when presented with an unfair offer. However, from an economic perspective, participants should not let their negative emotional reaction lead them to reject the unfair offer. Even if it is unfair, they can gain some money instead of sacrificing any chance of monetary gain. This is particularly true if the responder plays several rounds of the game with different participants. In this case, there is no rationale for rejecting offers such as worries about communicating a willingness to take less than an equal share. The responder will never interact with that same player again.

In the first neural study of this paradigm, the consideration of unfair offers was associated with ACC, dorsolateral

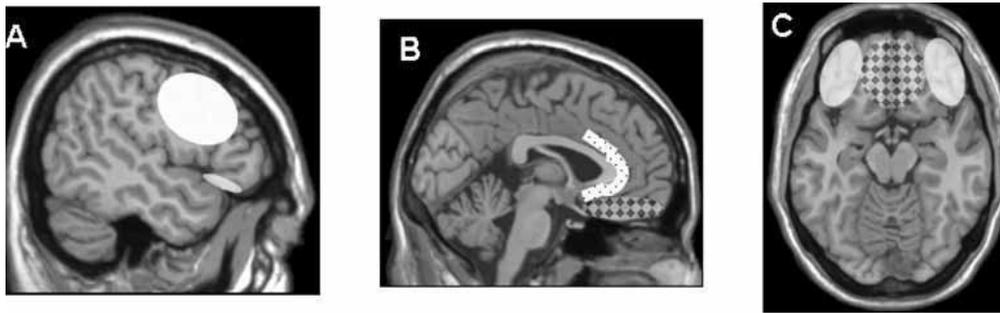

FIGURE 66.3 Regions associated with regulating emotional expression on decision making. Lateral prefrontal cortex (white in *A*), medial (checkerboard in *B*, *C*) and lateral (light gray in *A*, *C*) orbitofrontal cortex, and anterior cingulate cortex (dotted *B*).

prefrontal cortex, and insula activity (Sanfey, Rilling, Aronson, Nystrom, & Cohen, 2003). Insula activity has often been associated with negative emotions such as disgust, anger, pain, and distress suggesting that this activity may have reflected these emotional reactions to the unfair offers. Furthermore, increased insula activity during consideration of an unfair offer predicted the likelihood that the offer would be rejected. Although dorsolateral prefrontal cortex activity did not directly correlate with the acceptance of unfair offers, the authors of the study noted that participants tended to accept unfair offers if they activated their dorsolateral prefrontal cortex more strongly than their insula when considering unfair offers. They suggest that the differential activation between insula and dorsolateral prefrontal cortex reflects a difference in decision making driven by an emotion reaction supported by the insula in comparison to decision making driven by a cognitive control system supported by the dorsolateral prefrontal cortex.

Although it would be tempting to interpret the dorsolateral prefrontal activation to indicate a reappraisal of the unfair offers as suggested by the studies of reappraisal, two studies using transcranial magnetic stimulation (TMS) suggest that it is somewhat more complicated. Unfair offers violate norms of fairness, and participants' initial reaction is to reject the offer. Therefore it might be expected that the dorsolateral prefrontal cortex supports the reappraisal of the unfair offer so that participants are able to regulate their initial negative reaction and focus on the choice between earning some money compared to no money. If the dorsolateral activation is needed to generate a reappraisal of the unfair offer so that it becomes appealing, then disruption of this region through TMS should increase rejection rates of unfair offers. However, two TMS studies have found that disruption of this region is associated with higher rates of acceptance of unfair offers compared to sham stimulation (Knoch, Pascual-Leone, Meyer, Treyer, & Fehr, 2006; Knoch et al., 2007). In light of the replication of an unexpected finding, the authors of the TMS studies suggest that these results could indicate that the dorsolateral prefrontal cortex is actually needed to implement fairness

norms when they conflict with the temptation of selfish interests. In other words, the dorsolateral prefrontal cortex is not needed to suppress negative reactions to unfair offers but rather to suppress the desire for monetary gain when giving into that desire could be costly for your social standing. Social norms of fairness dictate that people should not have to accept unfair offers. Therefore deciding to accept unfair offers is not the rational choice, as it might indicate that you are willing to receive less than your share in future situations.

The role of the dorsolateral prefrontal cortex in implementing social norms has also been suggested in neural research on moral judgments. For example, participants had to make decisions about what course of action to take for various moral dilemmas. The most difficult dilemmas created a conflict between the course of action suggested by an initial emotional response and the course of action suggested by utilitarian values (e.g., what is good for the group rather than the individual) (Greene, Nystrom, Engell, Darley, & Cohen, 2004). For example, one dilemma placed participants in a situation in which they were part of a group of people hiding from soldiers in wartime. The participants were told that their baby was crying and that this could cause discovery of the whole group, which would mean certain death. Participants then had to decide whether they would smother the baby to stop the crying in order to save the group. Difficult moral judgments were associated with ACC and dorsolateral prefrontal cortex activity. The authors of the study suggest that the ACC helps to detect the conflict presented by these dilemmas and the dorsolateral prefrontal cortex supports the selection of the utilitarian response.

Regulation of the clash between self-interest and fairness norms may also be supported by orbitofrontal cortex. For example, one fMRI study required participants to determine how much of a sum of money they were willing to share with another participant (Spitzer, Fischbacher, Herrnberger, Groen, & Fehr, 2007). Participants made these decisions in two conditions. In a control condition, the offer was seen only by the participant and the other player. In the punishment condition, a third person had the power to take away

the money if the offer was perceived as unfair. The study found that dorsolateral prefrontal cortex and bilateral lateral orbitofrontal cortex activation were associated with offering more money in the punishment condition than in the control condition. Furthermore, a high score on a measure of Machiavellianism predicted bilateral orbitofrontal cortex activation in the punishment condition. Machiavellianism measures the extent to which individuals are willing to compromise their behavior as long as it helps them to achieve their ultimate goal. These results suggest that individuals who are most likely to adhere to norms of fairness only as a means of achieving their self-interest in gaining money are those individuals who tend to activate frontal regions associated with emotion regulation.

Other research has implicated the orbitofrontal cortex in regulating the influence of emotion on decision making. For example, the presentation of equivalent gambling decisions that are framed as guaranteed gains or losses measures people's tendency to let emotion guide their decisions in favor of controlling its influence. A host of research has shown that people want to avoid loss and therefore will choose to gamble when faced with a guaranteed loss even if the money at stake is the same as a bet that is framed as a guaranteed gain. In other words, if people are endowed with 50 dollars and given a choice between a guaranteed loss of 30 dollars or gambling it all, people will choose to gamble. In contrast, if given a choice between a guaranteed gain of 20 dollars and gambling it all, people will choose to keep the 20 dollars. However, the guaranteed money in both bets is equivalent. A guaranteed loss elicits a negative emotional response and makes people focus on any option that will help them to avoid the guaranteed loss. However, acting on emotion is detrimental because, as was mentioned above, participants are not making decisions based on their actual monetary consequences. An fMRI study of equivalent bets framed as gains or losses found that participants who permitted their betting behavior to be swayed by the loss frames showed significant amygdala activation and those who bet according to monetary amount (rather than frame) showed increased medial and lateral orbitofrontal cortex activation (DeMartino, Kumaran, Seymour, & Dolan, 2006).

Although some previous research suggests that the orbitofrontal cortex is important for regulating the influence of emotion on decision making, it is possible that the orbitofrontal cortex activation reflected the regulation of the emotional experience itself because the emotional reactions occurred simultaneously with the decision. However, another fMRI study disentangled the regulation of emotional experience from the regulation of emotional influence on decision making and found that lateral orbitofrontal cortex and insula activity are associated with the regulation of emotional influence on decision making (Beer, Knight, & D'Esposito, 2006).

Participants were presented with negative and neutral cues and were asked to either rate the valence of the cues or ignore them. After each cue, participants were presented with the odds and payoff information for a roulette bet and were asked to select a monetary amount to wager. Previous research has shown that negative moods make participants less willing to risk money. Therefore if participants fail to successfully ignore the negative cues, then they will risk less when primed with a negative cue compared to a neutral cue. Participants who successfully regulated the influence of these negative primes on their betting behavior were most likely to engage the lateral orbitofrontal cortex and insula (Beer, Knight, & D'Esposito, 2006).

Assessment of neuroimaging research of emotion regulation

The chapter began by posing a number of questions regarding the neural basis of emotion regulation and sought to address them by comparing and contrasting research on the emotion regulation processes of distraction, reappraisal, and controlling the influence of emotional expression on decision making. These bodies of research suggest that although there is overlap between the neural regions associated with emotion regulation, there are systems that appear more consistently in relation to particular emotion regulation strategies. Furthermore, the neural systems that are associated with instructed and spontaneous emotion regulation share some similarities. Finally, there is not strong evidence for a "special" executive function system that controls emotion. The neural regions associated with emotion regulation are regions that are also associated with the control of nonemotional information.

COMMONALITIES ACROSS EMOTION REGULATION STRATEGIES

All three of the emotion regulation processes that we consider in this chapter were associated with the lateral prefrontal cortex and ACC. These regions have long been associated with executive function; therefore it is not surprising that they would also support control over emotional processes. Although very little research has experimentally manipulated emotion regulation in human lesion populations, there is some evidence that lesions to the lateral prefrontal cortex and ACC disrupt emotion regulation abilities. For example, patients with lateral prefrontal cortex damage have reported increases in depression and anxiety, and patients with ACC damage have been associated with both increased and decreased emotionality, suggesting that these patients' ability to engage in emotion regulation is impaired (see Beer, 2007a, for a review). The role of lateral prefrontal cortex in emotion regulation appears to extend across both instructed regulation efforts and spontaneous regulation of emotion. In addition

to the research on the spontaneous regulation of emotional influences on cognition, it is the case that individual differences associated with spontaneous tendencies toward emotion regulation are associated with lateral prefrontal cortex activity. For example, lateral prefrontal cortex activity is associated with the regulation efforts of participants whose high levels of agreeableness motivate them to regulate their attention to threat cues (Haas et al., 2006) and with physicians who spontaneously regulate empathic pain when watching patients receive acupuncture (Chen et al., 2007). Additionally, the lateral prefrontal cortex is recruited less strongly by individuals who are poor at emotion regulation, such as highly anxious subjects (Bishop et al., 2004) and highly ruminative subjects (Ray et al., 2005).

DIFFERENCES ACROSS EMOTION REGULATION STRATEGIES

However, there were differences across the emotion regulation strategies as well. For example, the studies suggest that distraction is supported by the inverse relation between the ACC and the amygdala (e.g., Etkin et al., 2006; Egner et al., 2008), whereas reappraisal is supported by the inverse relation between the lateral orbitofrontal cortex and the amygdala (e.g. Banks et al., 2007; Ochsner et al., 2002; Phan et al., 2005). These relationships parallel findings in nonhuman animal research. For example, the process of extinction requires animals to no longer respond to the emotional association of a stimulus. This process is arguably similar to the process of distraction in which people suppress their emotional response. A similar inverse relationship between a region in the rat medial prefrontal cortex and the amygdala is associated with extinction (see Quirk & Beer, 2006, for a review). Similarly, an inverse coupling between the lateral orbitofrontal cortex and the amygdala is associated with reversal learning in rats (see Holland & Gallagher, 2004, for a review). Studies of reversal learning in nonhuman animals suggest that the amygdala stores emotional associations and the lateral orbitofrontal cortex supports the flexible use of these associations (e.g., Jones & Mishkin, 1972).

Additionally, the neural systems that are associated with distraction and reappraisal are more widespread than are those found in relation to the spontaneous regulation of emotion's influence on decision making. Although there are a number of differences between these bodies of research, one possibility is that spontaneous regulation of emotion relies on fewer neural structures when compared to effortful regulation. It may also be that similar systems support spontaneous emotion regulation regardless of the specific strategy; the additional neural activity found in distraction and reappraisal studies might reflect the participants' efforts to follow a set of instructions. The neural distinction between emotion regulation that is instructed versus spontaneous emotional regulation is illustrated in the dissociation between

the ability of patients with orbitofrontal lesions to comply with instructions to regulate their response to emotional film clips (Beer, 2007b) and their failure to regulate their emotional self-disclosures in everyday social situations (Beer, Heerey, Keltner, Scabini, & Knight, 2003, Beer, John, Scabini, & Knight, 2006).

A UNIQUE EXECUTIVE FUNCTION SYSTEM FOR EMOTION REGULATION? Some emotion regulation research has examined the possibility that there could be distinct neural regions that support the control of emotional processes when compared to nonemotional processes. For example, some research has suggested that an Emotional Stroop task recruits a rostral portion of the ACC that is distinct from the caudal portion associated with traditional Stroop tasks (e.g., Egner et al., 2008). In contrast, other research has found caudal anterior cingulate involvement in Emotional Stroop tasks (e.g., Haas et al., 2006; Davis et al., 2005). Although it seems most parsimonious to propose a general control system that can be recruited to handle both emotional and nonemotional information, emotion regulation is a particularly difficult task. By definition, emotional stimuli are highly salient and therefore more difficult to control. Therefore any differences in the neural regions associated with emotion regulation might not indicate a special system for the control of emotion but instead reflect differences in difficulty.

Future directions

In a short time, the neural research on emotion regulation has flourished, but there are also a number of fruitful avenues to broaden this body of research. The most important direction will be studies that are aimed at understanding how these neural systems interact to support emotion regulation and their relationship to peripheral nervous system indicators of emotion regulation. The large body of extant work provides a strong foundation for hypothesized activations; therefore it will be most beneficial to move past the identification of regions and understand how they interact. These studies will be beneficial in making progress on understanding the psychological function of each region in the emotion regulation process. At the moment, most models relating the anatomy to psychological process can only speculate on the psychological contribution of neural regions on the basis of studies of cognitive control (e.g., Ochsner & Gross, 2005). For example, the debate about the role of the ACC in detecting conflict or resolving conflict extends to research on emotion regulation, for example, detecting conflict (Bishop et al., 2004) and resolving conflict (Etkin et al., 2006). More careful research will permit stronger conclusions about the specific function of the ACC in relation to different emotion regulation strategies. Additionally, some studies have begun

to examine how neural activations relate to indicators of emotional regulation in the peripheral nervous system, and it will be helpful to continue understanding how these systems interact in order to gain a fuller picture of the process of emotion regulation.

More lesion work is needed in the study of emotion regulation. Almost no experimental manipulations of emotion regulation have been conducted in human lesion populations (see Beer, 2007a, for a review). An obvious place to begin is to understand the emotion regulation capabilities of patients with dorsolateral prefrontal cortex damage and orbitofrontal cortex damage because these regions have been identified in the neural research and patients with selective damage to these regions are more likely to exist than patients with damage to other relevant regions. Studies of distraction, reappraisal, and regulating emotional influence on decision making are needed to complement the work that has been done with neuroimaging techniques such as PET, fMRI, and TMS.

Future studies should also aim to directly compare the strategies of distraction and reappraisal. Although a number of overlapping regions are associated with both strategies, the two strategies may be distinguished by the frontal modulation of amygdala activity (ACC for distraction and orbitofrontal cortex for reappraisal). However, the overlap might occur because participants tend to distract themselves somewhat while reappraising and vice versa. A stronger test of the regions that might be more strongly activated in relation to a specific strategy will be to directly compare these strategies within the same study.

Future studies should include more varied emotional stimuli and samples that are balanced for gender. Much of the current work on reappraisal involves reducing negative emotional reactions to IAPS pictures. This paradigm has been helpful in permitting comparison of findings across laboratories, but it will also be helpful to extend this research to different emotional stimuli. Some studies have found that participants exhibit individual differences in the strength of their emotional reactions to this standardized set. Therefore, researchers sometimes have to specifically examine the trials that received the hypothesized emotional ratings by participants in order to detect neural activity (e.g., Ochsner et al., 2002). The use of films could elicit stronger and more uniform emotional responses and make it easier to elicit a wider range of emotions. Investigating the regulation of emotions that are more complex will be particularly important for understanding how the frontal lobes support regulation through the modulation of other neural structures. The extant work suggests that an inverse relationship between amygdala activity and regions within the frontal lobe is important for the regulation of emotion (e.g., ACC in the case of distraction and lateral orbitofrontal cortex in the case of reappraisal). However, the focus on the modulation of the

amygdala might have arisen because many of these studies focus on the regulation of reactions to negative pictures that are likely to elicit basic emotions associated with amygdala function such as fear, anger, sadness, and disgust. The investigation of more complex emotions, often called *social emotions* or *moral emotions* (e.g., pride, embarrassment, shame, guilt), could reveal different inverse relationships in cases of regulation because the generation of these emotions tend to be associated with activity in the frontal lobes (see Beer, 2007c, for a review).

Additionally, samples that include both men and women are needed for future studies of distraction and reappraisal. As was mentioned above, the neural regions associated with regulating emotional experience, whether through distraction or reappraisal, tend to be more widespread than the neural regions associated with regulating the influence of emotion on decision making. However, many of the distraction and reappraisal studies include only female participants, whereas the studies of regulated decision making typically include a more even gender balance.

Conclusion

Although emotion is a useful deviation from our homeostatic baseline, we need to flexibly regulate its experience and expression. Just as the frontal lobes permit the control of nonemotional information, they are recruited for the task of regulating our emotions. Although a strong foundation of research has identified neural regions that typically support emotion regulation, more research is needed to fully understand how these neural regions work together to allow us to feel good most of the time and avoid social banishment when those inconvenient emotions clash with societal norms.

67 Sharing the Emotions of Others: The Neural Bases of Empathy

TANIA SINGER AND SUSANNE LEIBERG

ABSTRACT With the emergence of social neuroscience, researchers have started to investigate our ability, known as empathy, to share other people's feelings. After defining empathy and delineating the difference between empathy and related concepts such as sympathy, cognitive perspective taking, and emotional contagion, we present a neuroscientific account of empathy and provide both peripheral and central neurophysiological evidence for it. We then discuss the central role of insular cortex in interoceptive awareness and empathy as well as in pathological conditions such as autism or alexithymia. After that, we show that the amplitude of empathic brain responses is modulated not only by dispositional factors, but also by contextual factors such as the attitude toward the other person or the appraisal of the situation. We conclude the chapter with suggestions for future research.

Introduction

With the emergence of social neuroscience, researchers have started to investigate the human ability to understand other people's minds, including their emotions (for reviews, see de Vignemont & Singer, 2006; Decety & Jackson, 2004; Leiberg & Anders, 2006; Preston & de Waal, 2002). The ability to share and understand others' emotions is called *empathy*. Empathy constitutes a major component of social intelligence and is essential for successful interactions in our social environment. The inability to understand what people around you are feeling would not only impair your ability to predict their future behavior, as emotions are strong motivators, but also leave you devoid of close relationships. Apart from being important on a personal level, understanding empathy and its neural underpinnings could have fundamental implications on a societal level, as empathy has been identified as a prerequisite for prosocial motivation and behavior.

In this chapter, we will first address the difficult issue of delineating the concept of empathy and provide a definition that allows us to formulate hypotheses that can be tested with neuroscientific methods and that differentiates empathy

from other, sometimes synonymously used, concepts. Second, we will present a putative neural account of empathy and review pertinent peripheral and central neurophysiological evidence. Third, we will focus on the insula, a brain structure that has been ascribed a crucial role for empathy, and discuss its empathy-related functions. Fourth, we will review studies of normal populations as well as those with deficient and superior empathic ability, respectively, to demonstrate the importance of studying individual differences to increase our understanding of the neural bases of empathy. Fifth, we will demonstrate that empathic reactions are influenced not only by dispositional, but also by contextual factors. We will conclude with a summary and an outlook on future research.

Definition

In recent years, a growing body of social neuroscience research has been devoted to delineating the neural substrates that underlie our ability to understand the beliefs, intentions, motives, and emotions of other people. In acknowledgment of the fact that our brains do not exist in isolation, but are part of a complex social environment, interactive mind paradigms have been developed to comprehensively study how inferences about others' mind states are drawn (King-Casas et al., 2005; Montague et al., 2002; Sebanz, Knoblich, Prinz, & Wascher, 2006; Singer et al., 2004, 2006; Tomlin et al., 2006). Until recently, separate lines of research have been pursued: one investigating our understanding of others' beliefs and thoughts, also referred to as *mentalizing* or *cognitive perspective taking*, another studying our ability to understand action intentions by simulating others' motor actions, and still another studying how we share others' emotions and sensations, that is, how we empathize with other people. In this chapter, we will describe the neuronal bases of empathy.

Most definitions of the term *empathy* are rather broad. However, to render empathy investigable with neuroscientific methods, a clear definition that distinguishes it from related concepts such as mentalizing, emotional contagion, sympathy, and empathic concern is crucial (see also Batson,

TANIA SINGER and SUSANNE LEIBERG Laboratory for Social and Neural Systems Research, Institute for Empirical Research in Economics, University of Zurich, Zurich, Switzerland

1991, 2008; Decety & Lamm, 2006; Eisenberg, 2000; Eisenberg & Strayer, 1987; Hoffman, 2000; Singer, 2006). De Vignemont and Singer (2006), for example, identified four constitutive factors of empathy: (1) the presence of an affective state in ourselves, (2) isomorphism between our own and another person's affective state, (3) elicitation of our affective state upon observation or imagination of another person's affective state, and (4) knowledge that the other person's affective state is the source of our own affective state. The first aspect differentiates empathy from mentalizing. The term *mentalizing* refers to the drawing of inferences about other people's mental states, including their affective states, but it does not entail emotional involvement. In contrast, empathy (i.e., the sharing of other people's emotions) does entail emotional involvement. Take psychopaths, for example: Psychopaths readily understand others' mental states, including their affective states, but lack the feeling of empathy. Recently, neuroscientific evidence has accumulated demonstrating that the abilities to empathize and to mentalize indeed rely on distinct neural networks (Blair, 2005; Hynes, Baird, & Grafton, 2006; Völlm et al., 2006).

The second aspect differentiates empathy from sympathy (Eisenberg, 2007; Wispé, 1986). Empathy involves sharing another person's emotions, while sympathy entails an emotional response that is congruent with the other person's emotion but not necessarily isomorphic. For example, when someone is angry about something, you might not share the person's anger (empathize), but you might pity him or her (sympathize).

The third aspect of de Vignemont and Singer's definition states that empathy is elicited not only by observing another person's display of emotion, but also by imagining another person's emotion (i.e., putting oneself in someone else's shoes)—for example, when you read a letter from a friend in which he or she describes a sad event or in other situations in which you cannot glean information about another person's affective state from facial, vocal, or other indicators but have to imagine the circumstances that person is facing.

The last aspect of the definition pertains to the distinction between empathy and emotional contagion. The term *emotional contagion* refers to "the tendency to automatically mimic and synchronize facial expressions, vocalizations, postures, and movements with those of another person and, consequently, to converge emotionally" (Hatfield, Cacioppo, & Rapson, 1994) and has been seen as an important precursor to empathy that is already present in infants (Hoffman, 1984). In contrast to empathy, there is no self/other distinction in emotional contagion: The person is not aware that the emotion he or she is having was elicited by the other person. To summarize, empathy shares features with concepts such as mentalizing, sympathy, and emotional conta-

gion, but we argue that only the co-occurrence of the above-mentioned factors makes an affective experience an instance of empathy.

A shared network hypothesis of empathy

How is the isomorphic affective state that we defined as empathy elicited by merely observing or imagining another person's affective state in the absence of any emotional or sensory input to our own body? Theodor Lipps (1903), who introduced the concept of empathy, assumed that we come to know about others' inner states by internally imitating their gestures and actions. This idea of motor mimicry has been revived in experimental psychology and social neuroscience. Inspired by the discovery of mirror neurons, which fire when we perform an action as well as when we merely observe someone else performing that action (Rizzolatti & Craighero, 2004), and by ideomotor theory (Hommel, Müsseler, Aschersleben, & Prinz, 2001; Prinz, 1987), which assumes that the observation of others performing motor actions automatically activates motor representations in ourselves, Preston and de Waal (2002) proposed a perception-action model of empathy. They suggested that the observation or imagination of a person in an emotional state automatically activates in the observer or imaginer a representation of that emotional state, including its associated autonomic, somatic, and motor responses. This internal simulation then aids one's understanding of the other person's emotions. Supporting evidence has been adduced by peripheral physiological as well as neuroimaging studies.

PERIPHERAL NEUROPHYSIOLOGICAL EVIDENCE FOR THE SHARED NETWORK HYPOTHESIS Assuming that activating a representation of an observed emotional state entails the activation of the associated autonomic, somatic, and motor responses renders the shared network hypothesis testable, albeit indirectly, via several means of measurement besides the central neurophysiological one. For example, electromyographic (EMG) studies have shown that looking at different emotional facial expressions evokes corresponding differential changes in facial muscle activity in the observer (Cacioppo, Petty, Losch, & Kim, 1986; Dimberg, 1982; McHugo, Lanzetta, Sullivan, Masters, & Englis, 1985; Vaughan & Lanzetta, 1980; Weyers, Muhlberger, Hefele, & Pauli, 2006). Upon viewing pictures of angry and happy facial expressions, subjects showed increased activity in the corrugator supercilii muscle and the zygomaticus major muscle, respectively (Dimberg, 1982, 1988), even when they were not conscious of which facial expressions they had seen (Dimberg, Thunberg, & Elmehed, 2000). Furthermore, longer onset latencies were observed when subjects viewed

emotional facial expressions and were then able to exhibit the opposite (as compared to the same) facial expression, suggesting that facial motor actions that have been activated concurrently with the neural representation of the depicted emotional state are inhibited (Lee, Dolan, & Critchley, 2008). Indirect evidence for the shared network hypothesis also comes from studies investigating concordance between the observer's and target's autonomic responses. Gottman and Levenson (1985) demonstrated that subjects experienced the same physiological changes when participating in a conversation themselves and when watching a videotape of that conversation later. Furthermore, when subjects watched videotapes of marital interaction and were instructed to rate the feelings of one spouse, a positive relationship was found between the synchrony of the observer's and target's heart rate changes and rating accuracy (Levenson & Ruef, 1992). Harrison, Singer, Rotshtein, Dolan, and Critchley (2006) showed that the subject's pupil size increased linearly with the pupil size of sad facial expressions they viewed.

CENTRAL NEUROPHYSIOLOGICAL EVIDENCE FOR THE SHARED NETWORK HYPOTHESIS Peripheral neurophysiological studies can provide only indirect evidence for the postulated activation of the cortical representation of an emotional state by the mere observation or imagination of another person in that emotional state. These studies measure the putatively associated motor and autonomic responses. However, the seminal discovery of mirror neurons in the premotor cortex of macaque monkeys provides a possible model for the implementation of the shared network account of empathy on a brain level. These neurons are activated both when the monkey executes certain actions and when the monkey observes the same actions being executed by others (Rizzolatti and Craighero, 2004). While this strong version of the shared network account of understanding others' motor actions (i.e., the same neural population is responsive to information from both visual and motor domains) can be proven in monkey research, it is inherently problematic to test it in humans with single-cell recordings (but see Hutchison, Davis, Lozano, Tasker, & Dostrovsky, 1999).

In neuroimaging research in the domain of action observation, a region is therefore typically considered to be part of a shared network when it is activated during self-generated actions as well as during observation of the same action performed by others. Certainly, overlapping brain activity patterns during action generation and action observation do not necessarily indicate the presence of neurons with mirror-like properties, as the overlap could also result from activation of two distinct subpopulations lying very close to each other (Dinstein, Hasson, Rubin, & Heeger, 2007; Morrison & Downing, 2007). However, the existence

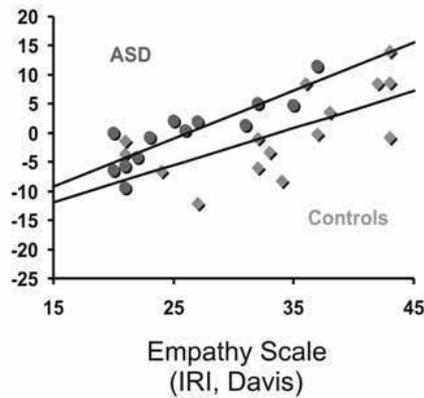

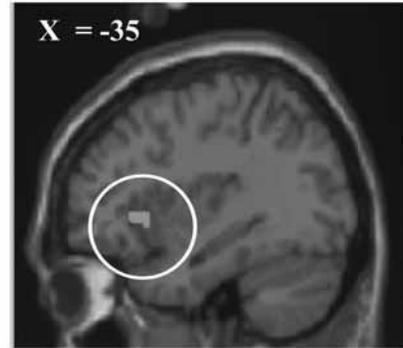

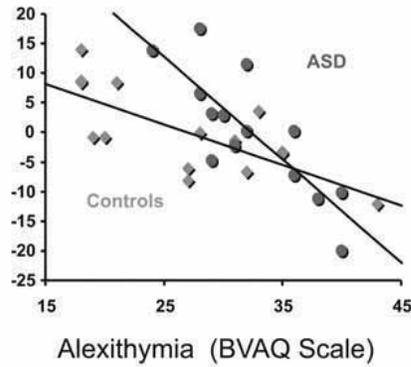

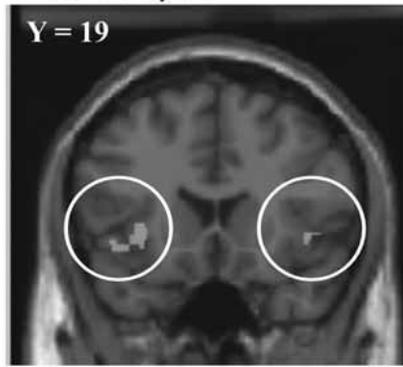

of mirror-like networks in human prefrontal and inferior parietal cortex has been ascertained by using functional magnetic resonance imaging (fMRI) (Grezes & Decety, 2001), transcranial magnetic stimulation (TMS) (Fadiga, Fogassi, Pavesi, & Rizzolatti, 1995), and magnetoencephalography (MEG) (Hari et al., 1998). These studies revealed that the same neural networks are engaged when subjects execute and observe actions.

Even though neurons with "mirror neuron" properties in the emotional domain have not yet been recorded in the monkey brain, recent fMRI studies on humans in the domain of emotions and empathy suggest that neural networks with mirror-like properties are not restricted to the motor domain or confined to the prefrontal cortex but extend to other brain areas such as somatosensory and insular cortices. Thus evidence is accumulating for the existence of shared neural networks for facial expressions, sensations, and emotions, which enable one to feel—by merely perceiving or imagining another person's sensations or emotions—what the other is feeling.

First evidence for overlapping neural activation during one's own experience and the observation of another person's experience of emotion comes from a study by Wicker and colleagues (2003). Experiencing disgust oneself upon smelling disgusting odors and observing someone else's odor-elicited expression of disgust evoked similar neural responses in the anterior insula (AI) and the anterior cingulate cortex (ACC). A recent study revealed similar overlapping AI activation when subjects drank pleasant and unpleasant drinks and when they saw someone else drinking pleasant and unpleasant drinks and producing the corresponding facial expressions (Jabbi, Swart, & Keysers, 2007).

Most studies on shared networks in the affective domain have been conducted on empathy for pain (Avenanti, Buetti, Galati, & Aglioti, 2005; Avenanti, Paluello, Bufalari, & Aglioti, 2006; Botvinick et al., 2005; Bufalari, Aprile, Avenanti, Di, & Aglioti, 2007; Cheng et al., 2007; Gu & Han, 2007; Jackson, Brunet, Meltzoff, & Decety, 2006; Jackson, Meltzoff, & Decety, 2005; Lamm, Nusbaum, Meltzoff, & Decety, 2007; Lamm, Batson, & Decety, 2007; Lamm & Decety, 2008; Moriguchi et al., 2007; Morrison, Lloyd, di Pellegrino, & Roberts, 2004; Morrison & Downing, 2007; Morrison, Peelen, & Downing, 2007; Saarela et al., 2007; Singer et al., 2004, 2006; Valeriani et al., 2008). For example, Singer and colleagues (2004) recruited couples and measured empathy in vivo by assessing brain activity in the female partner while painful stimulation was applied either to her own or to her partner's right hand via electrodes attached to the back of the hand. The male partner was seated next to the MRI scanner, and a mirror system allowed the female partner to see her own as well as her partner's hand lying on a tilted board in front of her. Differently

A Interoception

B Empathy

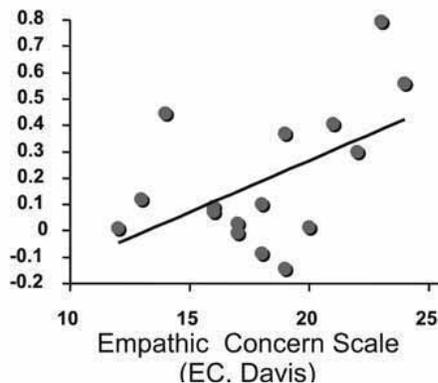

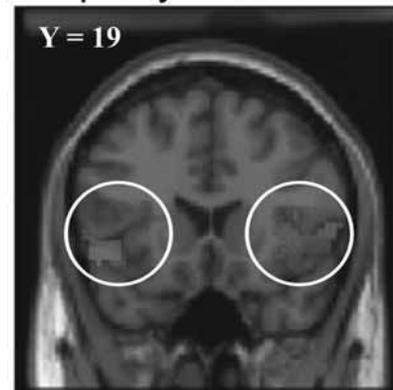

FIGURE 67.1 (A) Bilateral AI activation during interoception about one's own feelings correlates with the degree of alexithymia (measured with the Bermond-Vorst Alexithymia Questionnaire by Vorst and Bermond, 2001; BVAQ-B) and empathy (measured with the Interpersonal Reactivity Index by Davis, 1980; IRI) in healthy controls and in subjects with Asperger syndrome (adapted from Silani et al., 2008). (B) Overlapping brain activity in bilateral AI in

females experiencing pain themselves and empathizing with their partner (red; adapted from Singer et al., 2004) or an unfamiliar but likable person (pink; adapted from Singer et al., 2006) experiencing pain. Individual differences in self-reported empathy (measured with the IRI) covary with activation strengths in AI during empathizing. (From Singer et al., 2004.) (See color plate 81.)

colored flashes of light on a screen pointed to either the male or the female partner's hand, indicating which of them would receive painful stimulation and which would receive nonpainful stimulation. The results suggested that parts of the "pain matrix"—bilateral AI, the rostral ACC, brain stem, and cerebellum—were activated when subjects experienced pain themselves as well as when they saw a signal indicating that their loved one had experienced pain. These

areas are involved in the processing of the affective component of pain, that is, how unpleasant the subjectively felt pain is. Thus both the experience of pain to oneself and the knowledge that a beloved partner is experiencing pain activates the same affective pain circuits, suggesting that if a beloved partner suffers pain, our brains also make us suffer from this pain (see figure 67.1). This pattern of shared activation in AI and ACC when one is experiencing pain and

observing others in pain has now been replicated by other studies (Morrison et al., 2004; Singer et al., 2006) and is also consistently observed in studies in which subjects did not receive pain themselves but merely watched videos showing body parts in potentially painful situations (Gu & Han, 2007; Jackson et al., 2006; Jackson, Meltzoff, & Decety, 2005), painful facial expressions (Lamm, Batson, & Decety, 2007; Saarela et al., 2007), and hands being pricked by needles (Cheng et al., 2007; Lamm et al., 2007; Lamm & Decety, 2008; Morrison et al., 2004, 2007).

The finding that these empathic brain responses in the AI and the ACC correlate positively with subjects' trait empathy (Singer et al., 2004), as measured with empathy questionnaires and with unpleasantness ratings of the empathy-eliciting painful stimuli (Jackson, Meltzoff, & Decety, 2005; Lamm et al., 2007; Saarela et al., 2007), has given additional support to the claim that shared networks in the AI and the ACC underlie our ability to empathize with others' suffering (see also figure 67.1).

While fMRI studies probing empathy for pain reliably find activation of brain areas belonging to the affective part of the pain matrix, TMS (Avenanti et al., 2005, 2006), and electroencephalography studies (Bufalari et al., 2007; Valeriani et al., 2008) suggest the additional involvement of sensorimotor parts of the pain matrix in empathy for pain. These studies found reductions in motor- and laser-evoked potentials and increases in somatosensory-evoked potentials when subjects viewed needles penetrating hands. Notably, those changes in evoked potentials correlated with subjective ratings of the sensory but not the affective qualities of the pain and originated in primary and secondary somatosensory cortex. In line with an fMRI study demonstrating the coactivation of the secondary somatosensory cortex during the experience and observation of touch (Keyser et al., 2004), these findings indicate that sensorimotor aspects of pain are also mapped onto the observer's brain.

Insular involvement in interoception, emotion, and empathy

The above-mentioned studies investigating our ability to share others' feelings have ascribed a crucial role to the insula. The question arises as to what general function the insula subserves that is crucial for experiencing our own and others' emotions. We turn to early models of emotions to answer this question. According to the James-Lange theory of emotion, for example, the representation of internal bodily states is a necessary condition for emotional experience to occur. We are in love because our heart beats faster; we are sad because our eyes well up with tears. In recent years, these models have been rediscovered and extended by neuroscientists. Thus, Damasio (1994) formulated the somatic marker hypothesis, which postulates that body signals are a neces-

sary base of a hierarchy of conscious and emotional experiences as well as a crucial influence on motivational behavior especially when we are making risky decisions. More specifically, bodily arousal responses called *somatic markers* are generated in response to the risk of a negative outcome and fed back to unconsciously guide adaptive behavior in the form of "gut feelings" and "hunches."

On the basis of neuroanatomical studies on monkeys Craig (2002, 2003) has proposed that the insula, specifically the AI, underlies the representation and awareness of internal bodily states and thus interoception (i.e., one's sense of the physiological state of one's body). Craig (2002, 2003) suggested that brain afferents convey interoceptive information from the entire body to midbrain reticular nuclei that project to the ACC and posterior dorsal insula via the mediodorsal and ventromedial thalamic nucleus, respectively. The representation of the body's physiological condition in the posterior insula is remapped to the AI, where it is accessible to consciousness. Thus the concomitant projection of stimulus-induced changes in internal bodily states to the ACC and the insula allows for simultaneous awareness of visceral states and the generation of affective behavioral motivation. As the insula is reciprocally connected to multiple brain regions—among them the amygdala, the nucleus accumbens (Reynolds & Zahm, 2005), and the orbitofrontal cortex—it is ideally positioned to integrate contextual information with the bodily effects evoked by this context to a second-order conscious emotional experience. Furthermore, the higher-order representation can have a direct impact on autonomic activity via the insula's bidirectional connections to brain stem and hypothalamic nuclei (Barbas, Saha, Rempel-Clower, & Ghashghaei, 2003).

The notion that AI activity represents information about internal bodily states has been corroborated by several human fMRI studies by Critchley and colleagues. They have shown that activity in the right AI correlated with peripheral physiological indicators of arousal such as skin conductance (Critchley, Elliott, Mathias, & Dolan, 2000; Nagai, Critchley, Featherstone, Trimble, & Dolan, 2004) and cardiovascular responses (Critchley, Corfeld, et al., 2000; Critchley et al., 2005). Moreover, they reported reduced gray matter volume in the insula for patients with pure autonomic failure (PAF), a condition that entails the inability to generate autonomic arousal due to confined peripheral denervation of the autonomic nervous system (Critchley et al., 2003). In an fMRI fear-conditioning paradigm (Critchley, Mathias, & Dolan, 2002), individuals with PAF and controls evinced the typical reaction-time evidence that fear conditioning had taken place. However, subjects with PAF lacked the corresponding autonomic reactions and demonstrated reduced activity in the right middle insula. The role of the AI for interoceptive awareness was studied by introducing a second factor to the experiment, namely,

the awareness of the conditioned stimulus. Remarkably, in accordance with the hypothesis that the AI mediates the conscious experience of internal bodily states, the amygdala was activated by consciously and unconsciously perceived conditioned stimuli, whereas the AI was solely sensitive to consciously perceived conditioned stimuli. Fortifying evidence for the role of the insula in interoceptive awareness, it was demonstrated that the activity and size of the right AI were positively related to the degree to which participants were aware of their own heartbeat (Critchley, Wiens, Rotshtein, Ohman, & Dolan, 2004). Notably, the degree of interoceptive awareness and activity of the right AI were associated with self-reported negative emotional experience. This is in line with a study revealing increasing AI activity with increasing self-reported negative valence of emotional pictures (Anders, Lotze, Erb, Grodd, & Birbaumer, 2004).

The above-mentioned findings from studies addressing empathic responses suggest that the same brain structures (AI and ACC) that are crucial for representing our own affective states also play an important role in sharing the affective states of others. On the basis of this observation, Singer and colleagues (2004) extended an interoceptive model of emotions to the domain of empathy and suggested that cortical rerepresentations of internal bodily states in the AI might serve two functions. First, they might allow us to form subjective representations of our own affective states. These higher-level rerepresentations, however, allow us not only to understand our own affective states when emotional stimuli are present, but also to form forward models that let us predict the bodily effects of anticipated emotional stimuli to our own bodies. Furthermore, these representations may serve as the visceral correlate of a prospective empathic simulation of how something might feel for others. This would then help us to understand the emotional significance of a particular stimulus and its likely consequences.

Interindividual differences in healthy and clinical populations

So far, we have accrued evidence for the hypothesis that being in an affective state and observing another person in that affective state recruit overlapping brain regions and, most important, the insula. To strengthen the claim that a particular brain region does indeed play an essential role for a specific ability, the analysis of interindividual differences in this ability has proven to be a useful approach. Correlating questionnaire measures of empathy—for example, the Interpersonal Reactivity Index (IRI) (Davis, 1983) and the Balanced Emotional Empathy Scale (BEES) (Mehrabian & Epstein, 1972)—with activation strengths or structural indices as well as studying people with deficient or superior empathic abilities can yield additional indications for a functional role of the insula and other brain regions in empathy.

In this line, EMG studies have shown more pronounced mimicking behavior in subjects with high compared to low dispositional empathy when they passively viewed emotional facial expressions (Dimberg, Andreasson, & Thunberg, 2005; Sonny-Borgström, 2002). Subjects who scored high on dispositional empathy reported greater emotional responding and showed higher SCR than low-empathy subjects did when viewing an empathy-evoking film (Eisenberg et al., 1991). This confirmed earlier findings showing that high-empathy women exhibited larger SCR and more congruent facial expressions than low-empathy women did when watching videotapes of smiling, calm, and crying babies (Wiesenfeld, Whitman, & Malatesta, 1984).

As was mentioned above, analyses of empathic brain responses obtained while subjects were observing other people suffering—be it their loved ones or people they liked (Singer et al., 2004, 2006)—have revealed individual differences in activity in empathy-related pain-sensitive areas (ACC and AI) and covariations of these differences with interindividual differences in IRI and BEES scores (see figure 67.1). The higher subjects scored on these questionnaires, the higher their empathic brain activation in ACC and AI. Interestingly, Jabbi and colleagues (2007) observed similar correlations between IRI subscales and empathic brain responses in the AI in subjects who had observed others tasting pleasant or unpleasant drinks associated with facial expressions of joy or disgust, respectively. Empathic brain responses correlated positively not only with trait measures of empathy, but also with unpleasantness ratings that subjects gave after each trial of an empathy-inducing condition (Jackson, Meltzoff, & Decety, 2005; Lamm et al., 2007; Saarela et al., 2007).

Another way to investigate individual differences in empathy is to study experts in empathizing. Thus, for example, functional and structural changes in empathy-related brain areas have been found in people with a high degree of empathy stemming from long-term compassion meditation. In a recent study based on 15 long-term practitioners, Lutz, Brefczynski-Lewis, Johnstone, and Davidson (2008) demonstrated that during compassion meditation, insula activation by emotional as compared to neutral sounds was stronger in long-term meditators than in novice meditators. This illustrates the malleability of the neural systems underlying empathy and the role of the insula in affect sharing. Similarly, long-term meditators had significantly thicker cortex (Lazar et al., 2005) and greater gray matter volume in the AI (Hölzel et al., 2008).

In contrast to these studies on superior empathic ability, other studies have investigated the deficient empathic ability that is presumed to exist in several psychiatric disorders such as psychopathy and autism (Decety & Moriguchi, 2007). The study of these deficits not only is pertinent for the development of effective therapeutic strategies to treat these

conditions, but also informs us about the mechanisms underlying empathy in the healthy population.

Psychopathy is characterized by a lack of empathy, lack of guilt, and poor behavioral control, a precursor for aggressive behavior (Hare, 1991). Interestingly, people with psychopathy are known to show normal mentalizing ability but seem to lack the ability to empathize with others. Behavioral studies on psychopaths have found selective emotional dysfunction, such as impairment in aversive conditioning, autonomic response to threat, augmentation of the startle reflex to visual threat primes, impaired processing, and altered autonomic response to sad and fearful facial and vocal expressions (Blair, Colledge, Murray, & Mitchell, 2001; Flor, Birbaumer, Hermann, Ziegler, & Patrick, 2002; Levenston, Patrick, Bradley, & Lang, 2000). These deficits have been ascribed to amygdala dysfunction. Indeed, psychopathy is related to reduced gray matter volume in the amygdala (Tiihonen et al., 2000) and reduced amygdala activity during emotional memory (Kiehl et al., 2001) and aversive conditioning (Birbaumer et al., 2005; Veit et al., 2002). Hypoactivation during aversive conditioning in psychopaths has also been observed in the AI (Birbaumer et al., 2005). Importantly, Sterzer, Stadler, Poustka, and Kleinschmidt (2007) found reduced gray matter volume in the amygdala and AI in adolescents with conduct disorder as compared to normal controls. The gray matter volume in bilateral AI but not the amygdala correlated negatively with the empathy scores and observed aggressive behavior, underscoring the important role of insular cortex for the representation of affective states and subsequent appropriate empathic behavior. In a similar vein, boys with disruptive behavior disorder have been found to show lower scores on an empathy questionnaire and significantly less corrugator supercilii activity to angry expressions than did age-matched healthy controls, supporting the notion that deviant social behavior might be a result of diminished empathic responding (de Wied, van Boxtel, Zaalberg, Goudena, & Matthys, 2006). Even though these findings suggest that individuals with psychopathy have empathy deficits but normal mentalizing ability, future neuroimaging studies involving explicit empathy and mentalizing tasks with the same subjects will have to be performed to support this assumption.

Recent studies suggest that, in contrast to psychopathy, autism is associated with a lack of mentalizing ability (for a review, see Frith, 2001) but not necessarily a lack of empathy. Autism is a developmental disorder characterized by deficits in social abilities as well as in language skills (Kanner, 1943). Neuroimaging studies have revealed reduced activation in mentalizing-related brain areas such as the medial prefrontal cortex, the superior temporal sulcus, the temporoparietal junction, and the temporal poles when autistic subjects make inferences about others' mental states (Castelli, Frith, Happe, & Frith, 2002; Happe et al., 1996). The question concerning

whether all people with autism have empathy deficits was the subject of a recent discussion (Silani et al., 2008). The inconclusiveness concerning this question might arise from the fact that so far, studies investigating empathy in individuals with autism have not differentiated between subjects with and without alexithymia. Alexithymia, which is present in 50% of the high-functioning patients with autism or Asperger syndrome (Hill, Berthoz, & Frith, 2004), is a condition marked by impaired identification and description of feelings and differentiation of feelings from bodily signals. If we turn to the shared network hypothesis of empathy, which states that representations of one's own emotional states are obligatory for the ability to share others' emotions, an interesting prediction arises: Deficits in understanding one's own emotions, as present in alexithymia, should lead to empathy deficits and be correlated with reduced insula activation. Furthermore, might the prevalence of alexithymia in autism explain the sometimes found empathy deficits in autistic subjects? Silani and colleagues (2008) tested the assumption that subjects with Asperger syndrome and alexithymia, but not subjects with Asperger syndrome but not alexithymia, would evince reduced insula activation when introspecting about their own emotions. As depicted in figure 67.2, this study revealed that when subjects were to judge their own feelings while viewing emotional pictures, the degree of alexithymia but not autism was associated with less activation in the AI. Interestingly, individual differences in the degree of alexithymia correlated highly negatively with individual differences in trait empathy, and levels of both alexithymia and empathy were predictive of AI activation during introspection. These findings are in line with the prediction that deficits in understanding one's own emotions result in empathy deficits and that both should be correlated with lesser activation of the AI. Furthermore, autism per se does not seem to be associated with deficient empathy, but the comorbidity with alexithymia does. This notion awaits further support by studies that are trying to dissociate empathizing from mentalizing abilities using the appropriate paradigms.

The modulation of empathy

The shared network account of empathy and related empirical work presented above might suggest that empathizing proceeds in an automatic manner, albeit modulated by dispositional empathy. Every time we observe or imagine the affective state of another person, we unconsciously share it. However, in line with social psychological research (Batson, Lishner, Cook, & Sawyer, 2005; Zaki, Bolger, & Ochsner, 2008), social neuroscience has accumulated evidence that empathic responses not only underlie the influence of dispositional factors, but also might be modulated by contextual and stimulus-inherent factors and appraisal processes.

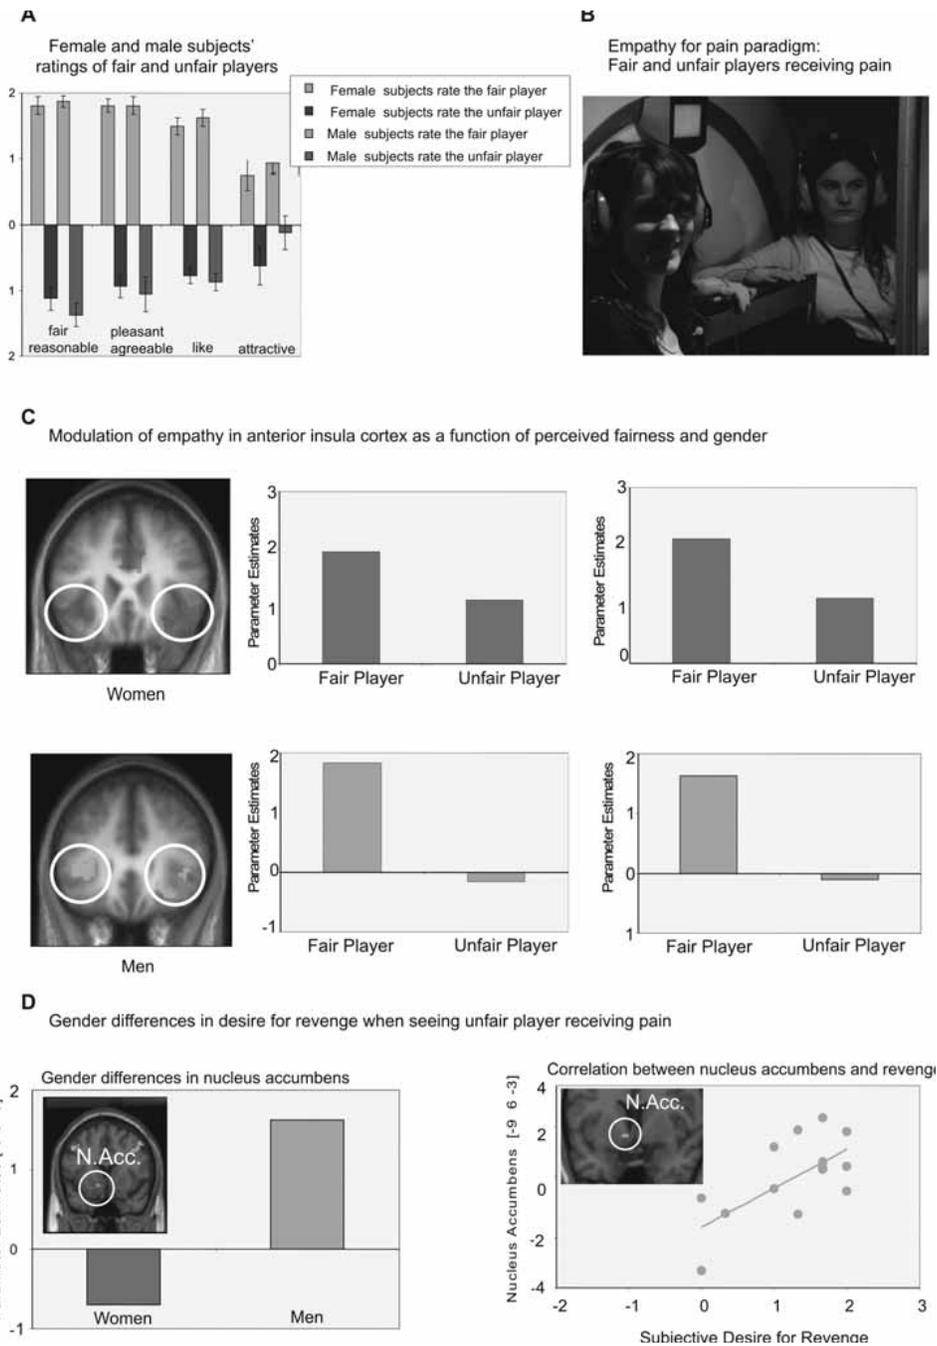

FIGURE 67.2 Modulation of empathic brain responses by perceived fairness (adapted from Singer et al., 2006). (A) Female (pink) and male (blue) subject's postscan ratings of perceived fairness, agreeableness, likeability, and attractiveness of the two confederates, who had always played fairly and unfairly, respectively, in a preceding monetary economic trust game. (B) Setup of the empathy-for-pain paradigm with the subject lying in the scanner and one fair and one unfair player (both confederates) sitting on either side of the scanner. Electrodes, which were attached to one of their hands, delivered painful or nonpainful stimulation as previously indicated by flashes on a screen in front of them. (C) Empathic

brain activation in bilateral frontoinsula cortex when males (blue) and females (pink) perceived either the fair or the unfair player suffering pain. Although both men and women showed empathic brain activity in frontoinsula cortex when they perceived a fair player in pain, only women did so when they perceived an unfair player in pain. (D) Enhanced activation in nucleus accumbens in men, but not in women, when they perceived unfair as compared to fair players suffering pain. The strength of this activation correlated positively with men's, but not women's, degree of subjectively expressed desire for revenge. (See color plate 82.)

Although facial mimicry has been considered automatic and hard-wired in that it is elicited even without subjects' awareness of the eliciting stimuli, it has been shown that experimentally induced attitudes toward computer avatars modulated the imitative EMG responses (Likowski, Mühlberger, Seibt, Pauli, & Weyers, 2008). A positive attitude toward the avatars evoked facial EMG responses that were congruent with their emotional expressions, whereas a negative attitude resulted in reduced or incongruent facial EMG responses. Furthermore, facial EMG responses have also been shown to be influenced by social group membership (Bourgeois & Hess, 2008; negative emotions were mimicked only when shown by in-group members), one's own affective state (Moody, McIntosh, Mann, & Weisser, 2007), and expectations (Lanzetta & Englis, 1989). Lanzetta and Englis (1989) found a striking influence of context on facial imitation during social interaction. Depending on whether subjects believed that they were cooperating or competing with a co-player in an investment game, their EMG responses were either congruent or incongruent with the co-player's facial expressions. Notably, the only difference between the cooperative and competitive setting was the subject's expectation. The behavior of the co-player as well as the gains and losses were fixed by a computer.

In a similar vein, but using fMRI, Singer and colleagues (2006) demonstrated the modulation of empathic brain responses by the perceived fairness of the other person. In this study, subjects first played a sequential prisoner's dilemma game with two confederates. One confederate played fairly; the other played unfairly. Subsequently, the three participated in a modified version of the empathy-for-pain paradigm by Singer and colleagues (2004) introduced above (see figure 67.2B). This time, subject's empathic brain responses were measured while either the subject or one of the confederates was receiving painful stimulation. When the fair player was in pain, empathy-related activation was observed in the subject's AI and the ACC (the latter only in women), again overlapping with activity evoked by the subject experiencing pain himself or herself. However, when observing the unfair player in pain, male, but not female, subjects showed an absence of such empathic activity (see figure 67.2C). Instead, men showed increased activation in the reward-related nucleus accumbens, which correlated positively with their desire for revenge as assessed by questionnaires after the scanning session (see figure 67.2D). This suggests that at least in men, empathic responding is modulated by perceived personality characteristics of the other person.

Other factors that have been identified by fMRI studies as contributing to intraindividual variation in empathic brain responses are the attention allocated to the stimulus, stimulus reality (Gu & Han, 2007), the subject's appraisal of whether the reason the other person is suffering is justified

(Lamm, Batson, & Decety, 2007), and the subject's prior experience with the situation (Cheng et al., 2007). Measuring evoked potentials, Aglioti's group demonstrated a modulatory role of stimulus intensity in that needles penetrating a hand yielded a reduction in motor excitability, whereas needles merely giving a hand a pinprick did not (Avenanti et al., 2006). Furthermore, they showed an influence of being in pain oneself on the brain responses evoked by seeing someone else in pain (Valeriani et al., 2008). Strikingly, not the perceived pain of the model, but the subject's own pain, was predictive of a brain response reduction, which has been associated with empathy. This suggests that people represent others' sensations and emotions more in line with their own feelings than with the other person's feelings.

Neuroscientific research has adduced considerable evidence for the modulation of empathic responses. This brings us to the question: Does this modulation occur before or during an empathic response? De Vignemont and Singer (2006) proposed two possible routes for the influence of appraisal processes. Either an empathic response is automatically initiated by an emotional cue and later modulated by contextual information or the emotional cue is first evaluated in its context and, depending on the outcome of the evaluation, either no empathic response or an enhanced or reduced empathic response is elicited. In the latter model, no automatic initiation of empathic responses occurs. The temporal resolution of fMRI is too coarse to distinguish between these two routes. Hence, electromagnetic studies need to be undertaken to address the timing of modulatory input.

Summary and conclusion

In recent years, major advances have been made in social neuroscience to study empathy in an ecologically valid way and to delineate its causes; underlying neural substrates; and autonomic, peripheral physiological, and behavioral consequences. We share and understand other people's affective states by means of shared affective neural networks that are activated when we experience an affective state as well as when we observe someone else experiencing an affective state. Thus an internal simulation of our own emotions is triggered by observing others' emotions, which provides the basis for understanding others' affective states. It remains to be seen whether the activation of a representation of another person's emotional state is necessary and sufficient for correctly understanding the other person's emotion. So far, the results concerning the relationship between activated representations, subjective feelings, and empathic accuracy are equivocal. There is initial evidence showing that the representation evoked by observing another person's affective state is biased by one's own affective state—a tendency called *egocentricity bias*.

Apart from one's own affective state, other factors have also been shown to modulate empathic responses. Hence, although shared representations might be evoked fairly automatically, they are nevertheless amenable to modulatory input. Future research needs to determine further modulatory factors and when they take effect. Are empathic brain responses modulated from the beginning, or are they influenced at a later point in time? MEG or EEG, with their excellent temporal resolution, or TMS might provide conclusive evidence here.

Neuroimaging studies of empathy have thus far exclusively investigated how we share the *negative* affective states of others, such as pain or disgust. One notable exception is the study by Jabbi and colleagues (2007), which addressed empathy for positive and negative emotions evoked by gustatory stimuli. Interestingly, as in empathy for pain or disgust, the AI showed overlapping activity for experiencing a positive affective state and observing someone else experiencing a positive affective state. Does the insula provide a general emotion-independent neural substrate of empathy, or do distinct neural populations in the insula code for negative and positive affective states? In this line, Craig (2005) proposed that left AI activation is predominantly associated with parasympathetic activity and thus is more closely related to positive affect, approach, and affiliative emotional behavior. In contrast, right AI may be preferentially coupled with efferent sympathetic activity and thus with arousal, negative affect, withdrawal, and survival-related behaviors. Empirical evidence, however, points to an alternative hypothesis: Negative affective states are mainly represented in the anterior part of the insula, whereas positive affective states are represented in the middle insula (Bartels & Zeki, 2004; Gray, Harrison, Wiens, & Critchley, 2007; Lutz et al., 2008). Jabbi and colleagues (2007) showed a correlation of dispositional empathy with bilateral AI activity during observation of disgusted faces and with left AI during observation of happy faces, thus tentatively supporting Craig's hypothesis. However, the search volume in this study was confined to the anterior part of the insula. Hence the question concerning which parts of the insula represent negative and positive affective states awaits further research.

The ability to empathize varies from person to person. This variation not only is reflected in self-reports of dispositional empathy, but is also related to differences in facial mimicry and neural activation in empathy-related brain areas such as the AI and the ACC. Two important issues still need to be clarified: First, can empathic ability be enhanced by means of training? Second, how is empathic ability related to prosocial behavior? Training-induced functional and structural brain changes in humans have been shown in a variety of domains, such as spatial navigation

(Maguire et al., 2000), motor (Draganski et al., 2004) and musical training (Besson, Schon, Moreno, Santos, & Magne, 2007), and memory (Draganski et al., 2006). However, no study demonstrating the effects of empathy training on cortical plasticity and behavior has ever been published. Studies reporting structural and functional brain changes in long-term compassion meditators suggest that affective neural networks are malleable. Evidence for positive neural and behavioral effects of empathy training could have important implications for therapeutic approaches to clinical conditions involving empathy deficits as well as for general education.

In social psychology, investigation of the link between empathy and prosocial behavior has a long history (Batson, 1998; Eisenberg & Fabes, 1991). It has been suggested that sharing another person's affect can lead either to empathic concern/sympathy, which is an other-oriented response or to personal distress, depending on one's emotion regulation ability and intensity of engagement with the other person. Empathic concern/sympathy increases prosocial action tendencies, whereas personal distress results in self-oriented responses, such as fleeing the scene, to alleviate one's own distress. Disentangling these two concepts and increasing our understanding of the neural bases of prosocial behavior are pertinent tasks for social neuroscience. It is conceivable that both empathic concern and personal distress are represented in the insula, since both entail interoceptive changes. However, the former can be construed as a positive affective response (e.g., related to love) and the latter as a negative affective response. Therefore the above-mentioned investigation of the neural substrates underlying positive affective states might also yield important insight pertaining to this differentiation. The social neuroscientific study of prosocial behavior is hampered by the lack of suitable experimental paradigms that are applicable to neuroscientific methods. Promising approaches might include the use of virtual reality and economic games. The latter have recently been used in neuroeconomic studies investigating the neural mechanisms underlying decision making in economic settings (de Quervain et al., 2004; Harbaugh, Mayr, & Burghart, 2007; Rilling, Sanfey, Aronson, Nystrom, & Cohen, 2004; Sanfey, Rilling, Aronson, Nystrom, & Cohen, 2003) and prosocial behavior (Moll et al., 2006). An integration of paradigms derived from the two emerging fields of social neuroscience and neuroeconomics would allow us to further specify the role of different social emotions such as empathy, our sense of fairness, and our desire for revenge in motivating prosocial and antisocial behavior.

68 The Cognitive Neuroscience of Moral Judgment

JOSHUA D. GREENE

ABSTRACT This article reviews recent advances in the cognitive neuroscience of moral judgment. The field began with studies of individuals who exhibit abnormal moral behavior, including neurological patients and psychopaths. Such studies continue to provide valuable insights, particularly concerning the role of emotion in moral decision making. Recent functional neuroimaging studies of normal individuals have identified neural correlates of specific emotional processes relevant to moral judgment. A range of studies using diverse methods support a dual-process theory of moral judgment according to which utilitarian moral judgments (favoring the “greater good” over individual rights) are enabled by controlled cognitive processes, while deontological judgments (favoring individual rights) are driven by intuitive emotional responses. Several recent neuroimaging studies focus on the neural bases of mental state attribution in the context of moral judgment. Finally, research in the field of neuroeconomics has focused on neural processing related to cooperation, trust, and fairness.

The aim of cognitive neuroscience is to understand the mind in physical terms. This endeavor assumes that the mind *can* be understood in physical terms and, insofar as it is successful, validates that assumption. Against this philosophical backdrop, the cognitive neuroscience of moral judgment takes on special significance. Moral judgment is, for many, the quintessential operation of the mind beyond the body, the earthly signature of the soul (Greene, in press). (In many religious traditions, it is, after all, the quality of a soul’s moral judgment that determines where it ends up.) Thus the prospect of understanding moral judgment in physical terms is especially alluring or unsettling, depending on your point of view.

In this brief review, I provide a progress report on our attempts to understand how the human brain makes moral judgments. In recent years, we have continued to learn valuable lessons from individuals whose abnormal brains dispose them to abnormal social behavior. We have developed new moral-psychological testing materials and have used them to dissociate and characterize the affective and cognitive processes that shape moral decisions. Finally, the field of neuroeconomics has brought a welcome dose of ecological

validity to the study of moral decision making. I discuss each of these developments below. (Important and relevant developments in other fields, such as animal behavior and developmental psychology (de Waal, 2006; Hamlin, Wynn, & Bloom, 2007; Warneken, Hare, Melis, Hanus, & Tomasello, 2007), are beyond the scope of this article.)

Bad brains

In the 1990s, Damasio and colleagues published a series of path-breaking studies of decision making in patients with damage to ventromedial prefrontal cortex (VMPFC), one of the regions that was damaged in the famous case of Phineas Gage (Damasio, 1994; Macmillan, 2000). VMPFC patients were mysterious because their real-life decision making was clearly impaired by their lesions, but their deficits typically evaded detection when standard neurological measures of executive function were used (Saver & Damasio, 1991). Notably, such patients showed no sign of impairment on Kohlberg’s (Colby & Kohlberg, 1987) widely used test of moral reasoning (Anderson, Bechara, Damasio, Tranel, & Damasio, 1999). Using a game designed to simulate real-world risky decision making (the Iowa Gambling Task), Bechara, Tranel, Damasio, and Damasio (1996) documented these behavioral deficits and demonstrated, using autonomic measures, that these deficits are emotional. It seems that such patients make poor decisions because they are unable to generate the feelings that guide adaptive decision making in healthy individuals.

A later study targeting moral judgment (Anderson et al., 1999) compared patients with adult-onset VMPFC damage to two patients who had acquired VMPFC damage as young children. While the late-onset patients make poor real-life decisions (e.g., neglecting relatives and friends, involvement in shady business ventures), indicating a deterioration of “moral character” (Damasio, 1994), their behavior tended to harm themselves as much as others. The early-onset patients, however, developed into “sociopathic” adults who, in addition to being irresponsible and prone to risk taking, were duplicitous, aggressive, and strikingly lacking in empathy. Furthermore, these two patients, unlike the late-onset patients, exhibited a childlike “preconventional” pattern of

JOSHUA D. GREENE Department of Psychology, Harvard University, Cambridge, Massachusetts

moral judgment, reasoning about moral issues from an egocentric perspective that focused on reward and punishment. This result suggests a critical role for emotion in moral development. The late-onset patients are prone toward bad decision making, but thanks to a lifetime of emotional experience, they are not truly sociopathic. The early-onset patients, in contrast, lacked the emotional responses necessary to learn the basics of human moral behavior (see also Grattan & Eslinger, 1992).

Studies of psychopaths and other individuals with antisocial personality disorder (APD) underscore the importance of emotion in moral decision making. APD is a catch-all diagnosis for individuals whose behavior is unusually antisocial. Psychopathy, in contrast, is a more specific, somewhat heritable (Blonigen, Hicks, Krueger, Patrick, & Iacono, 2005; Viding, Blair, Moffitt, & Plomin, 2005) disorder whereby individuals exhibit a pathological degree of callousness, lack of empathy or emotional depth, and lack of genuine remorse for their antisocial actions (Hare, 1991). Psychopaths tend to engage in instrumental aggression, while other individuals with APD are characterized by reactive aggression (Berkowitz, 1993; Blair, 2001).

Psychopathy is characterized by profound but selective emotional deficits. Psychopaths exhibit normal electrodermal responses to threat cues (e.g., a picture of shark's open mouth) but reduced responses to distress cues (e.g., a picture of a crying child) (Blair, Jones, Clark, & Smith, 1997). In a particularly revealing study, Blair (1995) demonstrated that psychopaths fail to distinguish between rules that authorities cannot legitimately change ("moral" rules, such as a classroom rule against hitting) and rules that authorities can legitimately change ("conventional" rules, such as a rule prohibiting talking out of turn). According to Blair, psychopaths see all rules as *mere* rules because they lack the emotional responses that lead ordinary people to imbue moral rules with genuine, authority-independent moral legitimacy.

Findings concerning the specific neural bases of psychopathy and APD are varied, implicating a wide range of brain regions, including the orbital frontal cortex (OFC)/VMPFC, insula, anterior cingulate cortex (ACC), posterior cingulate cortex (PCC), amygdala, parahippocampal gyrus, and superior temporal gyrus (Kiehl, 2006; Raine & Yang, 2006; Muller et al., 2008). Blair (2004, 2007) has proposed that psychopathy arises primarily from amygdala dysfunction, which is crucial for stimulus-reinforcement learning (Davis & Whalen, 2001) and thus for normal moral socialization (Oxford, Cavell, & Hughes, 2003). The amygdala exhibits reduced activity in psychopaths both in nonmoral contexts (e.g., in response to emotional words (Kiehl et al., 2001)) and in sociomoral contexts (e.g., during cooperative behavior in a prisoner's dilemma game (Rilling et al., 2007)). Consistent with this view, Yang, Raine, Narr, Lencz, and Toga (2006) found reduced amygdala volume in psychopaths.

The VMPFC, which is known to work in concert with the amygdala (Diergaarde, Gerrits, Brouwers, & van Ree, 2005; Schoenbaum & Roesch, 2005), also exhibits many of these effects and appears to play a role in (mis)representing the value of behavioral outcomes in psychopathy (Blair, 2007).

A broader suite of brain regions have been implicated in APD (Raine & Yang, 2006), suggesting, among other things, more general deficits in prefrontal function (Raine et al., 1994). These may be due to structural abnormalities involving reduced prefrontal gray matter (Raine, Lencz, Bihrlé, LaCasse, & Colletti, 2000; Yang et al., 2005). There is some evidence implicating abnormal function in dorsolateral prefrontal cortex (DLPFC) in patients with APD (Schneider et al., 2000; Vollm, Richardson, & Stirling, 2004) but not in patients with psychopathy. Given the DLPFC's role in cognitive control (Miller & Cohen, 2001), this is consistent with the notion that psychopaths' aggression results from lack of empathy for others rather than poor impulse control.

Mapping moral emotion

Consistent with research on APD and in keeping with a broader trend in moral psychology (Haidt, 2001), most research using functional imaging to study morality has focused on mapping the "where" and "when" of moral emotion in the brain. Some early studies compared moral and nonmoral stimuli (Moll, Eslinger, & Oliveira-Souza, 2001; Moll, de Oliveira-Souza, Bramati, & Grafman, 2002; Moll, de Oliveira-Souza, Eslinger, et al., 2002) and identified a suite of brain regions that are sensitive to moral stimuli, including the OFC, mPFC, frontal pole, PCC/precuneus, superior temporal sulcus (STS), and temporal pole. This approach, while informative, depends critically on the choice of nonmoral control stimuli and the assumption that the observed results are in some way specific to morality (Greene & Haidt, 2002). More recent functional imaging studies have focused on identifying and functionally characterizing different kinds of moral-emotional processes.

EMPATHY, CARING, AND HARM Greene, Sommerville, Nystrom, Darley, and Cohen (2001) identified a set of brain regions associated with judging actions involving "personal," as compared to "impersonal," harm: mPFC (BA 9/10), the PCC/Precuneus (BA 31), and the posterior superior temporal sulcus (pSTS)/temporoparietal junction (TPJ)/angular gyrus (BA 39). (See figures 68.1 and 68.2 and the section entitled "Dual-Process Morality" below for more details.) A study replicating these results using a larger sample (Greene, Nystrom, Engell, Darley, & Cohen, 2004) identified the same effect in the amygdala, among other regions. The aforementioned regions are implicated in emotional processing (Maddock, 1999; Phan, Wager, Taylor, &

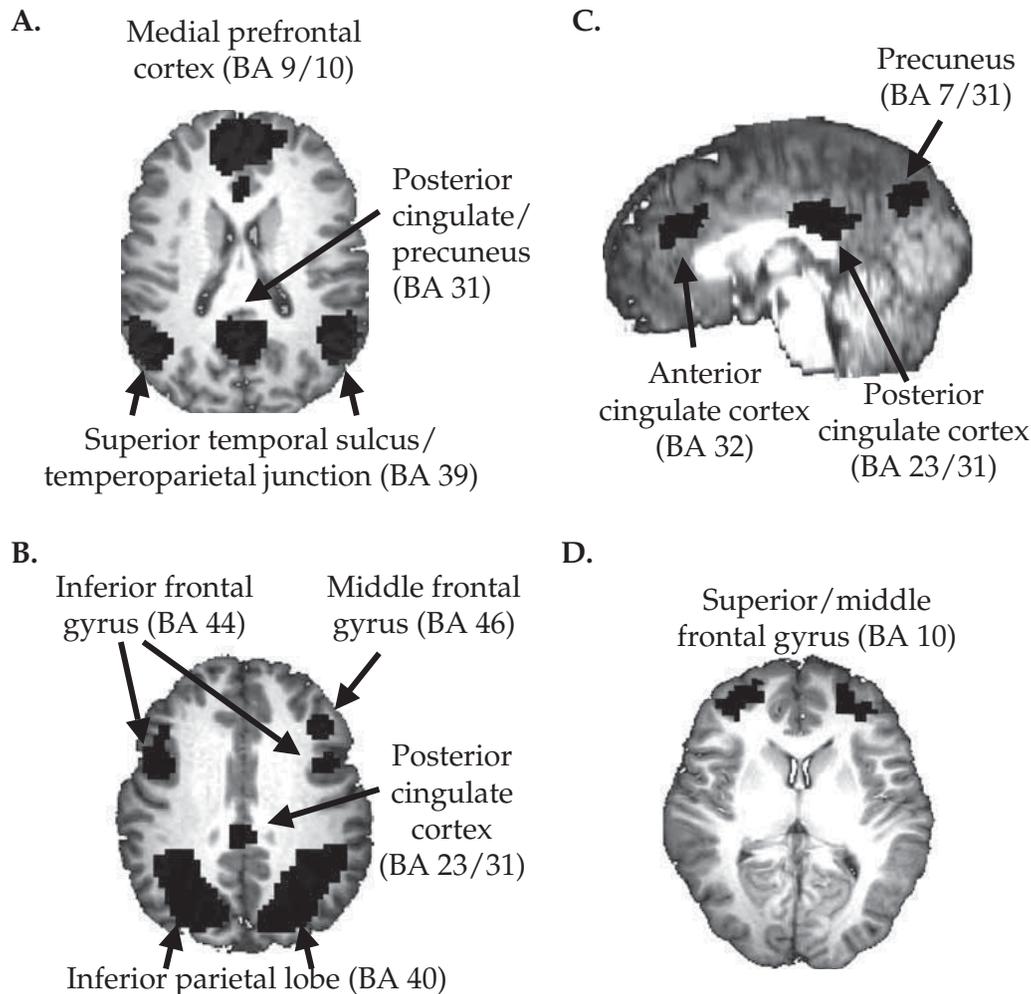

FIGURE 68.1 (A) Brain regions exhibiting greater activity in response to personal, as compared to impersonal, moral dilemmas. These regions are part of the “default network” (Gusnard & Raichle, 2001) and are widely activated in many functional imaging studies of moral judgment. (B) Brain regions exhibiting greater activity in response to impersonal, as compared to personal, moral dilemmas. (C) Brain regions exhibiting greater activity in response

to difficult (high-conflict) personal moral dilemmas, as compared to easy (low-conflict) personal moral dilemmas. (D) Brain regions exhibiting greater activity in association with utilitarian, as compared to deontological/nonutilitarian moral judgment. (Data are from Greene et al., 2004, Data in panels A–B replicate effects originally reported in Greene et al., 2001.)

Liberzon, 2002; Adolphs, 2003) as well as in theory of mind (ToM) (Frith, 2001; Adolphs, 2003; Amodio & Frith, 2006; Young, Cushman, Hauser, & Saxe, 2007). These regions, with the exception of the amygdala, are also part of the “default network” (Gusnard & Raichle, 2001; Fox et al., 2005), a set of brain regions that exhibits relatively high levels of tonic activity and that reliably decreases in activity during outwardly directed tasks. Parts of this network are also implicated in self-referential processing (Akbulak, Shulman, & Raichle, 2001; Kelley et al., 2002), episodic memory, “prospection” (Buckner & Carrol, 2007; Schacter, Addis, & Buckner, 2007), and mind-wandering (Mason et al., 2007). A persistent theme among these processes is the representation of events beyond the observable here and now, such as past, future, and imagined events and mental states. Thus

the activity that is observed in this network during the contemplation of dilemmas involving “personal” harm is probably related to the fact that these stimuli involve such nonsensory representations, although this alone does not explain why “personal” dilemmas engage this network more than “impersonal” ones. Consistent with this idea, the functional imaging studies of moral judgment that have most robustly engaged this network involve more complex, text-based, narrative stimuli (Greene et al., 2001, 2004; Schaich Borg et al., 2006, 2008; Robertson et al., 2007; Young et al., 2007; Greene et al., 2009b, 2009c; Schaich Borg, Lieberman, & Kiehl, 2008; Young & Saxe, 2008; Kedia, Berthoz, Wessa, Hilton, & Martinot, 2008).

Several studies have focused on neural responses to different types of harm. Luo and colleagues (2006) found that

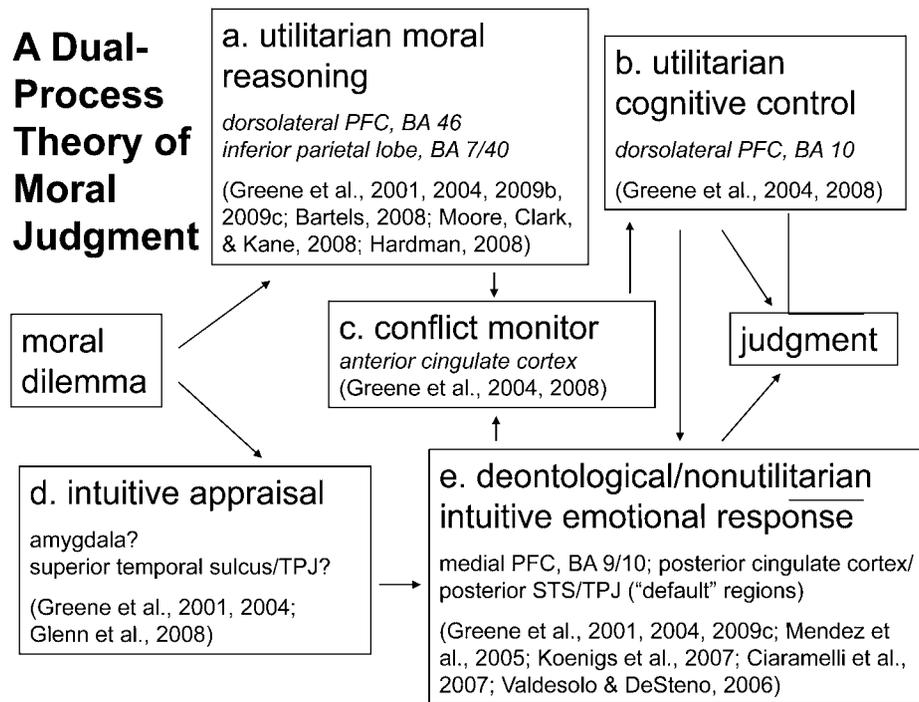

FIGURE 68.2 Diagram of Greene and colleagues' dual-process theory of moral judgment. Boxes a–e describe psychological processes, candidate neural substrates, and references to supporting evidence.

the right amygdala and left VMPFC are sensitive to the intensity of harm displayed in pictures, and Heekeren and colleagues (2005) found that the amygdala exhibits increased activity in response to narratives involving bodily harm. An earlier study (Heekeren et al., 2003) found no effects in the amygdala using stimuli devoid of violence. Finally, individuals with high psychopathy scores exhibited decreased amygdala activity during the contemplation of moral dilemmas involving “personal” harm (Glenn, Raine, & Schug, 2008). Thus the evidence from functional imaging suggests that the amygdala plays an important role in triggering emotional responses to physically harmful actions.

SPECIFIC EMOTIONS Several studies of moral judgment have focused on specific moral emotions, including moral disgust (Rozin, Lowery, & Ebert, 1994; Rozin, Lowery, Imada, & Haidt, 1999; Wheatley & Haidt, 2005). Moll and colleagues (2005) identified a number of brain regions that are sensitive to core/pathogen disgust in moral contexts. A more recent study (Schaich Borg et al., 2008) compared disgust in response to incestuous acts to pathogen disgust and moral transgressions of a nonsexual nature. Stimuli describing nonsexual moral transgressions (e.g., lying, cheating, stealing), as compared to pathogen-disgust stimuli, elicited increased activity in the familiar mPFC/PCC/TPJ network but also in the frontal pole/DLPFC and the ACC. Incest descriptions, as compared to descriptions of nonsexual moral transgressions, elicited increased activity in

the mPFC/PCC/TPJ network and other regions, including the inferior frontal gyrus, the left insula, the ventral and dorsal ACC, the left amygdala, and the caudate nucleus. Perhaps surprisingly (Phillips et al., 1997; Calder, Lawrence, & Young, 2001), the insula was preferentially activated only in the incest condition.

Other studies have focused on social emotions such as guilt, embarrassment, shame, pride, empathy, and anger. Robertson and colleagues (2007) found that stimuli associated with care-based morality, as compared to justice-based morality, elicited greater activity in the mPFC and OFC, while the reverse effect was observed in the intraparietal sulcus. In a notably clever study, Beer, Heerey, Keltner, Scabini, and Knight (2003) observed that patients with OFC damage exhibited an inappropriate lack of embarrassment when given an opportunity to disclose personal information, inappropriate embarrassment when overpraised for an unremarkable performance on a simple task, and inappropriate pride and lack of embarrassment when describing the nickname they had invented for the experimenter. Berthoz, Grezes, Armony, Passingham, and Dolan (2006) found that the amygdala is especially responsive to the evaluation of intentional transgressions committed (hypothetically) by oneself (guilt), while Kedia and colleagues (2008) observed increased activity in the mPFC, precuneus, and TPJ for evaluations of transgressions involving others (guilt, anger, compassion). These researchers also observed increased activity in the amygdala, ACC, and basal ganglia for trans-

gressions in which both the self and another are involved (guilt, anger) (see also Shin et al., 2000; Berthoz, Armony, Blair, & Dolan, 2002; Takahashi et al., 2004).

MORAL EMOTION IN CONTEXT Other studies have examined the contextual modulation of moral emotion. King, Blair, Mitchell, Dolan, and Burgess (2006) used a custom-designed video game to examine violent versus compassionate behavior in situations in which the behavior is either appropriate (harming an aggressive enemy, helping a distressed innocent person) or inappropriate (helping an aggressive enemy, harming a distressed innocent person). They found that appropriate behavior (whether violent or compassionate) was associated with increased activity in the amygdala and VMPFC. Harenski and Hamann (2006) found that increased mPFC activity and decreased amygdala activity were specifically associated with moral emotion-regulation. Finally, Finger, Marsh, Kamel, Mitchell, and Blair (2006) found that stimuli describing moral/social transgressions committed in the presence of an audience elicited increased activity in the amygdala, underscoring the importance of the amygdala in the social regulation of transgressive behavior (Blair, 2007).

Dual-process morality

The research described above emphasizes the role of emotion in moral judgment (Haidt, 2001), while traditional theories of moral development emphasize the role of controlled cognition (Kohlberg, 1969; Turiel, 2006). My collaborators and I have developed a dual-process theory (Kohlberg, 1969; Posner & Snyder, 1975; Chaiken & Trope, 1999; Lieberman, Gaunt, Gilbert, & Trope, 2002; Kahneman, 2003) of moral judgment that synthesizes these perspectives (see Figure 68.2). According to this theory, both intuitive emotional responses and more controlled cognitive responses play crucial and, in some cases, mutually competitive roles. More specifically, this theory associates controlled cognitive processing with utilitarian (or consequentialist) moral judgment aimed at promoting the “greater good” (Mill, 1861/1998). In contrast, this theory associates intuitive emotional processing with deontological judgment aimed at respecting rights, duties, and obligations (Kant, 1785/1959) that may trump the greater good.

We developed this theory in response to a longstanding philosophical puzzle known as the trolley problem (Foot, 1978; Thomson, 1985; Fischer & Ravizza, 1992). First, consider the following moral dilemma, which we will here call the *switch* case (Thomson, 1985): A runaway trolley is about to run over and kill five people, but you can save them by hitting a switch that will divert the trolley onto a side track, where it will run over and kill only one person. Here, most people say that it is morally acceptable to divert the trolley

(Petrinovich, O’Neill, & Jorgensen, 1993), a judgment that accords well with the utilitarian perspective emphasizing the greater good. In the contrasting *footbridge* dilemma, a runaway trolley once again threatens five people. Here, the only way to save the five is to push a large person off a footbridge and into the trolley’s path, stopping the trolley but killing the person who is pushed. (You are too small to stop the trolley yourself.) Here, most people say that it is wrong to trade one life for five, consistent with the deontological perspective, according to which individual rights often trump utilitarian considerations.

We hypothesized that people tend to disapprove of the action in the *footbridge* dilemma because the harmful action in that case, unlike the action in the *switch* case, elicits a prepotent negative emotional response that inclines people toward disapproval (figure 68.2E). We hypothesized further that people tend to approve of the action in the *switch* case because, in the absence of a countervailing prepotent emotional response, they default to a utilitarian mode of reasoning that favors trading one life for five (figure 68.2A). We proposed that the negative emotional response elicited by the *footbridge* case is related to the more “personal” nature of the harm in that case. We proposed, in other words, there is an emotional appraisal process (Scherer, Schorr, & Johnstone, 2001) that distinguishes personal dilemmas such as the *footbridge* case from impersonal dilemmas such as the *switch* case (figure 68.2D).

To test these hypotheses we devised a set of “personal” dilemmas modeled loosely on (and including) the *footbridge* case and a contrasting set of “impersonal” dilemmas modeled loosely on (and including) the *switch* case.¹ The effects of these stimuli were compared by using fMRI. As was predicted, the personal dilemmas preferentially engaged brain regions associated with emotion, including the mPFC, PCC, and the amygdala (Greene et al., 2001, 2004). (As was noted above, this contrast also revealed preferential engagement of the pSTS/TPJ.) Also consistent with our dual-process theory, the impersonal moral dilemmas, relative to “personal” ones, elicited increased activity in regions of DLFPC associated with working memory (Cohen et al., 1997; Smith & Jonides, 1997) and cognitive control (Miller & Cohen, 2001).

According to the dual-process theory, the *footbridge* dilemma elicits a conflict between utilitarian reasoning and emotional intuition in which the latter tends to dominate. In other cases, these opposing forces appear to be more balanced. Consider the *crying baby* dilemma: It is wartime. You and your fellow villagers are hiding from nearby enemy soldiers in a basement. Your baby starts to cry, and you cover your baby’s mouth to block the sound. If you remove your hand, your baby will cry loudly, and the soldiers will hear. They will find you, your baby, and the others, and they will kill all of you. If you do not remove

your hand, your baby will smother to death. Is it morally acceptable to smother your baby to death to save yourself and the other villagers?

Here, people are relatively slow to respond and exhibit no consensus in their judgments (Greene et al., 2004). According to the dual-process theory, these behavioral effects are the result of the aforementioned conflict between emotional intuition and controlled cognition. This theory makes two key predictions. First, if dilemmas such as the *crying baby* dilemma elicit response conflict, then we would expect these dilemmas (as compared to personal dilemmas that elicit shorter RTs and less disagreement) to be associated with increased activity in the ACC, a region that is known for its sensitivity to response conflict (Botvinick, Braver, Barch, Carter, & Cohen, et al., 2001) (see Figure 68.2C). Second, if making utilitarian judgments in such cases requires overriding a prepotent, countervailing emotional response, then we would expect such judgments to be associated with increased activity in regions of DLPFC associated with cognitive control (Greene et al., 2001, 2004) (see Figure 68.2B). Both of these predictions were confirmed (Greene et al., 2004).

Three more recent studies support the dual-process theory by indicating a causal relationship between emotional responses and deontological/nonutilitarian moral judgments. Mendez, Anderson, and Shapira (2005) found that patients with frontotemporal dementia, who are known for their “emotional blunting,” were disproportionately likely to approve of the action in the *footbridge* dilemma. Koenigs and colleagues (Koenigs et al., 2007) and Ciaramelli, Muccioli, Ladavas, and di Pellegrino (2007) observed similar results in patients with emotional deficits due to VMPFC lesions. The results of the former study, which distinguished high-conflict personal dilemmas such as the *crying baby* dilemma from low-conflict personal dilemmas, were particularly dramatic (see figure 68.3). In each of the high-conflict dilemmas, the VMPFC patients gave more utilitarian judgments than the control subjects did. Finally, Valdesolo and DeSteno (2006) found that normal participants were more likely to approve of the action in the *footbridge* dilemma following a positive emotion induction aimed at counteracting negative emotional responses.

Four other studies support the link between utilitarian judgment and controlled cognition. My colleagues and I conducted a cognitive load study in which subjects responded to high-conflict personal dilemmas while performing a secondary task (detecting presentations of the number “5” in a stream of numbers) designed to interfere with controlled cognitive processes. The cognitive load manipulation slowed down utilitarian judgments but had no effect on RT for deontological/nonutilitarian judgments, consistent with the hypothesis that utilitarian judgments, unlike deontological judgments, are preferentially supported by controlled cogni-

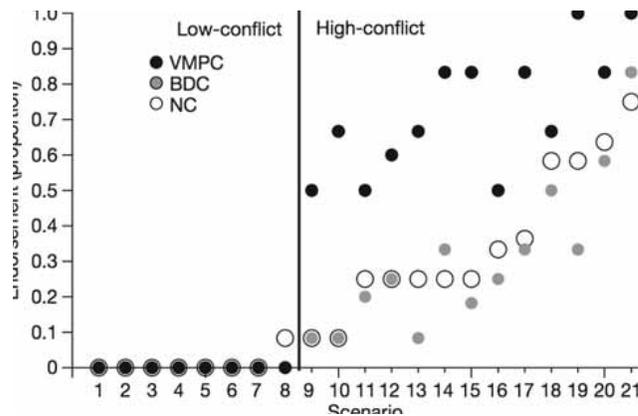

FIGURE 68.3 Frequency of utilitarian judgment in response to 21 personal moral dilemmas for VMPFC patients (black), brain-damaged controls (gray), and normal controls (white). Individual dilemmas are ordered from left to right along the x-axis in order of increasing frequency of utilitarian judgment among the normal controls. Dilemmas to the left of the vertical line are low-conflict and did not elicit group differences in moral judgment. Dilemmas to the right are high-conflict. The VMPFC group made a higher proportion of utilitarian judgments than both control groups in response to each of the high-conflict personal moral dilemmas. (Figure from Koenigs et al., 2007, courtesy of Nature Publishing Group.)

tive processes (Greene, Morelli, Lowenberg, Nystrom, & Cohen, 2008).

The three remaining studies examined the relationship between moral judgment and individual differences in cognitive style. Bartels (2008) found that individuals who are high in “need for cognition” (Cacioppo, Petty, & Cao, 1984) and low in “faith in intuition” (Epstein, Pacini, DenesRaj, & Heier, 1996) were more utilitarian. Along similar lines, Hardman (2008) examined moral judgment using the Cognitive Reflection Test (Frederick, 2005), which asks people questions like this: “A bat and a ball cost \$1.10. The bat costs one dollar more than the ball. How much does the ball cost?” The intuitive answer is 10¢, but a moment’s reflection reveals that the correct answer is 5¢. The people who correctly answered these questions were about twice as likely to give utilitarian responses to the *footbridge* and *crying baby* dilemmas. Finally, Moore, Clarke, and Kane (2008) found that individuals with higher working memory capacity were more likely to give utilitarian judgments in response to dilemmas in which harm to the victim is inevitable. Note, however, that Killgore and colleagues (2007) found that sleep deprivation made subjects more utilitarian. This effect, however, was not observed in individuals who were high in emotional intelligence, suggesting the operation of complex emotion-cognition interactions that are not readily explained by current theory.

Three more recent fMRI studies support and broaden the dual-process theory. My colleagues and I compared dilemmas such as the *switch* case to similar dilemmas in

which saving the five people requires breaking a promise (e.g., the agent had promised the potential victim that he would not be run over). In these cases, it is the harm's *social structure*, rather than its *physical structure*, that generates the tension between utilitarian and deontological judgment. We found, first, that introducing the promise factor reproduces the familiar pattern of mPFC/PCC/TPJ activity and, second, that utilitarian judgment in the promise dilemmas is associated with increased activity in the DLPFC (right BA 46) (Greene, et al., 2009c). In a second study (Greene, et al., 2009b), we compared utilitarian and non-utilitarian/deontological moral disapproval. The *footbridge* dilemma typically elicits deontological disapproval ("It is wrong to kill the one, despite the greater good"). One can generate utilitarian disapproval using dilemmas such as the *reverse switch* case, in which one can divert the trolley onto five people in order to save one person (an action that makes no utilitarian sense). Consistent with the dual-process theory, we found that utilitarian disapproval, as compared to deontological disapproval, was associated with greater activity in the same region of DLPFC, as above. It is worth noting that the region of DLPFC that is associated with utilitarian judgment in these studies (BA 46) is posterior to that associated with utilitarian judgment in response to high-conflict personal moral dilemmas (BA 10) (Greene et al., 2004). All utilitarian judgments appear to require utilitarian reasoning, but additional cognitive control is only required in the face of countervailing emotional responses. Thus it is possible that BA 46 is engaged during utilitarian moral reasoning, while BA 10 is engaged in the more extended cognitive processing elicited by high-conflict personal dilemmas. Finally, as was noted above, Glenn and colleagues (2008) found that individuals with high psychopathy scores exhibited reduced amygdala activity during the contemplation of personal moral dilemmas, thus providing further evidence for the connection between emotion and deontological impulses (which are reliably generated by personal moral dilemmas). They also found that individuals with high scores on the interpersonal factor of the Psychopathy Checklist (which involves manipulation, conning, superficiality, and deceitfulness) (Hare, 2003) exhibited decreased activation in the mPFC/PCC/TPJ network. (Note, however, that the psychopaths did not exhibit abnormal moral judgment behavior, complicating this interpretation.)

In sum, the dual-process theory of moral judgment, which emphasizes both emotional intuition and controlled cognition, is supported by multiple fMRI studies using different behavioral paradigms, multiple behavioral studies of neurological patients, and a variety of behavioral studies using both experimental manipulations and individual difference measures. (For an alternative perspective, see Moll & de Oliveira-Souza (2007). For my reply, see Greene (2007a).)

The mental states of moral agents

As Oliver Wendell Holmes, Jr. famously observed, even a dog knows the difference between being tripped over and being kicked. Holmes's comment highlights the importance of information concerning the mental states of moral agents and, more specifically, the distinction between intentional and accidental harm.

Berthoz and colleagues (2006) identified several brain regions that exhibit increased activity in response to intentional (versus accidental) moral transgressions, including the amygdala, the precuneus, the ACC, and the DLPFC. These results suggest a kind of dual-process response to intentional harms. That may be correct, but a more recent set of studies complicates this picture. Young and colleagues (2007) compared neural responses to intended harms, accidental harms, failed attempted harms, and ordinary harmless actions (a 2×2 design crossing mental state information (agent did/did not anticipate harm) and outcome information (harm did/did not result)). They found that the mPFC, PCC, and TPJ, all regions associated with theory of mind (Saxe, Carey, & Kanwisher, 2004), were sensitive not only to belief (i.e. anticipation) information, but also to the interaction between belief and outcome information. More specifically, the right TPJ was particularly sensitive to attempted harm, consistent with the behavioral finding that attempted harm is readily condemned, while accidental harm is not so readily excused (see also Cushman, Young, & Hauser, 2006). Interestingly, Young and colleagues (2007) found that judgments in response to accidental harm (as compared to intentional harm) were associated with increased activity in the ACC and DLPFC, regions that are associated respectively with conflict and control in the context of moral judgment (Greene et al., 2004). Young and colleagues argue that this is due to a conflict between an outcome-based response (the person caused harm) and one based on mental states (it was an accident). Thus we see here increased activity suggestive of cognitive conflict and control in response to accidental harms as opposed to intentional harms (Berthoz et al., 2006).

Further studies by Young and Saxe have examined the roles of various neural regions in processing mental state information in the context of moral judgment. They have found that the mPFC is sensitive to the valence of the agent's belief, while the TPJ and precuneus appear to be critical for the encoding and subsequent integration of belief information in moral judgment (Young & Saxe, 2008). A third study (Young & Saxe, 2009) suggests that the right TPJ, PCC, and mPFC are involved in the generation of spontaneous mental state attributions. Finally, they found, as predicted, that disrupting activity in the right TPJ using TMS produces a more childlike pattern of moral judgment (Piaget, 1965) based more on outcomes and less on mental state

information (Young, Camprodon, Hauser, Pascual-Leone, & Saxe, 2008).

While most humans (and perhaps some canines) are explicitly aware of the distinction between intended and accidental harm, people's judgments are also sensitive to a more subtle distinction between harms that are intended as a means to an end and harms that are merely foreseen as side effects (Aquinas, 2006). The means/side effect distinction is, in fact, a key distinction that distinguishes the *foot-bridge* dilemma (in which a person is used as a trolley-stopper) from the *switch* dilemma (in which the a person is killed as "collateral damage") (Foot, 1978; Thomson, 1985; Mikhail, 2000; Cushman et al., 2006; Moore et al., 2008). (Recent research suggests that the means/side effect distinction interacts with factors related to "personalness" in generating the effects that give rise to the trolley problem (Greene, et al., 2009a). Schaich Borg, Hynes, van Horn, Grafton, Hynes, and Sinnott-Armstrong (2006) found that the anterior STS and VMPFC exhibit increased activity in response to dilemmas in which the harm is an intended means, as opposed to a foreseen side effect. They also found increased DLPFC activity associated with harms caused through action, as opposed to inaction, consistent with the finding that people appear to have conscious access to the action/inaction distinction (Cushman et al., 2006).

While the studies described above highlight the importance of mental state representation in moral judgment, a study of moral judgment in autistic children indicates that some basic moral judgments do not depend on theory of mind abilities (Leslie, Mallon, & DiCorcia, 2006).

Neuroeconomics

Morality, broadly construed, may be viewed as a set of psychological adaptations that allow individuals to reap the benefits of cooperation (Darwin, 1871/2004). In economics, the most widely used experimental paradigm for studying cooperation is the prisoner's dilemma (Axelrod & Hamilton, 1981), in which two individuals maximize their total payoffs by cooperating but maximize their individual payoffs by not cooperating ("defecting"). Rilling and colleagues (2007) found that brain regions associated with reward (nucleus accumbens, caudate nucleus, VMPFC and OFC, and rostral ACC) were associated with cooperation, indicating that cooperative behavior is supported by general-purpose reward circuitry. A more recent study (Moll et al., 2006) in which people made charitable donations from inside the scanner teaches a similar lesson. Decisions to make costly donations were associated with increased activity in reward-related brain regions overlapping with those identified by Rilling and colleagues (2007). This study also found a remarkably high correlation ($r = .87$) between self-reported engagement

in voluntary activities and the level of activation in the mPFC during costly donation.

Several neuroeconomic experiments have used the Ultimatum Game (UG) (Guth, Schmittberger, & Schwarze, 1982) to examine neural responses to unfairness. In the UG, one player (the proposer) makes a proposal about how to divide a fixed sum of money between herself and the other player (the responder). The responder may either accept the proposal, in which case the money is divided as proposed, or reject it, leaving both players with nothing. Responders typically reject offers that are substantially below half of the total as unfair. Sanfey, Rilling, Aronson, Nystrom, and Cohen (2003) found that responders responded to such unfair offers with increased activity in the insula, which is associated with autonomic arousal (Critchley, Elliott, Mathias, & Dolan, 2000) and negative emotion (Calder et al., 2001). The level of insula activity scaled with the magnitude of the unfairness, responded more to human versus computer-generated proposals and was associated with higher levels of rejection. Unfair offers also elicited increased activity in the right DLPFC, which was interpreted as being involved in inhibiting the negative emotional response to unfairness. A more recent study (Knoch, Pascual-Leone, Meyer, Treyer, & Fehr, 2006), however, challenges this interpretation, finding that disrupting activity in the right DLPFC generated fewer rejections of unfair offers. These results suggest that the right DLPFC is involved in inhibiting the appetitive desire for more money rather than the punitive response to unfair treatment. Koenigs and colleagues (Koenigs & Tranel, 2007) found that patients with VMPFC damage exhibited the opposite behavioral pattern, suggesting that the VMPFC plays a critical role in regulating the emotional response that drives individuals to respond punitively to unfair treatment. (Increased rejection rates can also be generated by decreasing serotonin levels through tryptophan-depletion (Crockett, Clark, Tabibnia, Lieberman, & Robbins, 2008).) A more recent fMRI study of the UG (Tabibnia, Satpute, & Lieberman, 2008) found that increased activity in the ventrolateral PFC is correlated with increased acceptance of unfair offers, suggesting that this region may play the role originally attributed to the right DLPFC.

Other neuroeconomic studies have focused on how individuals track and respond to the moral status of others. Singer, Kiebel, Winston, Dolan, and Frith (2004) examined neural responses to faces of people who had played either fairly (i.e., cooperatively) or unfairly in a sequential prisoner's dilemma game. Surprisingly, they found that faces of fair players, but not unfair players, elicited increased activity in the insula and the amygdala, regions that are widely, but not exclusively, associated with negative affect (Adolphs, 1999). In a second study, Singer and colleagues (2006) exam-

ined the interaction between (un)fair behavior and empathy. Both males and females exhibited signs of pain-empathy (increased activity in the frontoinsula cortex and ACC) when observing fair players receive a painful shock, but this effect was significantly reduced in males when the players receiving the shock had played unfairly. Males, moreover, exhibited increased reward-related activity in the nucleus accumbens (correlated with self-reported desire for revenge) when observing unfair players getting shocked. In a similar vein, de Quervain and colleagues (2004) observed that reward-related activity in the caudate nucleus was associated with willingness to punish individuals who betrayed the subject's trust in a trust game. (A trust game is essentially a sequential prisoner's dilemma game in which cooperators must trust one another to continue cooperation.) A study by Delgado, Frank, and Phelps (2005) examined the effect of reputation on moral-economic interaction. They had subjects play a trust game with fictional individuals who were characterized as good, bad, or neutral on the basis of their personal histories. The individuals' reputations affected subjects' willingness to trust them and modulated the level of activity in the caudate nucleus, partially overriding the effect of feedback during the game. King-Casas and colleagues (2005) used a trust game to examine the temporal dynamics of trust development. They found that reward-related signals in the dorsal striatum were associated with the intention to trust and were shifted earlier in time as trust developed over the course of the game, mirroring effects that are observed in nonsocial reinforcement learning (Schultz, Dayan, & Montague, 1997). Taking a more molecular approach to the understanding of trust, Kosfeld, Heinrichs, Zak, Fischbacher, and Fehr (2005) found that intranasal administration of oxytocin, a neuropeptide that is known for its role in social attachment and affiliation in nonhuman mammals (Insel & Young, 2001), increased trusting behavior.

Hsu, Anen, and Quartz (2008) examined the neural bases of decisions concerning distributive justice, pitting deontological considerations for equality against utilitarian considerations in favor of maximizing aggregate benefits ("efficiency"). Their subjects allocated money to children in an orphanage, with some options favoring equality at the expense of efficiency and vice versa. Aversion to inequality was associated with increased activity in the insula, while activity in the putamen was positively correlated with the efficiency of the outcome. The caudate nucleus, in contrast, was sensitive to both factors, reflecting the subjective utility of the option. While at odds with the relatively simple dual-process theory presented above, these results are consistent with Hume's (1739/1978) conjecture (Greene et al., 2004; Greene, 2007b) that both deontological and utilitarian considerations ultimately have affective bases, despite the latter's greater dependence on controlled cognitive processing.

Conclusion

People often speak of a "moral sense" or a "moral faculty" (Hauser, 2006), but there is no single system within the human brain that answers to this description. Rather, moral judgment emerges from a complex interaction among multiple neural systems whose functions are typically not (and might not ever be) specific to moral judgment (Greene & Haidt, 2002). The bulk of the research discussed above rightly emphasizes the role of emotion, in all of its functional and anatomical variety. At the same time, it is clear that controlled cognitive processing plays an important role in moral judgment, particularly in supporting judgments that run counter to prepotent emotional responses.

Three positive trends emerge from the foregoing discussion: First, we have seen a shift away from purely stimulus-based studies in favor of studies that associate patterns of neural activity with behavior. Second, and relatedly, we have seen an increased reliance on behavioral data, both in neuroscientific research and in complementary behavioral studies. Third, we have developed more ecologically valid paradigms involving real decisions, while recognizing that more stylized, hypothetical decisions can, like the geneticist's fruit fly, teach us valuable lessons. With regard to this issue, it is worth noting that in modern democracies, our most important decisions are made indirectly by voters whose individual choices have little bearing on outcomes and are thus effectively hypothetical.

Our current neuroscientific understanding of moral judgment is rather crude, conceptualized at the level of gross anatomical brain regions and psychological processes that are familiar from introspection. But for all our ignorance, the physical basis of moral judgment is no longer a complete mystery. We not only have identified brain regions that are "involved" in moral judgment, but also have begun to carve the moral brain at its functional joints.

ACKNOWLEDGMENTS Many thanks to Joe Paxton and Liane Young for their helpful comments.

NOTE

1. We defined "personal" moral dilemmas/harms as those involving actions that are (1) likely to cause serious bodily harm (2) to a particular person and (3) this harm does not result from deflecting an existing threat onto a different party (Greene et al., 2001). The first two criteria exclude minor harms and harms to indeterminate "statistical" individuals, respectively. The third criterion aims to capture a sense of agency, distinguishing between harms that are "authored" rather than merely "edited" by the agent in question. Recent research suggests that the dilemmas that were originally classified as "personal" and "impersonal" can be fruitfully classified in other ways (Mikhail, 2000; Royzman & Baron, 2002; Cushman et al., 2006; Waldmann & Dieterich, 2007; Moore et al., 2008; Greene et al., 2009a).

Introduction

ELIZABETH A. PHELPS

HIGHER COGNITION encompasses a broad range of processes that allow us to take the products of more discrete cognitive functions and transform them to generate concepts, reason, and decide how to interact with the world. Given the complexity and diversity of processes that fall under the domain of higher cognition, part IX offers a wide variety of topics and approaches. One change from previous editions of *The Cognitive Neurosciences* is that the higher cognition section has been expanded to encompass both higher cognition and decision making. In previous editions, decision making was included sporadically under different section headings. With the exception of perceptual and motor decision making, the first edition did not include any contributions on decision making. In the second edition, decision making was included as a single contribution under higher cognition. The third edition was produced around the time neuroeconomics was starting to emerge as a new discipline within cognitive neuroscience. Reflecting this novelty, chapters on decision making were included in a section on perspective and new directions. Now, as interest in neuroeconomics has grown, research on the cognitive neuroscience of decision making has gained recognition as an important and exciting development in our endeavors to understand the neuroscience of human behavior. Reflecting this change, roughly half of the contributions in this section concern the processes driving decisions.

The contributions to section IX reflect three main themes and an interesting new perspective. The first two chapters focus primarily on the role of the prefrontal cortex as it represents higher cognitive functions. Knowlton and Holyoak in chapter 69 examine how the prefrontal cortex supports relational reasoning, that is, the ability to draw inferences based on relations, as opposed to specific features, a principle underlying analogies. By combining cognitive and

computational models with neuropsychological and imaging data, they isolate and describe the component processes and neural representations that underlie complex reasoning. Chapter 70 by Summerfield and Koechlin provides a global, hierarchical model of the prefrontal cortex that accounts for the integration of executive functions, including the representation of goals and selection, with motivational and evaluative information across the lateral, medial, and orbital prefrontal cortices. They outline how this model of the prefrontal cortex supports decision processes.

The next two chapters are concerned with the foundations of conceptual and semantic knowledge. How we group and organize the information we encounter to allow us to generalize across instances, avoid redundant representations, and extract general principles is fundamental to navigating a complex world. In chapter 71, Martin explores the foundations of conceptual knowledge by examining the neural systems mediating the formation, representation, and utilization of concepts about objects. In chapter 72, McClelland, Rogers, Patterson, Dilkina, and Lambon Ralph expand on the topic by introducing a computational framework for capturing the nature of semantic cognition. They explore how this model reflects the principles underlying both the development of conceptual knowledge and its disintegration with semantic dementia.

In chapter 73, Raichle provides a new perspective on how to view brain function. He argues that most functional imaging studies have a reflexive view of the brain, in which its primary purpose is to respond to external events. In con-

trast, he suggests that investigating the intrinsic operations of the brain may be equally important, if not more, in understanding brain function. Although this chapter sits apart from the other chapters in this section, in both the topic and the emphasis on methodological issues in functional imaging, it is hard to imagine what else intrinsic functions might entail, if not, at least in part, some components of higher cognition. In this way, the chapter by Raichle is not only an important perspective in how we approach our understanding of the human brain, but also, potentially, a contribution to understanding the cognitive neuroscience of higher cognitive processes.

Decision making, specifically from a neuroeconomic perspective, is the focus of the last three chapters. In chapter 74, Rangel uses a neuroeconomic approach to explore how we make a simple goal-directed choice between two options. By walking through the stages of a simple choice, he examines how computational approaches and human neuroscience studies can be combined to capture the complex representation of a relatively simple decision. In chapter 75, Glimcher highlights how the neuroeconomic approach has evolved by combining neuroscience research in human and nonhuman primates with economic and psychological models of decision making. He suggests that initial findings suggest a two-step neurobiological process that includes valuation and choice. The final chapter on this topic, chapter 76 by Delgado and myself, highlights the importance of emotion in decision making and reviews issues and progress in integrating affective neuroscience with neuroeconomics.

69 Prefrontal Substrate of Human Relational Reasoning

BARBARA J. KNOWLTON AND KEITH J. HOLYOAK

ABSTRACT Relational reasoning, including the distinctively human capacity to see analogies between disparate situations, requires the ability to mentally represent and manipulate the relationships among concepts. Over the past decade, studies of cognitive development, aging, and neurological disease have supported the hypothesis that the prefrontal cortex plays a critical role in relational reasoning. Analysis of the component processes of relational reasoning has motivated neuroimaging studies linking these components to distinct neural substrates. Studies using diverse reasoning tasks have converged on the conclusion that frontopolar cortex responds specifically when multiple relations must be integrated to solve a problem. Other subregions in the inferior and middle frontal gyri appear to be critical for resolving interference from distracting elements of the problem and for control of working memory. Mapping the components of relational reasoning is an essential first step toward understanding how the architecture of the prefrontal cortex supports human thinking.

Humans, more than any other species, are able to cope with novel problems that arise across a wide range of domains. This capacity depends in part on *role-based relational reasoning*—the ability to draw inferences about entities based on the roles they fill in relations, where the roles are not predictable by features of the entities and the relations cannot be reduced to roleless chunks (Penn, Holyoak, & Povinelli, 2008). A canonical example of role-based relational reasoning is reasoning by analogy, which enables detection of higher-order similarities between superficially dissimilar situations (Gick & Holyoak, 1980; Gentner, 1983; Holyoak, 2005). For example, modern medicine originated with Pasteur’s development of the germ theory of disease by analogy to the known role of microorganisms in fermentation of grapes, coupled with Lister’s extension of Pasteur’s analogy to explain infections (Thagard, 1996). Analogy requires representing and integrating relational knowledge in working memory, while coping with interference from salient distracting information. For example, Pasteur grasped that microorganisms need to *be alive* and *in contact with* grapes in order to *cause* fermentation; by integrating these relations and mapping them onto what he knew about certain silk-

worm diseases, he was able to infer that germs might be their cause (and hence the diseases might be prevented by killing the germs or blocking their contact with silkworms). At the same time, he had to ignore many salient but irrelevant dissimilarities between the two analogs (e.g., silkworms are animals, grapes are not).

While prefrontal cortex (PFC) has long been associated with problem solving and fluid intelligence, in the past decade there has been a surge in work specifically relating the PFC to processes supporting relational reasoning. In 1995, Robin and Holyoak advanced the thesis that the PFC is responsible for the creation and maintenance of explicit relational representations that guide thought and action. At that time, however, few or no neuropsychological or neuroimaging data were available to directly connect relational processing with the human PFC. Moreover, although several major computational models of analogical reasoning had been developed in cognitive science (e.g., Falkenhainer, Forbus, & Gentner, 1989; Holyoak & Thagard, 1989), none even attempted to incorporate constraints based on what was known about working memory, interference control, and their neural substrates.

Today the picture is very different. Behavioral studies with children (Richland, Morrison, & Holyoak, 2006), young adults (Cho, Holyoak, & Cannon, 2007), and older adults (Viskontas, Morrison, Holyoak, Hummel, & Knowlton, 2004; Viskontas, Holyoak, & Knowlton, 2005) have teased apart some of the major component processes in relational reasoning. Computational models of analogy have incorporated working-memory constraints (Halford, Wilson, & Phillips, 1998; Hummel & Holyoak, 1997, 2003). It has been shown that “virtual brain damage” in a neural-network model can simulate changes in reasoning related to normal aging (Viskontas et al., 2004), as well as reasoning deficits in patients with damage to their frontal or temporal cortices (Morrison et al., 2004). In addition to neuropsychological studies of relational reasoning conducted in our lab (Krawczyk et al., 2008; Morrison et al., 2004; Waltz et al., 1999, 2004), neuroimaging studies from multiple labs have identified subregions of PFC associated with integrating multiple relations (Bunge, Wendelken, Badre, & Wagner, 2005; Christoff et al., 2001; Green, Fugelsang, Kraemer, Shamos,

BARBARA J. KNOWLTON and KEITH J. HOLYOAK Department of Psychology, University of California, Los Angeles, California

& Dunbar, 2006; Kroger et al., 2002; Prabhakaran, Smith, Desmond, Glover, & Gabrieli, 1997; Wendelken, Nakhbenko, Donohue, Carter, & Bunge, 2008), as well as with interference control (Cho et al., 2009).

In this chapter we discuss how a clearer picture of the neural basis of relational reasoning has emerged from current conceptions of its component processes.

Component processes of relational reasoning

RELATIONAL INTEGRATION AND INTERFERENCE CONTROL As Robin and Holyoak (1995) argued, relational reasoning appears to require processes closely related to those assoc-

iated with the operation of the PFC. As the name implies, role-based relational reasoning requires drawing inferences about entities based on the *roles* they fill, rather than on direct similarity. A specific task that instantiates these requirements is illustrated in figure 69.1, which depicts examples of “scene-analogy” problems developed by Richland and colleagues (2006) for use with children as young as 3–4 years. For each pair of pictures, children were asked to identify the object in the bottom picture that “goes with” the object indicated by an arrow in the top picture. In some problems, such as that shown in figure 69.1*B*, the child is confronted with a conflict between two possible answers, one relational and one based on perceptual and/or semantic

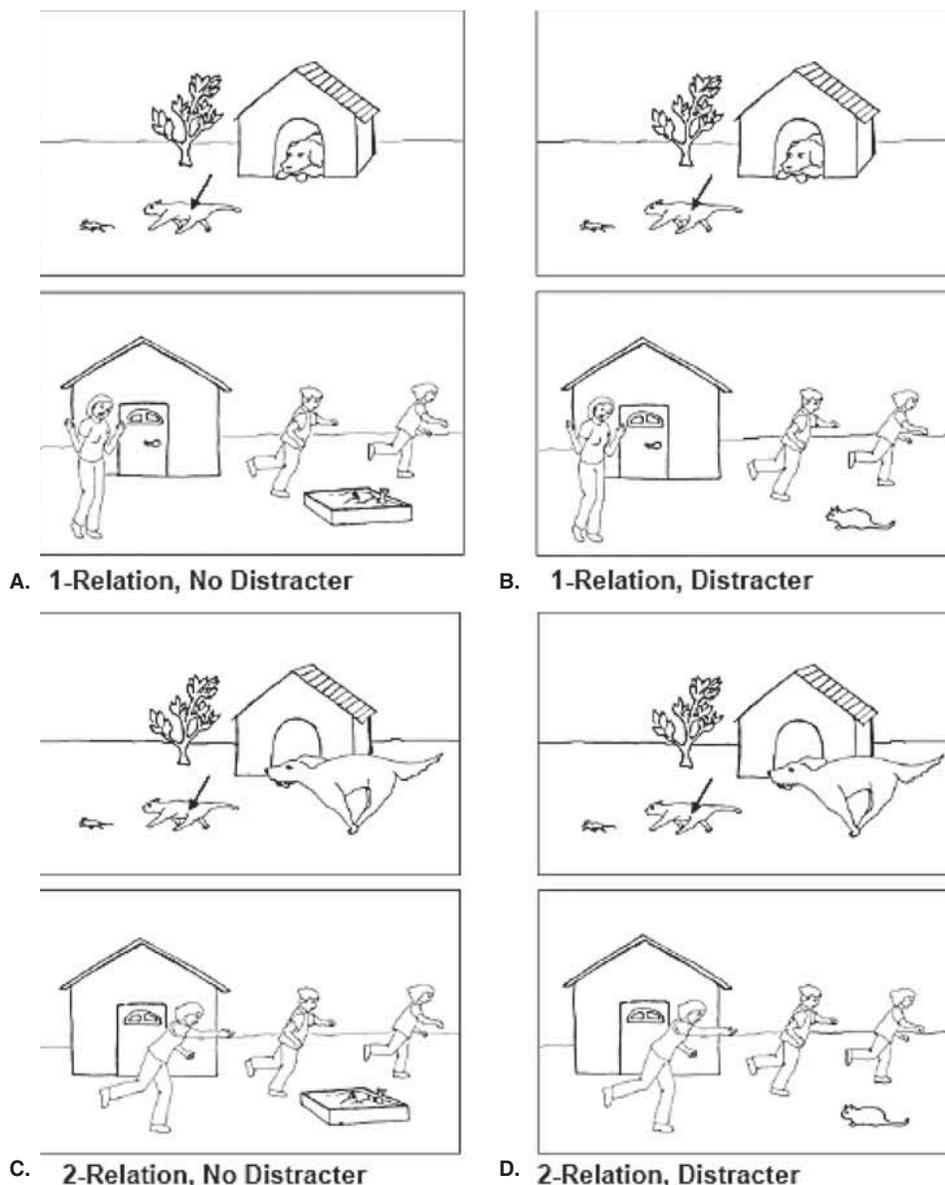

FIGURE 69.1 Example set of scene pairs constructed by Richland, Morrison, and Holyoak (2006). (A) 1-relation/no distracter; (B) 1-relation/distracter; (C) 2-relation/no distracter; (D) 2-relation/distracter. (Reprinted with permission from Richland, Morrison, & Holyoak, 2006.)

similarity. The cat in the top picture perceptually resembles the cat in the bottom picture, but plays a role (chasing a mouse) that parallels the role played by the boy in the bottom picture (chasing a girl). Richland and colleagues found that young children were less likely to give the relational response when an alternative based on direct similarity was available (figure 69.1*B*) than when no such distracter object was present (figure 69.1*A*, where in the bottom picture the cat has been replaced by a sandbox).

Relational reasoning varies in its complexity, which has been linked to the number of relational roles relevant to an inference (Halford, 1993; Halford et al., 1998). A critical distinction is whether a single relation is sufficient to determine the role-based inference (figure 69.1*A,B*), or whether multiple relations must be integrated to derive an inference (figure 69.1*C,D*). For example, in figure 69.1*D* it is not sufficient simply to relate the cat to another “chaser” in the bottom picture, as in the latter both the boy and the woman are chasing someone. Rather, the cat corresponds specifically to the boy because each is both being chased (by the dog and the woman, respectively) as well as chasing (the mouse and the girl, respectively). Richland and colleagues (2006) found that preschool children gave fewer relational responses when either a similar distracter was present in the bottom picture (figure 69.1*B,D* versus *A,C*) or when two relations had to be integrated (figure 69.1*C,D* versus *A,B*). By age 13–14 years—roughly the age at which the PFC has undergone substantial further maturation (Giedd, 2004)—children reliably gave the relational response even when multiple relations had to be integrated and a similar distracter was present.

LISA: A NEUROCOMPUTATIONAL MODEL OF RELATIONAL REASONING Research on the development of analogical

reasoning thus suggests that relational reasoning depends on two major component processes: integration of multiple relations and the capacity to cope with interference from salient but relationally irrelevant information. Most computational analogies of analogy have not considered how analogical reasoning might be implemented in the brain, and traditional neural-network models of cognition encounter severe difficulty in representing explicit relations and the binding of objects into relational roles (Doumas & Hummel, 2005). However, a neural-network model of the component processes underlying relational reasoning has been developed in recent years. LISA (*Learning and Inference with Schemas and Analogies*; Hummel & Holyoak, 1997, 2003) uses a representation of knowledge based on a hierarchy of distributed and localist units (see figure 69.2). LISA’s representational scheme codes relations as sets of roles (e.g., for “cat chases mouse,” the cat fills the role of “chaser” and the mouse the role of “chased”). The model uses synchrony of firing to bind distributed representations of relational roles (e.g., chaser) to distributed representations of their fillers (e.g., cat). The process of “thinking about” a proposition entails keeping separate role-filler bindings firing *out* of synchrony with one another. In LISA, working memory is necessarily capacity-limited: It is only possible to keep a finite number of role-filler bindings simultaneously active and out of synchrony with one another (for details see appendix A in Hummel & Holyoak, 2003).

LISA represents propositions using a hierarchy of distributed and localist units. Figure 69.2*B* provides a schematic representation of LISA’s architecture as applied to one of the scene-analogy problems used by Richland and colleagues (2006). At the bottom of the hierarchy, *semantic* units (small circles in figure 69.2*B*) represent objects and relational roles in a distributed fashion. For example, consider the

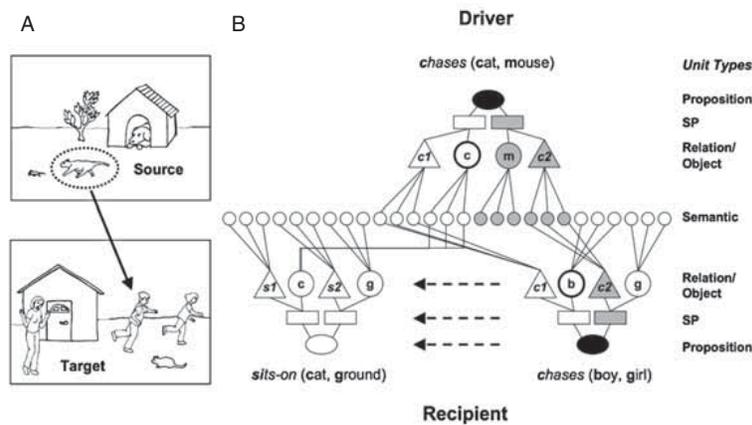

FIGURE 69.2 (A) Example of 1-relation/distracter scene-analogy problem (Richland et al., 2006). (B) LISA architecture as applied to this problem. In order for a reasoner to select the boy in the target as the correct analogical mapping to the cat in the source,

units in the recipient representing *chases* (boy, girl) must inhibit corresponding units in the propositional structure containing the featurally similar “sitting cat” distracter. (Reprinted with permission from Morrison, Doumas, & Richland, 2006.)

proposition *chase* (cat, mouse). Each role of the *chase* relation would be represented by units coding for its semantic content (e.g., *aggressor* for the first role, *victim* for the second, and *pursuit* for both). Similarly, the objects “cat” and “mouse” would be represented by units specifying their meaning (e.g., cat: *animal, pet, soft*). *Predicate* and *object* units (triangles and large circles, respectively, in figure 69.2B) represent relational roles and their object fillers, and have bidirectional excitatory connections to the corresponding semantic units. Subproposition (SP) units (rectangles in figure 69.2B) bind roles to their arguments, and have bidirectional connections to the corresponding predicate and object units. In the case of *chase* (cat, mouse), one SP would bind “cat” to the first role of *chase*, and another would bind “mouse” to the second. At the top of the hierarchy, proposition (P) units bind role-filler bindings into complete propositions by way of excitatory connections to the corresponding SPs. A complete analog (i.e., situation, story, or scene) is represented by the collection of semantic, predicate, object, SP, and P units that collectively code the propositions in that analog. The semantic units permit the units in one analog to communicate with the units in others.

To generate an analogical mapping, units representing one analog (the *driver*) are activated in working memory, and reasoning proceeds by passing activation from these units through distributed semantic units to units representing the *recipient* analog in long-term memory. As units in the recipient analog are fired, they enter working memory. LISA postulates a set of *mapping connections* between units of the same type in separate analogs. These connections grow whenever the corresponding units are active simultaneously and thereby permit LISA to rapidly learn the correspondences between structures in separate analogs.

The basic processes of LISA are closely related to the functions of the PFC. Hummel and Holyoak (1997, 2003) hypothesized that the rapid learning of mapping connections, which is critical to relational integration, is an important function of working memory as implemented in prefrontal cortex (cf. Assad, Rainer, & Miller, 1998). Inhibitory control, which is also considered an important function of prefrontal cortex (Miller & Cohen, 2001; Shimamura, 2000), plays a central role in several aspects of LISA. These include (1) LISA’s ability to select items for placement into working memory, (2) its working memory capacity for role-filler bindings, (3) its ability to control the spreading of activation in the recipient (i.e., its ability to disambiguate which elements of the recipient correspond to the active units in the driver), (4) its ability to use competition among mapping connections to enforce structural constraints on the discovery of analogical mappings, particularly the constraint that mappings tend to be one-to-one, and (5) its ability to select a relation-based response despite the availability of a salient but superficial distracter.

Importantly, LISA predicts that relational integration and inhibitory control are distinct but closely linked processes. Relational integration requires the ability to rapidly learn mapping connections, but inhibitory control is essential to set up the conditions for successful learning (i.e., simultaneous activation of objects that fill parallel relational roles). As we will see, LISA’s conception of the relationship between relational integration and inhibitory control is consistent with recent functional imaging data that indicate how these processes map onto subregions of PFC.

Neuropsychological evidence for the role of PFC in relational reasoning

One of the major sources of evidence concerning the dependence of relational reasoning on the integrity of the PFC comes from neuropsychological studies of patients diagnosed with frontotemporal lobar degeneration (FTLD), a dementia subtype distinct from Alzheimer’s disease (Brun, 1993; Snowden, Neary, & Mann, 2007). FTLD occurs in three variants: a progressive aphasia, in which areas involved in language production are primarily affected initially; a frontal variant, which is characterized in early stages by prefrontal atrophy; and a temporal variant (also known as *semantic dementia*) in which degeneration includes left anterior temporal cortex (Hodges, Patterson, Oxbury, & Funnell, 1996). Frontal-variant FTLD provides a model for investigating what reasoning processes are dependent on PFC, while the temporal variant provides a closely matched control with the same underlying disease.

RELATIONAL COMPLEXITY AND THE PFC Waltz and colleagues (1999) examined performance of FTLD patients and age-matched normal control subjects on simple reasoning tasks, using closely matched variants of problems that differed specifically in whether or not success required integration of multiple relations. They hypothesized that patients with prefrontal cortical dysfunction would exhibit impaired performance when asked to integrate multiple relations, yet would perform normally when only one relation needed to be considered. The performance of frontal-variant FTLD patients was compared to that of temporal-variant patients, as well as age-matched healthy controls.

Figure 69.3 illustrates how relational complexity was manipulated for problems adapted from the Raven’s Standard Progressive Matrices Test (RPM), which has long been used as a measure of reasoning ability (Raven, 1941). Non-relational problems (level-0 complexity) involved a visual pattern, with a blank space in the bottom right-hand corner (see figure 69.3A). On these problems, the participant could simply pattern-match to select the correct completion. Each one-relation problem (level-1 complexity) involved a 2×2 matrix that required processing one relational change over

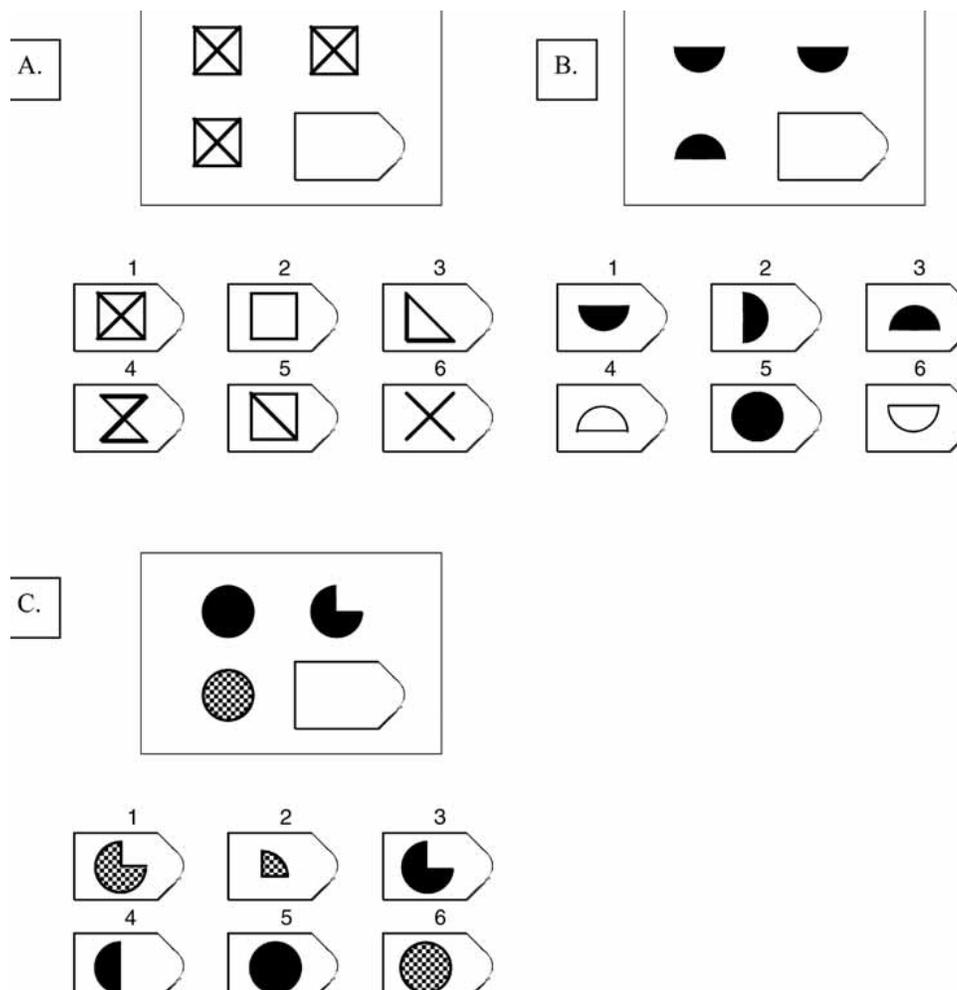

FIGURE 69.3 Examples of problems adapted from the Raven Standard Progressive Matrices Test by Waltz and colleagues (1999). (A) Nonrelational problem (level 0), requiring only perceptual matching (correct response is choice 1). (B) One-relation problem (level 1), requiring processing of the transformation along the vertical dimension only (reflection across the x -axis) in order to choose

the correct alternative (choice 3). (C) Two-relation problem (level 2), requiring integration of the relation along the vertical dimension (solid to checked pattern) and the relation across the horizontal dimension (removal of the upper-right quadrant) in order to choose the correct response (choice 1). (Reprinted with permission from Waltz et al., 1999.)

either the horizontal or vertical dimension; the other dimension was constant (figure 69.3B). Two-relation problems (level-2 complexity) required integrating two relational changes over the horizontal and vertical dimensions, respectively (figure 69.3C). Thus, although the basic form of the task was constant across the three types of matrix problems, only the two-relation problems necessitated relational integration.

Figure 69.4 presents the results obtained by Waltz and colleagues (1999) for the matrix problems. The temporal-variant FTLD patients and the normal controls achieved very high accuracy at all levels of relational complexity. The frontal-variant patients also performed at a high level for level-0 and level-1 problems; however, their performance plunged dramatically for level-2 items (just 11% correct, not different from chance). At the same time, the performance

of frontal-variant patients was superior to that of temporal-variant patients on a test of recognition memory and on tests dependent on semantic knowledge. The resulting double dissociation between relational reasoning versus both episodic memory and semantic knowledge rules out a general “difficulty” factor as the source of the prefrontal group’s impairment.

The frontal-variant patients also were completely unable to solve transitive-inference problems that required integration of two relations. Reasoning deficits of a similar but less pronounced nature have also been observed in patients with Alzheimer’s disease with pronounced frontal signs (Waltz et al., 2004). Taken together, these findings indicate that the human PFC plays an essential role in relational reasoning—specifically, in the integration of multiple relations. Furthermore, the role of the PFC in relational integration

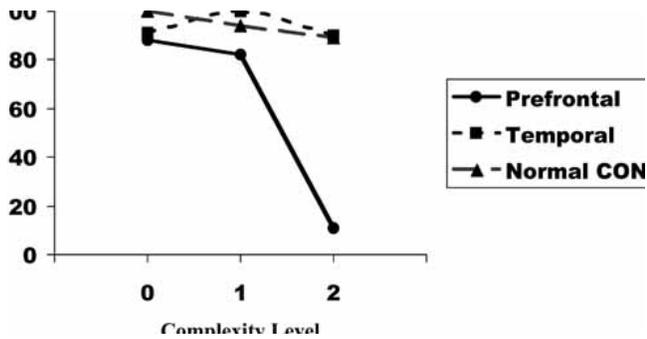

FIGURE 69.4 Accuracy on matrices test (Waltz et al., 1999). Groups show similar performance in the solution of nonrelational problems (level 0), as well as those requiring maintenance of a single relation (level 1); but patients with prefrontal damage show catastrophic impairment in the ability to solve problems requiring the integration of multiple relational premises (level 2). (Reprinted with permission from Waltz et al., 1999.)

was shown to generalize across both inductive (RPM) and deductive (transitive inference) reasoning tasks.

INTERFERENCE CONTROL AND THE PFC Other recent neuropsychological studies using FTLN patients have examined the role of the PFC in controlling interference from distracting information during analogical reasoning. Morrison and colleagues (2004) tested both frontal- and temporal-variant FTLN, as well as age-matched controls, on a verbal analogy task. Four-term analogy problems of the form A:B::C:D or D' were employed, where D is the analogical answer and D' is a nonanalogical foil (adapted from Sternberg & Nigro, 1980). A semantic facilitation index (SFI) was calculated for each problem to characterize the association of the correct relational pair (C:D) relative to the distracter pair (C:D'). For example, for the problem PLAY:GAME::GIVE: (1) PARTY (2) TAKE, the C:D pair (GIVE:PARTY, the correct analogical answer) is less associated than is the C:D' pair (GIVE:TAKE, the non-analogical foil), yielding a negative SFI for the problem. The problems were divided into those with negative SFI, neutral SFI, and positive SFI in order to examine the effect of semantic interference on the ability to identify the analogical answer.

Morrison and colleagues (2004) predicted that because these 4-term analogy problems were based on a single, fairly simple relation between the A and B terms, frontal-variant FTLN patients should be able to perform the basic analogical mapping needed despite their diminished working memory. However, if the PFC is also critical for interference resolution, then these patients should be selectively impaired on problems in which the D' distracter is a strong competitor to the analogical choice, D. In the positive and neutral SFI conditions, the analogical answer (D) does not face competition from an alternative (D') that is more strongly associated

with the C term. Accordingly, the analogical answer can simply be activated and produced as a response. However, in the negative SFI condition the D' foil is in fact more strongly associated with C than is the analogical response D. It follows that in order to make the analogical response for these problems, it will be necessary not just to activate the D response, but also to inhibit the semantically related D' response.

Accordingly, because of their postulated deficits in inhibitory control, it was predicted that frontal-variant FTLN patients would be selectively impaired in the negative SFI condition relative to the positive and neutral SFI conditions. In contrast, it was predicted that temporal-variant FTLN patients would show a more uniform decline in verbal analogy performance across all three conditions because of their loss of the conceptual information necessary to encode the relations in the analogy problem. Both of these patterns were in fact observed by Morrison and colleagues (2004). A more recent study using 4-term picture analogies also found that frontal-variant FTLN patients are especially impaired on problems that include semantically related distracters (Krawczyk et al., 2008).

The deficits in the frontal- and temporal-lobe patient groups that Morrison and colleagues (2004) found with the verbal analogy task were modeled using LISA. It proved possible to simulate the observed pattern of frontal-lobe deficits by impairing the rate of rapid learning of analogical connections in LISA's working memory, coupled with reduction of a parameter for inhibitory control. Both the rapid learning of new connections in working memory and inhibitory control appear to be key functions of prefrontal cortex (Miller & Cohen, 2001; Shimamura, 2000). When both these functions (not either one alone) were impaired in LISA, the model yielded the selective impairment on negative SFI problems shown by frontal-lobe patients. Thus LISA would predict that distinct prefrontal regions would be activated during analogical reasoning corresponding to these two components. When the extent of semantic death (loss of connections between semantic units representing a relational role and the predicate unit for that role) was increased in LISA, thereby modeling loss of conceptual knowledge in anterior temporal cortex, the simulation yielded the pattern of impairment found for temporal-variant FTLN patients: a relatively uniform decrease in accuracy across all verbal analogy problems, regardless of SFI condition.

RELATIONAL REASONING IN THE AGING BRAIN The PFC has been shown to be vulnerable to the effects of aging (Raz et al., 1997). Decreased PFC function in older adults may affect the ability to cope with relational complexity and interference during reasoning. Viskontas and colleagues (2004) manipulated both factors using a set of analogy problems based on cartoons of human figures, each defined

by four binary-valued characteristics (height, girth, clothing color, and gender). Figure 69.5 illustrates examples of these People Pieces Analogies (PPA; Sternberg, 1977; Morrison, Holyoak, & Truong, 2001; Cho et al., 2007). In the PPA task, subjects are asked to verify as quickly as possible whether the relationship between the A:B pair corresponds to the relationship between the C:D pair with respect to selected dimension(s). This task has a major advantage over other paradigms because visual complexity is controlled by having all problems, regardless of the level of relational

complexity, consist of four characters from the basic set of 16. Before each trial in the PPA task participants see a list of the traits that they are to attend to on that trial. They then see an analogy problem that they have to judge as true or false based on the dimensions specified as relevant. The number of traits to which participants attend can be varied from one to four, thus manipulating the relational complexity of the problem. In addition, 1- and 2-relation problems may have 0, 1, or 2 irrelevant dimensions that need to be inhibited to avoid interference with the analogical answer. “False” trials are constructed by introducing the wrong value on one relevant dimension.

Viskontas and colleagues (2004) administered the PPA tasks to three groups of adult subjects: younger, middle-aged, and older (mean ages of approximately 20, 50, and 75 years, respectively). The mean response times (RTs) for correct “true” trials are shown in figure 69.6 (left). For both young and older subjects, RTs were significantly increased for greater levels of relational complexity (compare figure 69.6A to 69.6C). For young subjects RTs increased only slightly when distracting information was present. In older adults, however, distracting information had a profound effect on response time when it was necessary to integrate more than one relation (figure 69.6C). Age-related impairments in relational integration have also been obtained with other deductive and inductive reasoning tasks (Viskontas et al., 2005).

Viskontas and colleagues (2004) showed that the LISA model could successfully capture the interaction among age, complexity, and the amount of distracting information simply by varying an inhibition parameter. Reducing the model’s inhibition parameter has the effect of increasing sensitivity to distracting information, particularly when multiple relations need to be mapped in working memory (see figure 69.6, right). Such loss of inhibitory control for older adults is consistent with the decline in prefrontal functions that accompanies cognitive aging. In younger adults, performance on analogy problems that require interference control can be impaired by imposing dual-task conditions (Morrison et al., 2001; Waltz, Lau, Grewal, & Holyoak, 2000), by delaying the cue signaling the relevant dimensions on a trial (Cho et al., 2007), or by inducing anxiety prior to administering the analogy task (Tohill & Holyoak, 2000). All these factors plausibly act by imposing excessive load on working-memory processes dependent on the PFC.

Functional imaging of component processes in relational reasoning

Neuropsychological evidence has established the critical role of the PFC in relational reasoning, and behavioral and computational modeling studies point to the distinctive roles of relational integration and inhibitory control. In recent years, considerable progress has been made in localizing specific

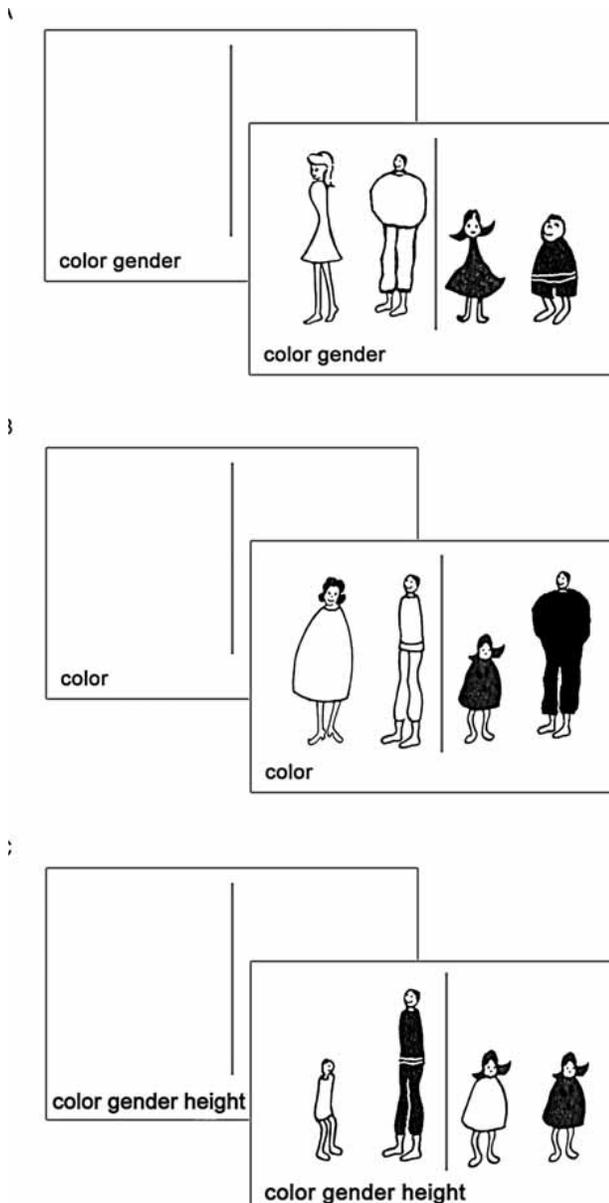

FIGURE 69.5 Example problems from People Pieces Analogy task (Viskontas et al., 2004). human data for complexity level 2; and (D) corresponding LISA simulations. Error bars depict standard error of the mean. (Reprinted with permission from Viskontas et al., 2004.)

PFC and other brain areas associated with relational reasoning using PET (Wharton et al., 2000) and fMRI.

RELATIONAL INTEGRATION Several fMRI studies have manipulated relational complexity using variants of RPM problems, similar to those used by Waltz and colleagues (1999) with FTLD patients. With healthy young adults, more complex problems can be used (typically 3×3 matrices with up to four dimensions of variation; Kroger et al., 2002). For matrix problems, relational integration has been shown to consistently activate prefrontal regions. In particular, bilateral middle (MFG) and inferior (IFG) frontal gyri, as well as parietal and occipital regions, have been found to increase activity when multiple relations must be integrated in order to arrive at a solution, compared to problems that require processing of only a single relation (Prabhakaran et al., 1997; Christoff et al., 2001; Kroger et al., 2002).

Among these regions, which constitute a network commonly activated in visuospatial working memory tasks, the

activation pattern of the most anterior part of the PFC has been particularly noteworthy. Christoff and colleagues (2001) found that the left frontopolar region remained preferentially activated even after controlling for the influence of increased problem-solving time. Kroger and colleagues (2002) confirmed and extended these results, providing evidence that although the left anterior prefrontal region becomes increasingly activated as more relations need to be integrated, activation in this subarea is not affected by increases in perceptual difficulty (achieved by adding visuospatial distracters to RPM problems while holding relational complexity constant). Thus the frontopolar region seems to be uniquely associated with the specific requirement of integrating multiple relations, and not general cognitive difficulty.

Similarly, studies of verbal analogical reasoning have distinguished neural substrates of reasoning from semantic processing demands within working memory. Activation in the left frontopolar region increases selectively when making

judgments of analogical similarity compared to processing of semantic associations or categories (Bunge et al., 2005; Green et al., 2006; Wendelken et al., 2008). Thus, based on a substantial body of findings involving solution of different types of relational reasoning problems, the frontopolar region seems to play a special role in the process of integrating multiple relational representations to arrive at a solution.

SEPARATING RELATIONAL COMPLEXITY AND INTERFERENCE CONTROL

While several studies have examined the neural correlates of relational integration, less is known about the neural basis of interference control in the context of analogical reasoning. Interference resolution (often linked to selection and inhibitory control) has been extensively studied using a wide variety of paradigms. Studies have identified the lateral PFC, including regions in the dorsolateral PFC and inferior frontal gyrus, as important for interference resolution across diverse tasks including inhibition of a motor response, proactive interference resolution in working memory, selection among competing alternatives, and controlled semantic retrieval (Aron, Robbins, & Poldrack, 2004; Badre, Poldrack, Pare-Blagoev, Inslar, & Wagner, 2005; D'Esposito, Postle, Jonides, & Smith, 1999; Jonides, Smith, Marshuetz, Koeppe, & Reuter-Lorenz, 1998; Nee, Wager, & Jonides, 2007; Thompson-Schill, D'Esposito, Aguirre, & Farah, 1997; Thompson-Schill et al., 2002; Wagner, Pare-Blagoev, Clark, & Poldrack, 2001; Zhang, Feng, Fox, Gao, & Tan, 2004). It seems plausible that these regions also support interference resolution in relational reasoning.

Recently, work in our lab (Cho et al., 2009) has jointly examined the neural substrate for relational integration and for interference resolution using the PPA task described earlier (Viskontas et al., 2004). In this task, it is possible to vary both factors simultaneously while holding visuospatial complexity constant. As in previous studies using the PPA task, the subject had to determine whether the analogy between the two pairs was valid, based on a subset of trait(s) randomly selected for each trial. Participants were instructed to solve each problem based on relevant ("to-be-attended") trait(s) only, to ignore irrelevant ("to-be-ignored") traits, and to decide as quickly and accurately as possible. A trait list consisting of four words naming each trait was displayed in the center of the screen, between the A:B and C:D pairs of cartoon characters. On each 8-second trial, the target pair (A:B) appeared on the screen for 1.7 s (target phase). The trait names were all shown in black font during the target phase. After the target pair disappeared, the to-be-attended trait cue(s) turned red (cue phase) and remained on the screen. After 0.3 s, the probe pair (C:D) appeared on the right side of the screen (probe phase), and subjects were allowed a maximum of 6 s to respond with a key press. The delayed cuing of to-be-attended traits ensured that subjects

had to actively pay attention to all visual information about the A:B pair and that potential sources of interference would therefore be encoded into working memory.

Relational complexity level (number of to-be-attended traits, 1 or 3) and need for interference resolution (number of to-be-ignored traits that supported an incorrect response, 0 or 1) were manipulated in a factorial event-related fMRI design. There was a large increase in response time (RT) for PPA problems at the higher level of relational complexity. There was also an interactive effect of interference, which resulted in a reliable increase in RT only at the higher level of relational complexity. This overadditive interaction in the RT data resembled that found in previous studies using the PPA task (Cho et al., 2007; Viscontas et al., 2004). Both higher complexity and presence of interference significantly reduced accuracy in solving the analogy problems.

The fMRI analyses revealed cortical regions sensitive to increase in demands on relational integration, interference resolution, or both component processes of reasoning (see figure 69.7). In a whole-brain analysis, clusters activated by an increase in relational complexity were identified in bilateral frontal pole, as well as other regions including the MFG and IFG. In an a priori defined anatomical region-of-interest analysis of the lateral PFC comprising bilateral MFG and IFG, regions sensitive to increase in demands on interference resolution were found in bilateral MFG and IFG pars opercularis and the IFG pars triangularis in the right hemisphere. Regions sensitive to both component processes of analogical reasoning were found in bilateral MFG and IFG pars opercularis and the right IFG pars triangularis. It is possible that the neural basis for the behavioral RT interaction that was observed between relational complexity and interference may lie in this region of spatial overlap of activation. As suggested by the LISA model, inhibitory control is particularly critical when multiple relations are mapped in working memory. These overlapping regions may thus be involved in inhibitory control in working memory.

Consistent with proposals that the frontopolar region plays a specific role in reasoning when the outcomes of two or more relational comparisons must be integrated to arrive at a solution (Waltz et al., 1999; Christoff et al., 2001; Kroger et al., 2002), Cho and colleagues (2009) found signal increases in bilateral frontal pole related to increases in relational complexity but not to increased difficulty created by adding interference. By eliminating alternative explanations based on visual complexity or general cognitive difficulty, these results provide strong evidence supporting the hypothesis that the frontal pole plays a distinct role in reasoning tasks that require the integration of multiple relations.

The region-of-interest analyses found that areas of the lateral PFC that have been identified as important in executive control in a variety of cognitive tasks (dorsolateral and inferior frontal region) are also activated by the need

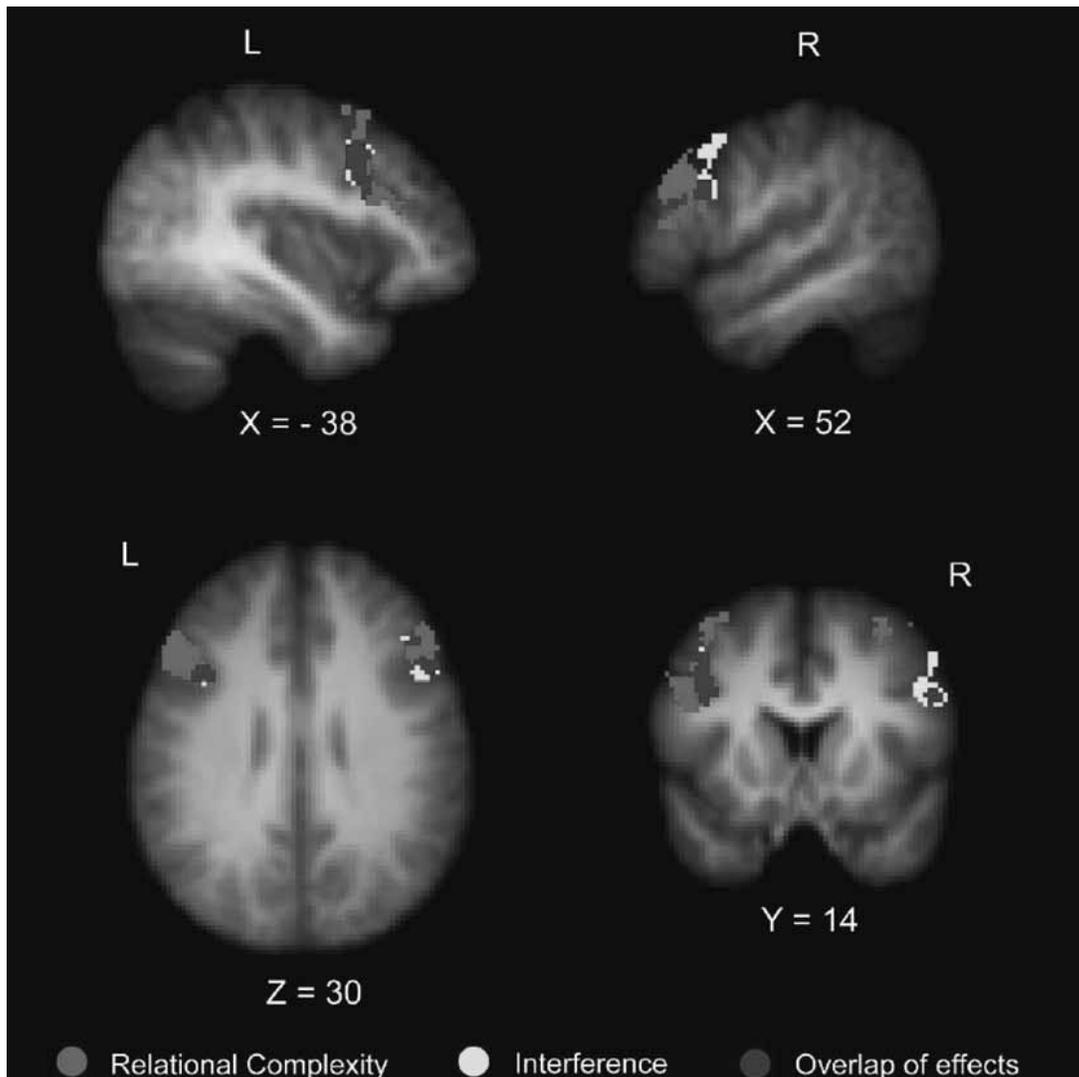

FIGURE 69.7 Neuroimaging results from Cho and colleagues (2009). Regions showing the main effects of relational complexity (shown in red), interference (shown in yellow; small volume corrected, uncorrected cluster-forming threshold $T > 2.3$, corrected cluster extent significance threshold, $p < .05$), and regions where

to resolve interference during analogical reasoning. This finding is consistent with a broad role for these regions in cognitive control. By manipulating multiple cognitive demands simultaneously in a single reasoning task, the Cho and colleagues (2009) study was able to elucidate the neural architecture underlying behavioral interactions between complex cognitive processes. These findings show that analogical reasoning, which requires integration of multiple relations in the face of interference, is associated with the coordination of activity in multiple functionally dissociable regions of the prefrontal cortex. These subregions include those that are relatively more sensitive to demands on one component process, as well as regions that are jointly taxed by both relational integration and interference resolution.

main effects overlapped (blue) within an a priori defined anatomical ROI mask of the bilateral MFG and IFG pars opercularis and pars triangularis. R, right; L, left. Coordinates are in MNI space (mm). (See color plate 83.)

THE TOPOGRAPHY OF THINKING As our survey of recent research makes clear, recent neuropsychological studies have demonstrated the dependence of relational reasoning on PFC, and neuroimaging studies have begun to delineate the functional anatomy of reasoning processes. These studies have converged on the finding that the frontopolar region is specifically activated when a problem requires the integration of multiple relations. As reviewed by Ramnani and Owen (2004), this region has several properties consistent with its playing an important role in complex cognitive tasks. First, the frontopolar region is comparatively larger in humans than in nonhuman primates. Second, unlike other PFC regions, it primarily has reciprocal connections with other supramodal regions in the PFC, suggesting that it is suited for processing abstract information. Third, the cellular

properties of the frontopolar cortex are consistent with its being a site of convergence. Although the density of neurons is not particularly high in this region, postsynaptic spines are extremely plentiful and dense in the dendritic arbors of these neurons.

While neuroimaging data from studies using reasoning tasks is consistent with the hypothesis that the frontopolar cortex subserves relational integration, this region is also activated in several other tasks involving complex cognition. For example, frontopolar cortex is active when subjects interrupt one task temporarily to perform another (a task requirement termed “branching”; Koechlin, Basso, Pietrini, Panzer, & Grafman, 1999) and during episodic memory retrieval (Rugg et al., 1998). It may be possible to develop a theory of frontopolar cortex function that can account for the full range of findings. According to one proposal, the role of the frontopolar cortex is to process internally generated information (Christoff & Gabrieli, 2000). Relational integration might be subserved under this view if it is assumed that the reasoner must manipulate internally generated relations. On the face of it, however, the basic relations that must be integrated in a task such as the RPM (e.g., change in size or shape of a figure) are perceptually available in the problem itself. According to another view, the role of the frontopolar cortex is to integrate the results of multiple cognitive operations (Ramnani & Owen, 2004). Rather than focusing on the type of information being manipulated, this view emphasizes the cognitive processes supported by this region. Ramnani and Owen’s proposal appears to be consistent with the relational integration hypothesis, as the outputs of cognitive processes underlying planning and problem solving (e.g., selected operators and new subgoals) may constitute relations that need to be integrated in order to sequence actions.

Another approach to developing a more precise theory of frontopolar functions is to search for subdivisions that support distinct cognitive processes. Recently, Wendelken and colleagues (2008) argued that the frontopolar region activated by relational integration in analogical reasoning is more lateral than the frontopolar region activated by branching, which is in the most rostral aspect of this region. A similar conclusion was reached by Gilbert and colleagues (2006) in a meta-analysis of neuroimaging studies showing frontopolar activations. Gilbert and colleagues also concluded that multitasking paradigms elicited more rostral activation. Thus it is possible that the most rostral subregion is involved in coordinating multiple task sets and goals, whereas more caudal, lateral subregions are involved in integration of relations (or perhaps, those relations represented in an explicit, declarative code of the sort employed in models of relational thought, such as LISA).

It also appears that there may be dorsoventral differences within the lateral frontopolar cortex, with more dorsal areas

activated during solution of visuospatial problems such as the RPM task and more ventral areas activated during verbal analogy tasks. Such variations may reflect a difference in the type of materials used in the tasks (visuospatial versus verbal), or other differences between the tasks (e.g., generating an analogical solution versus evaluating an analogical mapping). Future research using high-resolution fMRI may be able to further tease apart the contributions of distinct subregions of frontopolar cortex.

Over the past decade, understanding the neural basis of relational reasoning has for the first time become a tractable research problem. Much of the recent progress has been the product of neuroimaging and neuropsychological studies guided by theoretical frameworks developed in cognitive science. As the component processes of reasoning are mapped onto brain regions, it will be possible to delineate a functional network for reasoning. This accomplishment will represent a major step toward understanding the remarkable capabilities of human thought.

70 Decision Making and Prefrontal Executive Function

CHRISTOPHER SUMMERFIELD AND ETIENNE KOECHLIN

ABSTRACT Decision making—the selection of one course of action from among many—critically involves the frontal lobes. Here, we propose a theory of the functional architecture of the human frontal lobes that details the cognitive and motivational processes underlying decision making. We argue for a fractionation of both lateral and medial prefrontal cortices into hierarchical, rostrocaudally arranged control processes, permitting action selection to be guided by task-related information arising across multiple contexts and episodes, and in accordance with likely investment and outcome over both the short and long term. We suggest that the temporal dimension of the decision process may be the key to understanding the functional organization of the frontal lobes, with caudal frontal regions processing the cognitive and motivational demands of immediate action selection, and more rostral frontal cortex responsible for maintaining a task set and its associated value across an extended behavioral episode. Finally, we discuss how cognitive and motivational information might be integrated into a central executive system in the service of decision making.

Decision making is the cognitive process that allows one course of action to be chosen from among several possible options. The human brain is capable of making decisions of astonishing complexity—for example, when a great number of hypothetical outcomes are compared in order to select the winning move in a game of chess. Much of the time, however, the brain is occupied with much more mundane choices—for example, should I reach for that opportunely placed cup of coffee and take a sip? Even quotidian decisions such as this can require a great wealth of information to be integrated in order for the optimal course of action to be identified. First, on a visceral or affective level, many decisions depend on personal preferences—a good starting point might be simply whether you like the taste of coffee. Second, in the vast majority of decisions, a range of complex motivational factors will come into play. What are the likely costs and benefits associated with drinking that cup of coffee—even if it is warm and tasty, might it be too strong, and make me feel rather jittery and nervous? Finally, these motivational factors interact at each stage with a cognitive architecture

that brings relevant contextual information from past and current episodes to bear upon the decision. For example, if the coffee is sitting on the desk in front of you, but belongs to your boss, you might think twice about reaching for it and taking a sip.

How then, does the brain integrate all this cognitive and motivational information to make the right choice? After many years, a picture is emerging of how decision making is controlled by the frontal lobes, that is, the anterior portion of the cerebral cortex stretching from the motor cortex to the rostral pole (see figure 70.1). In this review, we argue that discrete sectors of the frontal lobes make distinct contributions to decision making, with the orbital sector underlying the affective value of the stimulus (e.g., I like coffee), the medial sector controlling the motivation to act (I want coffee), and the lateral sector overseeing the higher-order cognitive structure of plans or goals (I *select* a coffee).

Second, we argue for *hierarchical control* over decision making. Some decisions—such as selecting to press the brake pedal (rather than the accelerator) at a red traffic light—can be undertaken automatically, on the basis of overlearned, habitual routines that require little intervention from the executive processes typically associated with the brain's most anterior zones. Other decisions—for example, electing to drive through a red traffic light, once you suspect that it is malfunctioning—require these sensorimotor affordances to be integrated with specific information pertaining to the current context—for example, the fact that the wait has been unusually long or that other drivers have also chosen to ignore the red light. We call this type of decision process, where basic sensorimotor codes are integrated with information from the current situation, *contextual control*. Finally, relevant past experience or recent task instructions can add yet another layer of pertinent information to a decision. If you have been waiting in front of a red traffic light for several minutes, but you have also just driven past a sign warning that long delays are anticipated, that past information can help you decide whether to continue your frustrating wait. We call this process, by which yet more temporally distant information is brought to bear upon a decision, *episodic control*, because the instruction cue defines the onset or offset of a discrete episode in which a given set of behavioral rules apply. We will argue that sensorimotor, contextual, and

episodic control have both a cognitive dimension, pertinent to the selection of the appropriate action, and a motivational dimension, relevant to calculating the likely investment or outcome associated with a decision (for brevity, we do not discuss the orbitofrontal cortex and the affective component of decision making). Moreover, we will argue that the functional organization of the frontal cortex reflects this dissocia-

tion, with the neural substrates of episodic, contextual, and sensorimotor cognitive control implemented in a hierarchical, anteroposterior fashion along its lateral surface. Last, we will present some new evidence that the medial frontal cortex may exhibit a parallel, hierarchical organization for the motivational dimension of episodic and contextual information.

The lateral frontal cortex: Selection of responses, tasks, and goals

TWO VIEWS OF LATERAL FRONTAL FUNCTION Historically, our understanding of the function of the lateral frontal cortex (LFC) has been informed by two distinct strands of research. The first originated with now classic electrophysiological recordings in the awake behaving monkey, which demonstrated that prefrontal neurons exhibit tonic spiking activity across a delay period in which information has to be temporarily stored (Fuster & Alexander, 1971). Extensive neuroimaging work has built upon this finding to reveal that the LFC is engaged when humans perform short-term memory tasks, analogous to maintaining a telephone number for a span of a few seconds (Curtis & D'Esposito, 2003). The second major framework for characterizing research into the PFC argues that the lateral prefrontal cortex is the source of “biasing” signals that flow back to more posterior cerebral zones. These signals can selectively modulate perceptual (Desimone & Duncan, 1995) or motor (Passingham, 1996) codes on the basis of the currently active task or goal (Miller & Cohen, 2001). A common theme running through both these accounts, thus, is a role for the LFC in selecting actions on the basis of stimuli that are absent, obscured by distracters, or too novel or unexpected to benefit from automated behavioral routines formed by habit (Shallice, 1988). This function has been termed *cognitive control*, and it has proved a useful concept for summarizing the global significance of the prefrontal cortex in orchestrating thought and behavior (Miller & Cohen, 2001). However, despite the notable success of these two perspectives in explaining a wealth of data from brain imaging and electrophysiological recordings, neither view provides an entirely satisfactory answer to the twin problems of functional specialization (how the LFC is organized) and functional integration (how information flows through the LFC) during decision making (Koechlin & Summerfield, 2007).

HIERARCHICAL CONTROL OF ACTION SELECTION IN THE LFC As outlined in the preceding paragraph, action selection can be conceived as a hierarchical process, in which both past and present contextual information can be integrated into the decision process along with elementary associative links between stimulus and response. A hierarchical structure to the prefrontal cortex has been proposed in which successively more anterior prefrontal regions encode increasingly abstract “perception-action” complexes—sustained neural activations that span the bridge between input and output—by way of reciprocal connectivity with parallel hierarchies in the posterior neocortices (Fuster, 2000). Indeed, this view squares well with the widespread observation that content- or domain-specific representations (for example, spatial versus object

codes) tend to be more posteriorly in the LFC (Brodmann's area [BA] 8/44), whereas mid- and anterolateral prefrontal regions are less sensitive to the contents of the information being treated, but rather encode more general aspects of task structure (Christoff & Gabrieli, 2000; Ramnani & Owen, 2004; Sakai & Passingham, 2003). Indeed, the view that the frontal cortex comprises a pyramid for action selection, with abstract plans and goals encoded in more anterior regions, and concrete motor acts in motor and premotor cortical zones, is the centerpiece of several recent theories of lateral prefrontal function (Badre & D'Esposito, 2007; Fuster, 2000; Koechlin & Summerfield, 2007; Petrides, 2005).

THE CASCADE MODEL Koechlin and colleagues (Koechlin, Ody, & Kouneiher, 2003; Koechlin & Summerfield, 2007) have proposed a hierarchical account of decision making in the LFC that suggests a tripartite division among the biasing mechanisms that underpin top-down control of action (figure 70.2). Deciding which action to select, it is argued, requires the convergence of information from three different types of control process: “episodic” control, the tonic maintenance of task-relevant information across the interval separating an instruction cue from the decision; “contextual” control, reflecting the need to integrate information from contextual cues in the immediate environment; and “sensorimotor” control, treating the association between a stimulus and response. Koechlin and colleagues suggest that episodic, contextual, and sensorimotor control are implemented in an anteroposterior fashion along the LFC, with midlateral prefrontal regions (BA 9/46) underpinning episodic control, posterior lateral PFC regions (BA 8/44) subserving contextual control, and sensorimotor control the province of the premotor cortex (lateral BA 6). At the heart of the cascade model is the notion of *subsidiarity*, whereby successively higher regions are recruited only when processing in lower regions is not sufficient to allow optimal decision making to occur. For example, sensorimotor control (the selection of an action on the basis of a simple stimulus-response routine) requires only the premotor cortex but not higher regions, whereas contextual control (where the response is contingent both on the stimulus and context) requires posterior lateral PFC and premotor regions to come online. By extension, episodic control requires all three nodes in the chain to be active. Neural information thus “cascades” down the action selection hierarchy, from anterior to posterior lateral frontal regions, to be integrated at the base, in premotor cortex, where a response can then be prepared and passed to primary motor zones for execution. This model thus describes the gross functional organization of the LFC and simultaneously outlines how information flows between lateral prefrontal regions during decision making—thereby offering a joint solution to the problems of function

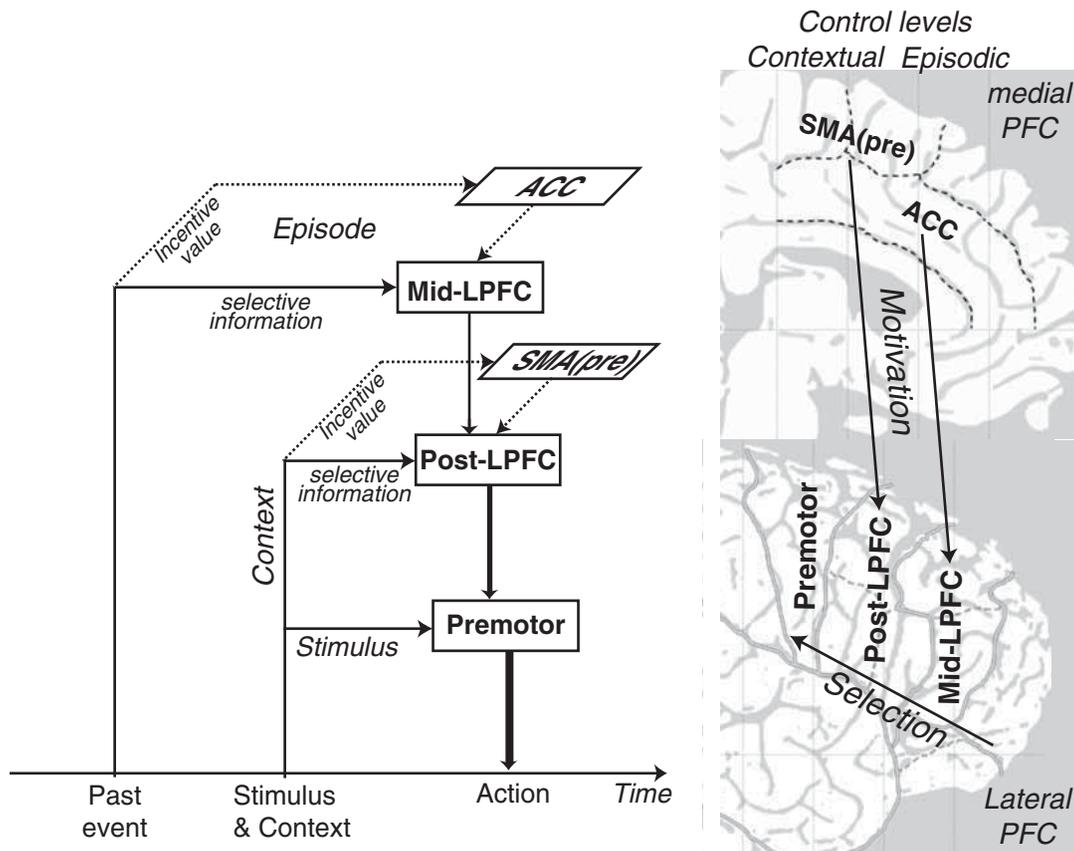

FIGURE 70.2 A model of the architecture of prefrontal executive function. The posterior and middle PFC subserve contextual and episodic control of behavior, respectively. The lateral PFC is involved in contextual and episodic selection based on information extracted from the immediate context and occurrence of past events, respectively. Selection operates through top-down interactions

from anterior to posterior lateral PFC regions. The medial PFC is involved in contextual and episodic motivation based on incentive values extracted from the immediate context and occurrences of past events. Motivation operates through lateral interactions between medial and lateral PFC regions.

localization and functional integration in the frontal cortex (Koechlin and Summerfield, 2007).

EVIDENCE FOR THE CASCADE MODEL Despite its apparent simplicity, this “cascade” model can account for a wide range of data obtained from neurocognitive paradigms directed at understanding the function of the frontal lobes.

Premotor cortex The cascade model noncontroversially supports a rich literature implicating the premotor cortex in basic stimulus-response selection. For example, classic lesion experiments in the monkey demonstrated that selecting a movement in response to a colored cue—with or without an interposed delay—is greatly impaired following bilateral removal of the premotor cortex (Passingham, 1988). Single-cell recordings have confirmed that premotor neurons integrate information from a visual (or somatosensory) cue and its relevant action, presumably affording low-level control over reaching and grasping for objects in peripersonal space (Romo, Hernandez, & Zainos, 2004; Wise, Di Pellegrino, & Boussaoud, 1992). Subsequently, neuroimaging experiments

have drawn a link between simple visuomotor transformation and the premotor cortex (Jenkins, Jahanshahi, Jueptner, Passingham, & Brooks, 2000).

Posterior lateral PFC The function of the posterior lateral prefrontal cortex remains more controversial, but once again early lesion studies in monkeys forged the path to understanding its primary function, with the observation that removal of BA 8 impairs visuomotor selection that is contingent on a contextual cue (Petrides, 1985). Moreover, neurons found in posterior lateral portions of the macaque PFC seem to enact a triangular integration of stimulus, response, and task, precisely as if they were encoding how stimulus-response relations vary according to the currently active task or rule (Averbeck, Sohn, & Lee, 2006; Wallis, Anderson, & Miller, 2001). In humans, tasks that require decisions about “bivalent” stimuli, to which one of two possible responses is indicated by a concurrent (or immediately preceding) contextual cue—which are a feature of many experiments exploring the neural correlates of switching between tasks, or the neural basis for allocating attentional priority—invariably engage

the posterior dorsolateral prefrontal cortex, also known as the inferior frontal junction (Brass, Derrfuss, Forstmann, & von Cramon, 2005; Derrfuss, Brass, Neumann, & von Cramon, 2005). Posterior lateral PFC regions are also particularly sensitive to situations where a weak stimulus-response association must be favored over a stronger one, as is required for conflict resolution in the Stroop task (Kerns et al., 2004). All these effects can be conceived as instances of contextual control, where decision making demands the integration of neural signals linking stimulus and response with other information denoting the currently active task or rule (Bunge, 2004).

Midlateral PFC Third, in contradistinction to posterior lateral PFC regions, surgical removal of the more anterior lateral prefrontal zone (BA9/46) results in impaired performance on delayed “nonmatch to sample” tasks, in which information about an object or spatial configuration must be actively sustained across a delay period, to permit the selection of an alternate or nonmatching item (Petrides, 1991). Accordingly, neuroimaging studies tracking brain activity across the delay period on such tasks typically observe activations in midlateral portions of the prefrontal cortex, in BA9/46 (Curtis & D’Esposito, 2003; Wager & Smith, 2003). This region is probably the human homologue of the macaque periprincipal area in which tonically firing “memory” cells were first isolated by Fuster and his colleagues (Fuster & Alexander, 1971). There is thus considerable evidence underlining the role of the midlateral PFC in guarding task-relevant information active in a temporally extended fashion, thus allowing past task instructions to modulate action selection across a behavioral episode (episodic control), over and above more immediate contextual or sensorimotor signals.

The most direct evidence for the cascade model, however, comes from neuroimaging experiments that have measured brain activity on blocks of trials tailored to conform precisely to the demands of sensorimotor, contextual, and episodic control (Badre & D’Esposito, 2007; Koechlin et al., 2003). For example, Koechlin and colleagues acquired brain images while subjects performed (1) a simple choice among stimulus-response contingencies, for example, a right button press to a red square and a left button press to a green square (requiring sensorimotor control); or (2) either a vowel/consonant or an uppercase/lowercase discrimination on singly presented Roman letters, with the relevant task indicated by the color of the stimulus (requiring contextual control); or these tasks where (3) color-response (or color-task) assignments, rather than occurring consistently across experimental blocks (i.e., red = right, green = left), cycle from block to block (e.g., for some blocks, cyan = left, yellow = right; for others, cyan = right, yellow = left), requiring subjects to encode, maintain, and implement episodic information

derived from the instruction cue at the debut of each block (requiring episodic control). Crossing sensorimotor, contextual, and episodic tasks in a factorially designed neuroimaging experiment has confirmed that midlateral prefrontal, posterior lateral prefrontal, and premotor cortices subserve episodic, contextual, and sensorimotor control, respectively (Badre & D’Esposito, 2007; Koechlin et al., 2003).

Patterns of anatomical connectivity observed in the lateral prefrontal cortex of the macaque lend further plausibility to hierarchical accounts of cognitive control, as each subregion of the PFC seems to share connectivity both with higher and lower regions in the chain of command, as well as with corresponding regions in posterior neocortex (Barbas, 2000). Premotor cortex and posterior lateral and midlateral PFC are thus ideally placed to make complementary contributions to top-down control of perception and action, by means of reciprocal interconnectivity with zones responsible for perceptually treating and encoding the objects prompting the decision process. Moreover, assaying functional connectivity during the implementation of episodic and contextual control has revealed that coupling from relevant higher to lower regions is increased by each of these control processes, consistent with a backward cascade of information through the processing hierarchy during decision making (Koechlin et al., 2003).

An emerging view thus characterizes the decision processes leading to action selection in the LFC as a hierarchical system. In the cascade model, successively anterior regions are not homuncular command centers that orchestrate behavior in lower modules, but rather an integrated network that collectively extends the temporal frame across which a decision is taken. This permits information from the more and more distant past to be brought to bear upon a decision, allowing the flexible selection of action across diverse and rapidly changing contexts and episodes.

The medial frontal cortex: Movement, monitoring, and motivation

Neural activity in the medial frontal cortex (MFC) frequently accompanies LFC activity during decision making. The MFC comprises the gray matter extending along the median walls of the frontal lobe, from the motor cortex to the orbitofrontal cortex. The anterior cingulate cortex (ACC), also including caudal and rostral sectors, follows the length of the medial frontal cortex at its inferior aspect abutting the white fiber bundles of the corpus callosum, making up about half its total volume. In contrast to the emerging consensus about the functional organization of the LFC, however, much less is known about how different regions within the MFC might contribute to decision making. Here, drawing together a spectrum of current theories of MFC function, we argue that the primary role of the MFC is *motivational control*, that is, a

calculation of the requisite investment for optimal control over action selection. Subsequently, we will raise the possibility that there may be a hierarchical implementation of motivational control along the rostrocaudal axis of the MFC.

ANATOMICAL DEFINITIONS For the purposes of this review, we divide the MFC into three sectors (Amodio & Frith, 2006; Koski & Paus, 2000; Picard & Strick, 1996). (1) The dorsal MFC (dMFC) comprises caudal motor areas and the SMA; (2) the posterior rostral MFC (prMFC) includes the pre-SMA and the dorsal portion of the ACC lying anterior to $y = 10$; (3) the anterior rostral MFC (arMFC) extends more anteriorly to the border with the orbitofrontal cortex, at $z > 0$, including regions often termed the paragenual and subgenual cingulate, and ventromedial prefrontal cortex. See figure 70.1 for details. Our discussion focuses largely upon sectors 1 and 2, and in much of what follows we use the term MFC to refer to the dMFC/prMFC.

THEORIES OF MFC FUNCTION Historically, the MFC has been considered a critical part of the motor system, and early theories focused on the various contributions of the SMA and ACC to action planning and execution (Dum & Strick, 1992) and to converting intentions into actions (Paus, 2001). Subsequent work framed the ACC as part of the “executive” attention system of the human brain, as early PET studies revealed its participation in domain-independent target-detection processes (Posner & Petersen, 1990) or the acquisition of novel complex information (Raichle et al., 1994), giving rise to the view that the MFC may participate in “attention to action” (Passingham, 1996). However, it was the stream of research that began with the observation that the dorsal MFC responds vigorously to errors (Carter et al., 1998; Falkenstein, Hohnsbein, & Hoormann, 1995; Niki & Watanabe, 1979; Taylor, Stern, & Gehring, 2007) and situations involving conflict among competing response options (Botvinick, Nystrom, Fissell, Carter, & Cohen, 1999) that forms the basis for most contemporary thinking about the function of the MFC. Current perspectives, which will be summarized in more detail later, emphasize an *evaluative* role for the MFC, arguing that its primary function is to monitor and adjust levels of control needed for efficient implementation of task and action selection in the lateral PFC (Botvinick, 2007; Holroyd & Coles, 2002; Ridderinkhof, Ullsperger, Crone, & Nieuwenhuis, 2004; Rushworth & Behrens, 2008). This evaluative role might be important for maximizing outcome across an instrumental learning schedule (Holroyd & Coles, 2002; Rushworth & Behrens, 2008) and/or assessing the costs associated with an action (Walton, Rudebeck, Bannerman, & Rushworth, 2007), casting the ACC as a critical part of the reward system of the human brain, with a role in representing the subjective

value of actions (Rushworth, Behrens, Rudebeck, & Walton, 2007). These approaches assume that control is a flexible resource whose allocation can be increased to meet the needs of a particularly challenging task or to encourage optimal performance in a situation where the stakes (potential gains or losses) are raised. We call this process by which investment is adjusted to modulate decision making *motivational control*, and we suggest that it may be implemented by way of recurrent interactions between the LFC and MFC.

ADJUSTING MOTIVATION TO MEET CHANGING TASK DEMANDS

Many environments are inherently unstable, and levels of control required to arbitrate among possible actions in a stable, familiar milieu are unlikely to suit efficient decision making in a novel or unpredictable situation (Behrens, Woolrich, Walton, & Rushworth, 2007). For example, even a seemingly tranquil, uneventful drive along the open motorway can abruptly require higher levels of control to be engaged, for example, when sudden heavy rain reduces visibility, the traffic bunches up, and you are diverted through an unfamiliar section of the carriageway. Neuroimaging studies are often designed to mimic this volatility, intermixing high-demand and low-demand trials in rapid succession (such as “congruent” and “incongruent” in the Stroop task, or “switch” and “stay” trials in task-switching paradigms). Noting the striking sensitivity of medial prefrontal regions to the onset of conflict among competing stimulus-response assignments (Botvinick et al., 1999), as well as to negative performance outcomes, such as errors (Carter et al., 1998; Gehring, Gross, Coles, Meyer, & Donchin, 1993), many theorists have argued that the MFC keeps track of the likely demand associated with a forthcoming event or behavioral episode (Brown & Braver, 2005), perhaps signaling this information to the lateral PFC in order to dynamically adjust cognitive control according to current needs. Evidence in favor of this view comes from studies reporting neural signals in the MFC that precede and predict task-induced adjustments in performance. Among the best described of these is the speed-accuracy trade-off, whereby challenging or high-risk situations tend to be approached more cautiously, with slower but more accurate responses. For example, the slowing in reaction times that immediately follows an error trial (“posterror slowing”) (Rabbitt, 1966) is predicted by the amplitude of the error-related negativity (ERN), a potential with a probable source in the MFC (Gehring et al., 1993; Yeung, Cohen, & Botvinick, 2004). Similarly, activity in the ACC predicts “conflict adaptation” (Kerns et al., 2004), that is, the reduced response-time cost on an incongruent trial following another incongruent trial (Gratton, Coles, & Donchin, 1992), as well as predicting LFC activity on the subsequent trial. Conflict adaptation may occur because

levels of control are increased once conflict has been detected, such that the second incongruent trial is tackled more effectively than the first (Egner, 2007).

ADJUSTING MOTIVATION TO MEET CHANGING ACTION-OUTCOME ASSOCIATIONS In addition to these moment-to-moment fluctuations in the level of cognitive resources or effort required to tackle the local environment, so also the risk, stake, and value associated with actions are subject to change. Adjustments to the gains and losses associated with an action might be gradual, as with encroaching satiety during feeding, but they can also reverse abruptly; for example, the slot machines at an amusement park might yield nothing for several successive trials, but then suddenly offer a large payout. Accumulating evidence suggests that the MFC can step in to increase control on the basis of shifting reward contingencies, allowing motivational signals to guide decision making on the basis of likely reward and punishment (Holroyd & Coles, 2002; Rushworth, Walton, Kennerley, & Bannerman, 2004). Notably, large portions of the MFC respond to aversive stimuli, such as pain (Vogt, 2005), but primary (Amiez, Joseph, & Procyk, 2006) and secondary (McClure, Laibson, Loewenstein, & Cohen, 2004) rewards also evoke potent responses in the posterior MFC, with cells responsive to positive and negative feedback often intermingled in the same stretch of tissue (Matsumoto, Matsumoto, Abe, & Tanaka, 2007). However, just as for negative-valenced or conflict-based signals, this response to positive feedback is often contingent on its relevance for future behavior. For example, neurons in the MFC respond to an unexpected reduction in the level of reward associated with a given action—but only when the monkey takes this event as a cue to switch to another movement, in order to maximize overall outcome (Cohen & Ranganath, 2007; Shima & Tanji, 1998). The responses of both neurons that prefer positive feedback and those that prefer negative feedback are scaled by the disparity between the reward that is expected and that which is actually received—with greater signals elicited by more surprising events in both cases (Matsumoto et al.; Oliveira, McDonald, & Goodman, 2007). This evidence has given rise to an emerging consensus that the MFC monitors for the mismatch between expected and observed outcomes—whether positive or negative—adjusting motivational control in order to maximize the benefits and minimize the costs associated with a chosen course of action.

Functional fractionation of the MFC

Does the MFC contribute to motivational control monolithically, or are dissociable contributions made by different sub-sectors, such as the dMFC, prMFC, and arMFC? In this final section we propose a theory of functional organization

of the MFC, inspired by the intuition that motivational control signals may be engaged on the basis of current, contextual information, such as the immediate presence of two stimuli associated with conflicting response tendencies (“contextual motivational control”) or may be required to adjust decision making over a longer episode with particular demand or outcome characteristics (“episodic motivational control”). Based on a review of the extant literature and on new work from our own laboratory, we propose that episodic and contextual motivational control are implemented in rostral (i.e., dorsal ACC) and caudal portions (i.e., SMA) of the posterior MFC, respectively (figure 70.2).

Initial support for this view comes from extant studies describing the implementation of conflict and error processing in the MFC. Although some researchers have suggested that the MFC response to errors on tasks requiring high levels of control (such as the Stroop) might mask a primary sensitivity to the response competition that provoked the error (Carter, Botvinick, & Cohen, 1999), it is interesting to reflect that response conflict (once detected) must be resolved immediately in order for an optimal decision to be made, whereas errors or negative feedback invariably occur too late to apply to immediate behavior—rather, they are relevant to future events occurring within the same episode (Ullsperger & von Cramon, 2004). Indeed, it is intriguing (but rarely noted) that posterror slowing and conflict adaptation have opposing effects on response time, consistent with the view that errors and conflict may have dissociable neurocognitive consequences. One possibility, therefore, is that resolving immediate response conflict thus demands contextual motivational control, but errors may lead to an up-regulation of episodic motivational control.

This contention is supported by a growing literature reporting that response conflict is primarily the province of more posterior, dorsal MFC regions, such as the SMA (and/or more anterior counterpart, the pre-SMA) whereas errors tend to activate the ACC proper (Nachev, 2006; Rushworth et al., 2004; Ullsperger & von Cramon, 2004), even in studies where the overlap between conflict- and error-sensitive voxels is emphasized (Kerns et al., 2004). One influential review (Rushworth et al., 2004) notes that across a number of fMRI studies in which response conflict was elicited—including versions of the oddball, flanker, and go-no-go tasks—error responses were isolated in unambiguous cingulate territory, whereas conflict without error additionally activated the motor zones of the superior frontal gyrus. Similarly, evoked scalp negativities recorded over the MFC of a patient with a lesion confined to the ACC dissociated error-monitoring responses from conflict-detection responses (Swick & Turken, 2002). These findings suggest that the SMA and ACC may make dissociable contributions to the processing of conflict and errors, respectively, and support

the view that the ACC is activated when motivational control is required over an extended episode, whereas the dorsal MFC is responsible for energizing control processes in response to immediate contextual incentives.

IMMEDIATE AND REMOTE RELEVANCE OF DEMAND Is this perspective at variance with the widely held view that it is the ACC, not the SMA, that is responsible for conflict detection? We find it useful to distinguish activations that predict trial-by-trial adjustments in the neurocognitive correlates of control on the *subsequent* trial and those that simply respond to a cognitive challenge on the *current* trial, such as voxels sensitive to incongruent events on a Stroop paradigm. Neural correlates of adjustment to future events, such as those observed during conflict adaptation, tend to occur in the ACC but not the SMA (Botvinick et al., 1999), whereas the simple demand for response competition to be addressed—such as is found on incongruent, relative to congruent, trials—activates a swath of medial frontal cortex extending well beyond the ACC into the pre-SMA and SMA (Barch et al., 2001; Nee, Wager, & Jonides, 2007). Other studies have specifically noted that the ACC is activated by motivational information that is relevant to forthcoming events, such as the probability that an error will be made on future trials (Brown & Braver, 2005). Moreover, in task-switching paradigms, where an entire experimental block is associated with increased likelihood of a switch, the ACC but not the SMA is engaged in a sustained fashion (Braver, Reynolds, & Donaldson, 2003; Dosenbach et al., 2006). These findings are wholly consistent with the view that the ACC tracks the need for motivational control across a future episode, in contrast to the SMA, which responds to conflict among current motor plans (Nachev, Wydell, O'Neill, Husain, & Kennard, 2007).

IMMEDIATE AND REMOTE RELEVANCE OF REWARD A substantial literature describing single-cell electrophysiology data in awake, behaving monkeys suggests that ACC neurons encode episodic aspects of reward—those whose relevance extends over the longer term. For example, the reward responsivity of ACC (but not SMA) neurons is dependent on whether the outcome triggers a change in strategy, such as a switch from one action to another (Shima & Tanji, 1998), and ACC neurons signal with responses of increasing potency the proximity of a reward obtained at the end of an extended behavioral sequence (Shidara & Richmond, 2002), and may encode an estimate of the value associated with an ongoing task (Amiez et al., 2006; Sallet et al., 2007). Perhaps the most striking evidence, however, comes from lesion studies in monkeys with comprehensive cingulate lesions, who exhibit relatively normal motor control but show deficits on a decision-making task that requires the reward history to be integrated across several trials to optimally select a response

(Kennerley, Walton, Behrens, Buckley, & Rushworth, 2006; Walton et al., 2007). The neural sequelae of reward are not so well characterized in human dorsal MFC, but it is intriguing that fMRI activity in the ACC tracks temporal discounting, the relative value of a reward as its arrival is delayed into the future (McClure, Ericson, Laibson, Loewenstein, & Cohen, 2007; McClure et al., 2004). Moreover, recent studies that have combined computational modeling with neuroimaging have noted the sensitivity of the ACC to parameters encoding variation in the reward rate associated with a response, tantamount to an estimate of the ongoing volatility of the environment (Behrens et al., 2007) or to the tendency for the organism to explore available options rather than exploit a reliable reinforcer (Daw, O'Doherty, Dayan, Seymour, & Dolan, 2006). These results imply that the ACC is particularly active whenever the environment contains rich information about the reinforcement available in the current episode (i.e., a higher learning rate), a contention that is consistent with its extensive interconnectivity with other limbic structures involved in learning and memory (Vogt, Pandya, & Rosene, 1987).

Direct evidence for a hierarchy of motivational control, however, comes from an fMRI study in which contextual and episodic motivational control were varied as independent factors (Kouneiher, Charron, & Koechlin, in press). During performance of a challenging cognitive task, subjects were financially rewarded for each block of 12 trials completed with no errors (+1 euro), received no reward for blocks with a single error, and were punished incrementally for each additional error (−1 euro). However, specific trials (bonus trials) designated with a contextual signal (a frame around the stimulus) carried additional incentives, which we reasoned would lead to increases in contextual motivational control. Critically, however, the stake associated with these additional incentives was scaled on a block-by-block (episodic) basis: on high-episodic-motivation blocks performance in bonus trials led to additional gains/losses (± 2 euros), whereas on low-episodic-motivation blocks, the additional gains/losses were negligible (± 5 cents). The neuroimaging results supported the proposed dissociation between episodic and contextual motivational signals: the ACC responded in a sustained fashion to high > low episodic motivation, with a response that deviated reliably from zero even on non-bonus trials falling within a high-episodic-motivation block. By contrast, a region falling on the SMA/preSMA border phasically responded to only bonus trials in high-motivation blocks, consistent with its participation in the processing of immediate contextual incentives. This dissociation between caudal and rostral subportions of the posterior MFC awaits confirmation by further studies.

ANTERIOR ROSTRAL MFC: OUTCOMES ASSOCIATED WITH HYPOTHETICAL STATES? A discussion of the functional

fractionation of the MFC would not be complete without consideration of the arMFC, which seems to constitute yet another functionally distinct subdivision of the MFC (Steele & Lawrie, 2004), notable for its participation in the cognitive processes underlying social behavior, such as evaluating the mental states of others (Amodio & Frith, 2006) or contemplating the self (Mitchell, Banaji, & Macrae, 2005). These findings are complemented by parallel studies implicating the arMFC in decisions based on emotional information (Bush, Luu, & Posner, 2000; Etkin, Egner, Peraza, Kandel, & Hirsch, 2006) and the regulation of emotional responding (Ochsner, Bunge, Gross, & Gabrieli, 2002), leading to the conjecture that control operates in neuroanatomically distinct (dorsal) “cognitive” and (rostral) “emotional” domains. However, in addition to their role in social/emotional processing, the arMFC and accompanying subgenual cingulate cortex are also sensitive to a perplexing variety of other cognitive and motivational factors, including autobiographical recollection and imagination (Gehring & Knight, 2000), and decision processes that require the estimation of the outcome associated with an ambiguous situation or “generative model” of the world. For example, lesions to the arMFC engender deficits on “reversal learning” tasks in which stimuli with a high or low probability of reward are switched unpredictably (Fellows & Farah, 2007), forcing subjects to formulate an internal model of which of two possible states is currently active (Daw et al., 2006; Hampton, Bossaerts, & O’Doherty, 2006; Koechlin, Danek, Burnod, & Grafman, 2002). Moreover, arMFC lesions impair economic decisions where short-term gain must be subsumed in favor of a response program that maximizes gain over the longer term (Fellows & Farah, 2005). We speculate that the hierarchy of motivational control in the MFC continues into anterior rostral regions, where an outcome value may be assigned to a hypothetical future or “model-based” state rather than a currently ongoing episode—including the assignment of likely outcome to the mental states of others (Amodio & Frith, 2006). This distinction would mirror the dissociation observed in the LFC between BA 9/46 and the frontopolar cortex (BA 10), the latter of which seems to form a “buffer” that is engaged whenever a currently active task set is placed in a pending state, allowing flexible scheduling among different tasks (Koechlin, Basso, Pietrini, Panzer, & Grafman, 1999; Koechlin & Hyafil, 2007) and thereby circumventing the well-described capacity limits (“attentional bottleneck”) on central processing (Pashler, 2000; Sigman & Dehaene, 2005). The most rostral cortical areas thus may subserve the cognitive and motivational processes that allow us to interleave several behavioral episodes associated with different decision rules, allowing us to simultaneously perform two tasks with minimal mutual interference and maximal common outcome.

Conclusions

Great strides have been taken in understanding how the frontal lobes contribute to decision making, but much remains to be discovered. A crucial question for future research is likely to be the nature of the interactions between medial and lateral prefrontal cortices during decision making. While many theories have argued that MFC computes the motivational significance of an event and transmits this information to the LFC for task implementation (Carter et al., 1999), this unidirectional flow of information between MFC and LFC has been questioned by a study demonstrating that the error-related negativity is altered in patients with LFC lesions (Gehring & Knight, 2000). Instead, we argue that MFC and LFC may engage in a reciprocal exchange of information, allowing the relative importance of sensorimotor, contextual, and episodic information to be weighted as a function of its likely motivational significance. This process would allow the frontal lobes to arbitrate among potentially competing past and present influences upon action selection, in the interest of optimally guiding decision making.

ACKNOWLEDGMENTS We would like to thank Tobias Egner, Alexandre Hyafil, and Frederique Kounieher for helpful comments on the manuscript. This work was supported by a European Young Investigator award to E.K.

71 Circuits in Mind: The Neural Foundations for Object Concepts

ALEX MARTIN

ABSTRACT Functional neuroimaging studies have provided convincing evidence to support three main conclusions about the neural circuitry that underpins our understanding of objects in the world. First, our conceptual system contains property-based neural circuits *grounded* in the systems that support perceiving, acting, and feeling. Second, our conceptual system prominently includes relatively distinct neural circuits for processing and storing *domain-specific* information. Third, these circuits reflect the *interpretation* or meaning assigned to an object, not its physical features. Outstanding questions and problems with an embodied, domain-specific view of conceptual representation, as well as the role of the anterior regions of the temporal lobes in conceptual processing and semantic memory, are discussed.

Every day we encounter new exemplars of objects that we have never seen before. Yet we identify each as belonging to a particular category—as a chair, a dog, a tree—instantly and effortlessly. In fact, it has been shown that as soon as we *see* it we *know* what it is (Grill-Spector & Kanwisher, 2005). This mundane phenomenon underscores the fact that object recognition must be—in part—an act of memory. Perceiving, as William James recognized 120 years ago, is largely dependent on stuff that “comes out of our own heads.” Indeed, for James, this idea was important enough to be considered “the general law of perception” (W. James, 1890). This chapter will focus largely on what we have learned about the stuff in our heads that allows us not only to perceive, but also to imagine and think about objects in the world.

What is an object concept?

For our purposes, *object concept* will be used to refer to the representation (i.e., the information stored in memory) of an object category (a class of objects in the external world) (Murphy, 2002). In this view, concepts are in our heads, categories are in the world. This distinction in no way under-

mines the fact that any object category (hammers, dogs) can be *categorized* in a nearly infinite variety of ways. For example, both hammers and dogs belong to the category of things that are smaller than a house. The neural basis for creating flexible ad hoc categories (Barsalou, 1989) will not be discussed here other than to note that the available neurophysiological evidence suggests that this ability rests heavily on activity in the prefrontal cortex, in interaction with the temporal lobes (see Miller, Nieder, Freedman, & Wallis, 2003, for review). Here I focus on the neural underpinnings for basic-level categories as defined in the following paragraphs.

The primary function of concepts is to allow us to quickly draw inferences about an object’s properties. That is, identifying an object as, for example, a “hammer” means that we know that this is an object that is used to pound nails, so that we do not have to rediscover this property each time the object is encountered (see Murphy, 2002, for an extensive review of cognitive studies of concepts). In this sense, object perception involves not only making contact with stored information about the features present in the stimulus (e.g., what hammers typically look like), but also inferred information about other features or properties (e.g., those related to its function).

A major feature of object concepts is that they are hierarchically organized, with the broadest knowledge represented at the superordinate level, more specific knowledge at an intermediary level commonly referred to as the basic level, and the most specific information at the subordinate level. For example, “dog” is a basic-level category that belongs to the superordinate categories “animal” and “living things,” and has subordinate categories such as “poodle” and “collie.” As established by Eleanor Rosch and colleagues in the 1970s, the basic level has a privileged status (Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976; Rosch, 1978). It is the level used nearly exclusively to name objects (e.g., “dog” rather than “poodle”). It is also the level at which we are fastest to verify category membership (i.e., we are faster to verify that a picture is a “dog” than an “animal” or a “poodle”). It is also the level at which subordinate category members share

ALEX MARTIN Laboratory of Brain and Cognition, National Institute of Mental Health, Bethesda, Maryland

the most properties (e.g., collies and poodles have similar shapes and patterns of movement). Finally, the basic level is the easiest level at which to form a mental image (you can easily form an image of an elephant but not of an “animal”). This hierarchical organization has played a prominent role in the neuropsychology and computational modeling of semantic memory (e.g., McClelland & Rogers, 2003; and see chapter 72 in this volume by McClelland, Rogers, Patterson, Dilkina, & Lambon Ralph). Nevertheless, the great majority of neuropsychological and neuroimaging studies have concentrated on understanding how basic-level concepts are represented in the brain.

Neural foundations for conceptual representations

Before describing what we know about the circuitry underpinning the representation of basic object concepts, it is important to draw a distinction between explicit and implicit levels of knowledge representation and expression. There is no need for any organism to acquire information unless that information can be expressed. Organisms learn, and the evidence for that learning is demonstrated by a change in behavior. What is represented (stored) in the brain is information. What is expressed is knowledge. How this knowledge is expressed is of fundamental importance for understanding how information is represented. For humans, a primary, and arguably *the* primary mode of expression, is the language system. Questions designed to probe knowledge about a specific entity are posed orally or in written form, and subjects respond verbally. Occasionally, a manual response may be required (e.g., show me how you would use a hammer) either by actually manipulating the object or by pantomime. However, regardless of whether the response is verbal or manual, knowledge is expressed explicitly. This explicit knowledge is typically referred to as associative knowledge or encyclopedic knowledge, and it is this level that is typically probed in both normal and brain-damaged individuals. Associative or encyclopedic knowledge has three main characteristics. First, as noted earlier, retrieval is explicit. Second, there is no intrinsic limitation on the amount of information that can be stored and retrieved. For a specific category of objects, (e.g., *dogs*), we may know lots of things. We know they are living things, have four legs, are smaller than a car, like to take walks, like to play fetch, and so on, and so on. Moreover, it does not matter whether the information is true. If you believe that dogs can fly, then that information is part of your semantic knowledge about dogs and is represented somewhere in your brain. Finally, this level of knowledge is idiosyncratic. Some people know lots about dogs, whereas others know very little.

This explicitly expressed knowledge about objects can be contrasted with a different level of object concept representation referred to as core properties or “semantic primitives”

(Martin, 1998). In contrast to encyclopedic knowledge, semantic primitives are accessed implicitly and automatically in the service of comprehension, are highly constrained in number, and are universal. This level of representation allows us to quickly and efficiently identify objects and understand words, and forms the foundation for our vast stores of encyclopedic knowledge about objects.

While the model to be described here does not address the organization of encyclopedic knowledge, it makes strong claims about the organization of semantic primitives with regard to both their representational content and organization in the brain. For example, the semantic primitives associated with common tools include stored representations of what they look like, how they move when used, and how they are manipulated. They are stored within the same neural systems active when we learned about those properties. Specifically, they are stored within visual processing systems for perceiving object form and object motion, as well as action systems responsible for visuomotor transformations and for grasping and manipulating objects. These primitives are assumed to underpin object meaning in perception—regardless of the stimulus modality (visual, auditory, tactile) or format (pictures, words)—and in thought and imagination.

The distinction between an implicit level and an explicit level of representation underscores the fact that the embodied view of conceptual representation to be discussed in this chapter is not meant to provide an exhaustive description of a concept. It is undoubtedly true that a great deal of what we know about any concept is mediated by, and stored in, the language system. As will be described, some of this information is directly grounded in perceiving, acting, and feeling (e.g., verbal information about sensory- and motor-system-based properties). Other types of information may be truly abstract (nonembodied) and verbally mediated only (although see Barsalou, 1999, for a different view of the relationship between abstract concepts and perceptual systems).

Object concepts are grounded in the neural systems that support perceiving, acting, and feeling

Embodied cognition, including the notion that object concepts are grounded in perception and action systems, has become an increasingly popular view in modern cognitive science (e.g., Barsalou, 1999, 2008; Lakoff & Johnson, 1999; Wilson, 2002; Zwaan & Taylor, 2006). Although it is new to cognitive science, this idea has, in fact, a long history in behavioral neurology. For example, in an article published in the first volume of the journal *Brain*, the neurologist W. H. Broadbent wrote, “The formation of an idea of any external object is the combination of the evidence respecting it received through all the senses” (Broadbent, 1878). This claim was echoed a number of years later by a young

Sigmund Freud in his classic monograph *On Aphasia*: “The idea of the object is a complex of associations composed of the most varied visual, auditory, tactile, and kinesthetic and other impressions” (Freud, 1891) (see figure 71.1). Of course, the idea of an object must include information obtained through the senses. Where else would the information come from? What made these claims nontrivial, however, was that for both authors the information they spoke of was located or stored in the sensory processing systems themselves. In their view, our concepts were not abstract, verbal information stored in a place (association cortex?), but rather concepts were directly grounded in our sensory systems (see also Lissauer, 1890/1988). This very modern view of embodiment stands in marked contrast to the view that dominated cognitive psychology since the downfall of behaviorism in the 1950s whereby concepts were considered to be abstract, propositional, and amodal (e.g., Anderson, 1983; for discussion see Barsalou, 1999). Strictly amodal formulations now have largely disappeared, largely because of neuropsychological and especially neuroimaging evidence. Thus, as recently stated by a prominent group of neuropsychologists specializing in the study of semantics, “Essentially all current theoretical positions about semantic memory share the view that much of the content of our semantic memory relates to perception and action, and is represented in brain regions that overlap with, or possibly even correspond to, the regions that are responsible for perceiving and acting” (Patterson, Nestor, & Rogers, 2007).

Most of the direct evidence to support this type of embodiment claim comes from neuroimaging studies. In one of the earliest attempts to explore this issue, we used positron emission tomography (PET) to measure brain changes when subjects verbally generate different types of object-associated properties. Subjects provided words denoting object-associated colors in one condition (e.g., “yellow” in response to an achromatic picture of a pencil), and the names of associated actions in another condition (“write” in response to that same object). In line with an embodied view, direct comparison of these conditions showed that generating color associates activated regions in the ventral temporal cortex, downstream from regions known to respond to low-level visual processing of object form and form-related properties like color, whereas verb generation produced activity in the lateral part of the temporal lobe just anterior to, and thus assumed to be downstream from, the region responsible for low-level visual motion processing (other regions were also selectively active, especially during verb generation; for details see Martin, Haxby, Lalonde, Wiggs, & Ungerleider, 1995). The findings and conclusions were strengthened by the fact that the same results were found regardless of whether the stimuli were object pictures or their written names (Martin et al., 1995).

Nevertheless, there was a bit of hand waving here. The brain regions engaged during color perception and motion perception were not mapped, so the claim of embodiment—the correspondence between knowing and

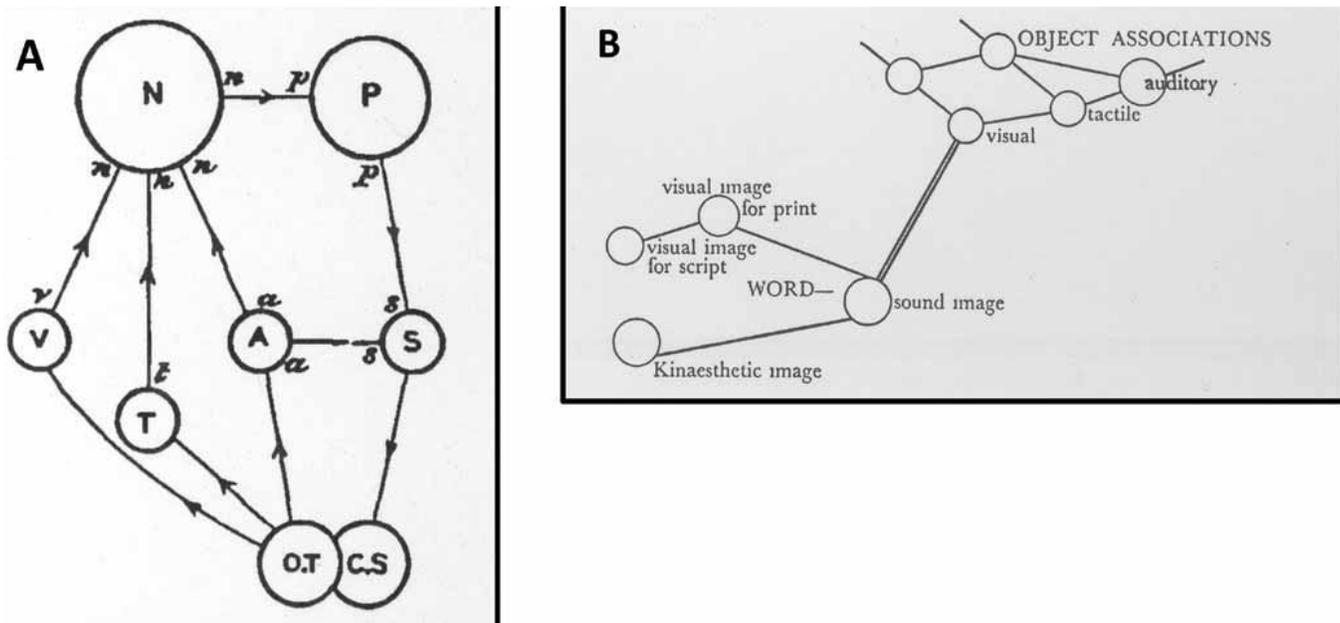

FIGURE 71.1 (A) Example of an embodied view of conceptual representation as depicted by W. H. Broadbent in 1878. *N* refers to the “Idea Centre” or “Naming Centre”; *V*, visual; *A*, auditory; *T*, tactile. *P* refers to “the propositional centre in which the phase

was formed” (Broadbent, 1878). (B) Freud’s diagram. He referred to this as “Psychological schema of the word concept” (Freud, 1891).

perceiving—was based on the presumed close spatial relationship between the activations elicited by the property-production tasks and the previously reported locations of the activity associated with color and motion processing. The embodied cognition view requires that the brain regions engaged when retrieving information about a sensory-based property like color overlap with the regions engaged when perceiving that property. In these initial studies overlap could not be determined. Moreover, subsequent attempts to directly evaluate this possibility failed to provide support. Rather, those data supported the initial conclusion that, although there was a close correspondence between the neural systems supporting perceiving and knowing (based on the location of their respective activations), they did not directly overlap (Chao & Martin, 1999). Consistent with previous reports (e.g., Zeki et al., 1991), viewing colors activated the lingual gyrus in occipital cortex, whereas retrieving information about color activated a more anterior region located in the fusiform gyrus in the posterior temporal lobes (Chao & Martin, 1999).

The finding that the neural substrates for perceiving and knowing were close but not overlapping could be used to undermine claims of embodiment (e.g., Mahon & Caramazza, 2008). After all, “close” is a relative term, and there is certainly no guarantee that there is any processing relationship between regions located a centimeter or more apart on the cortical surface (Chao & Martin, 1999). More recent evidence, however, has resolved this apparent problem by showing a direct overlap in the neural bases of perceiving and knowing. This result was accomplished by using a more demanding perceptual task than the passive viewing tasks previously employed to map sensory processing systems.

In a study on color perception, Beauchamp, Haxby, Jennings, and DeYoe (1999) reported activation in the lingual gyrus of the occipital cortex using a passive viewing task. This finding replicated previous neuroimaging studies, as noted previously. However, when the task was made more demanding by requiring subjects to judge subtle differences in hue, activity associated with perceiving color now extended downstream from the occipital cortex into the fusiform gyrus on the ventral surface of the temporal lobe. Thus the full extent of the color-processing system was revealed when the task was made more demanding, even though the same stimuli were used in both the passive-viewing and attention-demanding contexts (Beauchamp et al., 1999). Simmons, Ramjee, McRae, Martin, and Barsalou (2007) took advantage of this procedure to once again address the question of whether there was neural overlap between the systems underpinning perceiving and knowing about a specific object property. Using the attention-demanding hue-judgment task to evaluate color perception, and a verbal property-verification task to assess property knowledge, Simmons and colleagues found that retrieving information about object

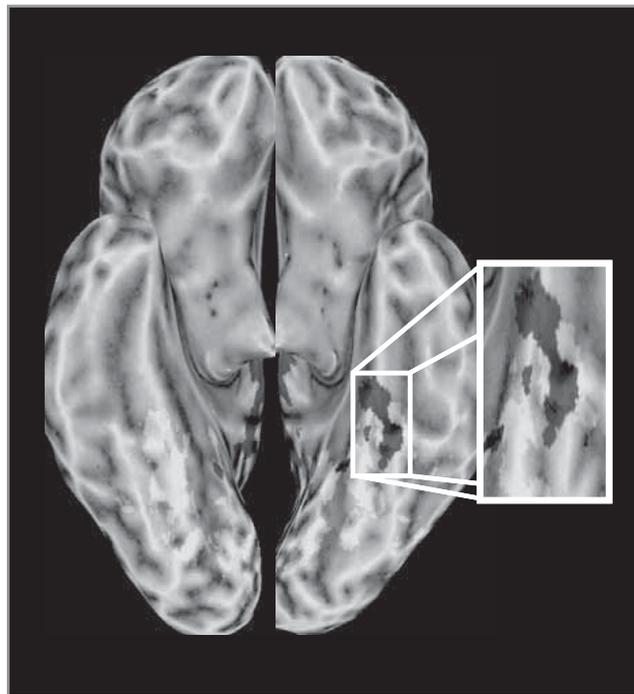

FIGURE 71.2 Overlap between the neural circuitry for perceiving and knowing about color. Shown is an inflated map of the ventral surface of the brain. Regions shown in yellow were more active when subjects performed a difficult color-perception task, relative to performing that same task with gray-scale stimuli. Regions in blue were more active when answering written questions about object color, relative to answering questions about object motor and motion properties. Red shows region of overlap in the left fusiform gyrus for the color-perception and color-knowledge tasks. (Adapted from Simmons, Ramjee, McRae, Martin, & Barsalou, 2007.) (See color plate 84.)

color—but not object motion—did, in fact, activate the same region in the fusiform gyrus active when color is perceived (Simmons et al., 2007) (figure 71.2). Thus, in support of the embodied concept view, these data provide strong evidence that information about a particular object property, like its typical color, is stored in the same neural system active when that property is perceived.¹

There are now many examples to support this claim (for extensive recent reviews and discussion see Barsalou, 2008; Gallese & Lakoff, 2005; Martin, 2007; Thompson-Schill, Kan, & Oliver, 2006). Examples include studies showing that retrieving information about different object-associated sensory properties (how they look, sound, feel, and taste) activated regions associated with sensory processing in each of these modalities (Goldberg, Perfetti, & Schneider, 2006), that making semantic judgments about words referring to body movements activated a region involved in perceiving biological motion (posterior region of the STS; Noppeney, Josephs, Kiebel, Friston, & Price, 2005), that reading emotionally charged words activated regions involved in perceiving emotions (amygdala, Kensinger &

Corkin, 2004), and that viewing pictures of appetizing foods activated gustatory processing and taste-specific reward areas (insula and orbitofrontal cortex, Simmons, Martin, & Barsalou, 2005). (It should be noted, however, that the majority of these studies did not independently localize the target sensory processing system, but rather relied on previously published localization studies.)

Similar findings have also been reported for the motor system. In perhaps the best known example, Pulvermuller and colleagues reported that simply reading words referring to actions performed with a particular body part (e.g., *lick*, *kick*, *pick*) activated corresponding regions in premotor and motor cortex (e.g., face, foot, and hand representations, respectively, as directly mapped by a movement study; Hauk, Johnsrude, & Pulvermuller, 2004). However, the correspondence between the primary motor representation for a specific body part (leg) and a concept associated with moving that same body part (*kick*) may be problematic, as will be discussed later (and see Mahon & Caramazza 2005, 2008, for insightful and penetrating critiques of the problems with some strong versions of the embodied viewpoint).

These findings underscore two important and related points. The first point concerns the need to distinguish between the neural bases for *sensation* and *perception* (Mesulam, 1998). As supported by the findings described previously, color *sensation* (color detection), as assessed by passive viewing, seems to be mediated by regions of occipital cortex located early in the visual processing stream, whereas color *perception* seems to require more extensive neural activity extending downstream into the fusiform gyrus. This distinction, in turn, fits nicely with the clinical literature that has documented a double dissociation between acquired color blindness (achromatopsia)—most commonly caused by a lesion of the lingual gyrus in the occipital lobes (Zeki, 1990)—and color agnosia—most commonly associated with lesions of posterior, ventral temporal cortex (Shuren, Brott, Schefft, & Houston, 1996). In this view, the posterior region in the lingual gyrus would be necessary for color sensation—detecting color and delivering this information to the rest of the processing system—whereas full perception of color—the experience of color bound to objects in the world—would require participation of more anterior regions. This anterior site may also provide the neural substrate for acquiring new object-color associations and representing those associations in memory.

The second important point concerns the fact that the overlap between perceiving and knowing is limited to only part, and in this case the most anterior part, of the sensory processing system. The claim then is not that conceptual information is stored throughout the entire sensory or motor processing system. Rather, the claim is that there is overlap between portions of these systems. This is an important point. Strong versions of embodied concept representation

that can be construed as maintaining that concepts are grounded in the early stages of perception (V1) or motor processing system (M1) are vulnerable to a charge of *reductio ad absurdum*. (For example, with regard to the representation of action concepts, why not include the spinal cord? Why not include the muscles? See Mahon & Caramazza, 2005.) Formulations of embodiment that include primary sensory and motor cortices as part of the conceptual system must also account for why we do not move when we read the word “kick.” They also need to explain how we are able to tell the difference between our visual perception of objects in the world and our visual imagery. In the current formulation, the overlap between the systems underpinning perceiving, acting, and knowing is limited. The overlap is partial, not complete. Information about a specific object property is stored in the anterior aspects of systems that are also active when objects are perceived and manipulated. This feature accounts for clinical dissociations and guards against a *reductio ad absurdum* argument while maintaining an embodied view. By so doing, however, the format and nature of the stored representations remain an open question. I will return to this issue at the end of the chapter.

Property information is organized in domain-specific neural circuitry

The most important point to come out of the studies that I have discussed, as well as from a wealth of neuropsychological investigations dating back well over 100 years, is that conceptual knowledge is not stored in a single location. The information that underpins our ability to know about our world is distributed throughout the brain. There is no single semantic memory store. Moreover, much of the available evidence suggests that this information is organized into relatively distinct, but broadly defined, domain-specific systems (e.g., Caramazza & Shelton, 1998). For our present purposes, a domain-specific system will refer to an information processing and storage system defined by the *type* or category of information it processes. These systems are composed of discrete cortical regions wired together to form relatively stable neural circuits. It is further assumed that the connections between the nodes or regions in these circuits are, in part, genetically predetermined. Different brain regions are predisposed to form connections with one another.

Motivated by the clinical literature on category-specific knowledge deficits, perhaps the most investigated domain-specific neural systems have been those concerned with representing animate entities, defined as living things that move on their own (people and other animals; Chao, Haxby, & Martin, 1999), and manipulable, manmade objects like common “tools,” defined as objects with a systematic relationship between their visual form and function/manipulation (Mahon et al., 2007). The neural substrate for

representing animate things includes two regions of posterior temporal cortex; one of these lies on the ventral surface and is located in the more lateral portion of the fusiform gyrus (including, but not limited to, the fusiform face area, FFA, and its adjacent region for body representation; Schwarzlose, Baker, & Kanwisher, 2005); the other is on the lateral surface located in the posterior region of the superior temporal sulcus (pSTS). There is a substantial body of literature linking these regions to the representation of biological form (lateral portion of the fusiform gyrus) and biological motion (pSTS) (for reviews see Adolphs, 2001; Bookheimer, 2002; Haxby, Hoffman, & Gobbini, 2000; Martin, 2001, 2007; Martin & Chao, 2001; Thompson-Schill, 2003). This circuitry also includes the amygdala. The amygdala is a highly differentiated structure and plays multiple roles in emotion processing and behavior, including being critical for acquiring, storing, and expressing conditioned fear responses (Phelps & LeDoux, 2005; Phelps, 2006). In addition, there is growing evidence that the amygdala is predisposed to respond automatically to animate things. This is especially so for faces expressing fear, but the amygdala also responds more to neutrally posed faces relative to other objects (e.g., Pessoa, McKenna, Gutierrez, & Ungerleider, 2002), suggesting a predisposition for certain categories of objects over others (Ohman & Mineka, 2001). Indeed, recent studies from our laboratory suggest that the amygdala responds more to animate entities (faces and animals) than to other objects. Moreover, this response is especially strong for animate objects rated as being highly threatening and arousing (i.e., faces with expressions of fear, spiders, snakes), even when compared to equally threatening and arousing inanimate things (e.g., weapons, dental drills) (Yang, Bellgowan, & Martin, 2008). These data and others (e.g., Vuilleumier, Armony, Driver, & Dolan, 2003; G. Williams, Nestor, & Hodges, 2005) provide support for the inclusion of the amygdala in the circuitry for animate entities, both for assessing affective valence and arousal value, and for the fast, early detection of stimuli that have, from an evolutionary standpoint, posed the greatest threat—animals and other people.

The three regions listed—the lateral portion of the fusiform, pSTS, and the amygdala—respond strongly to both people and animals relative to other object categories. The available evidence further suggests that these regions code for different properties of animate things such as form, motion, and affective valence, respectively. Nevertheless, it should go without saying that the substrate for representing a property like visual form must distinguish between people and animals. All objects must have a distinct neural substrate, or how else would we distinguish among them? This distinction is clear in the clinical literature (Caramazza & Shelton, 1998). Thus, although a number of prosopagnosia patients also have difficulty identifying animals—for example, one of the most carefully studied prosopagnosic patients

also was unable to identify animals from their shapes (patient LH; Etcoff, Freeman, & Cave, 1991)—convincing cases of pure prosopagnosia have been well documented (e.g., Riddoch, Johnston, Bracewell, Boutsen, & Humphreys, 2008). Thus these regions should be seen as part of the circuitry underpinning perceiving and knowing about animate entities, broadly defined, but with finer distinctions made between the representation of conspecifics and heterospecifics. Although how this distinction is represented in this circuitry has not been well defined, two hints are available. One hint comes from the neuroimaging literature that suggests that faces are more focally represented (Chao, Haxby, & Martin, 1999). This is not an unreasonable expectation given that different faces are highly homogeneous in shape and movement relative to animals, and they denote a single basic-level category, whereas animals are composed of stimuli with large variation in shape, and consist of multiple basic-level categories each with a unique name. The other hint comes from the clinical literature suggesting that they may be hemispheric difference, with a right-sided bias for lesions yielding face-processing deficits (Riddoch et al.) and a left-sided bias for lesions resulting in knowledge deficits for animals (Capitani, Laiacona, Mahon, & Caramazza, 2003).

In addition to the posterior, lateral region of the fusiform gyrus, pSTS, and the amygdala, other likely nodes in the animacy circuit include the medial portions of anterior and posterior cortex (ventral prefrontal and posterior cingulate/precuneus cortices, e.g., Mitchell, Macrae, & Banaji, 2006; Mitchell, 2008) and temporal polar cortices (Olson, Ploaker, & Ezzyat, 2007). Each of these nodes, along with a region located in posterior lateral cortex at the junction of the temporal and parietal lobes (Saxe, 2006), has been linked to rather abstract, higher-order aspects of social cognition, including the ability to make inferences about the mental state of others (with finer dissociations observed as well—for example, between different regions of medial prefrontal cortex when thinking about the mental states of similar versus dissimilar others; Mitchell et al.). Although some evidence exists that suggests that these regions may be involved in knowing about animacy in general (e.g., medial prefrontal cortex was found to be active when making judgments about mental states regardless of whether the target was another person or a dog; Mitchell, Banaji, & Macrae, 2005), most evidence suggests that these regions may be particularly important for thinking about conspecifics.

Each of the regions or nodes of this circuit has a specific function, and a major goal of cognitive neuroscience is to specify the functional properties of these regions in the service of social cognition. Clearly this issue is far from settled, and debate about the functional characteristics of each node is likely to continue for some time. Nevertheless, the critical point to be stressed here is that regardless of their function, each of the regions discussed so far is engaged

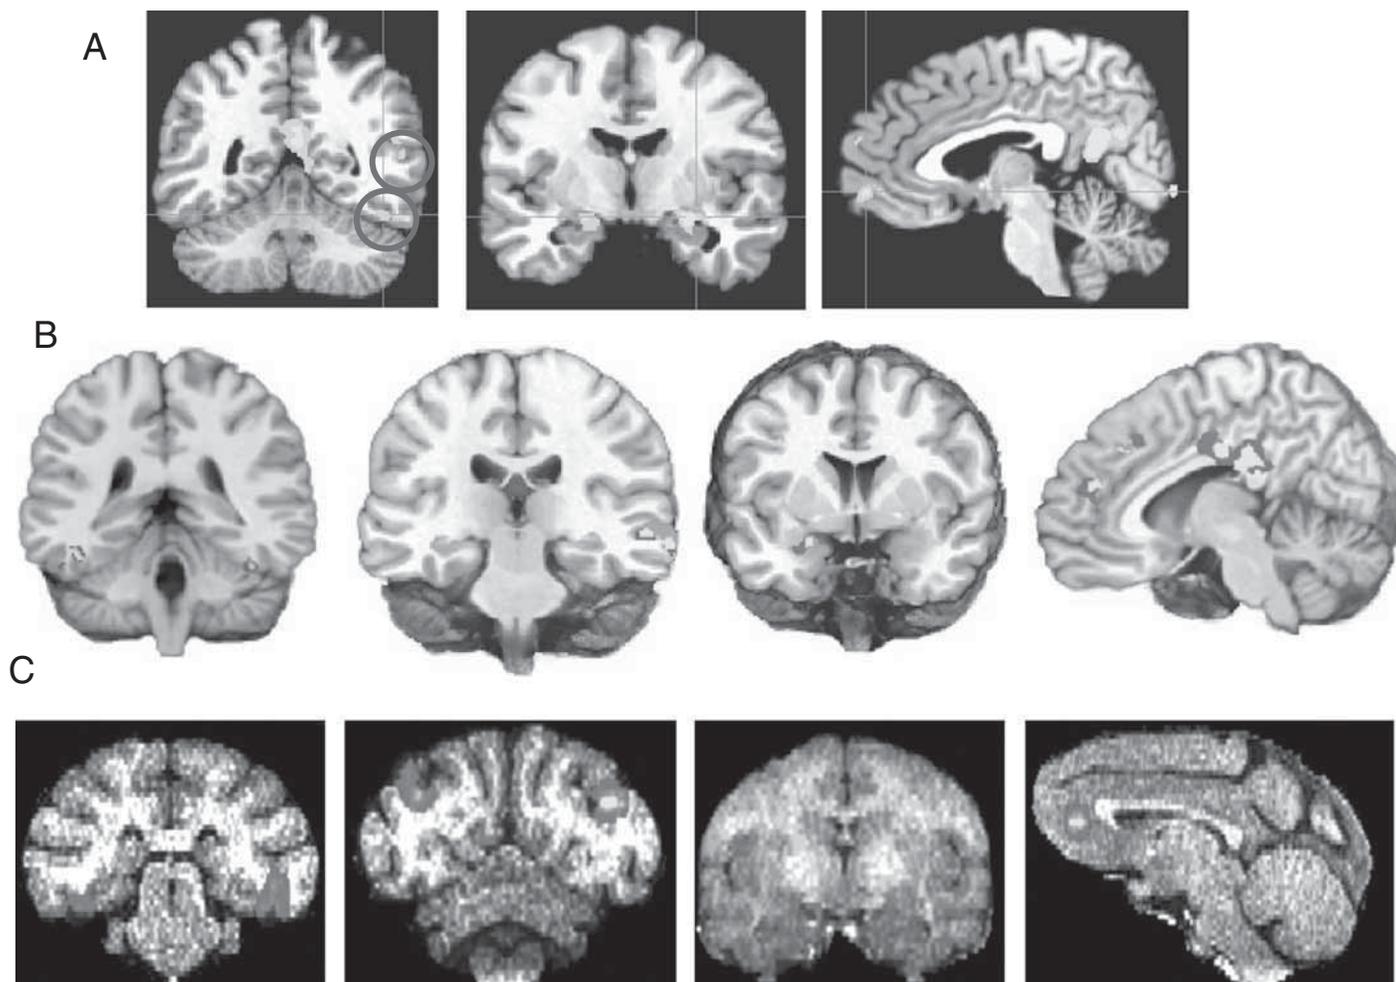

FIGURE 71.3 Correspondence across tasks and species in the location of the neural circuitry for perceiving and knowing about animate entities. (A) Regions shown in yellow were more active when subjects viewed photographs of faces relative to viewing photographs of common tools. Going from left to right, the first image shows a coronal slice through posterior cortex indicating the location of activity in the lateral portion of the right fusiform gyrus (lower red circle) and in the right pSTS (upper red circle). The next coronal image depicts bilateral activity in the amygdalae. The third image shows a sagittal section revealing activity in the medial prefrontal cortex and in the posterior cingulate/precuneus. (Unpublished data from our laboratory.) (B) Brain slices depicting conjunction of regions more active when subjects perceived simple shapes in motion as animate, relative to when they were judged to be inanimate, and when they imagined these stimuli as animate

whenever an animate object is attended to. For example, as illustrated in figure 71.3A, simply viewing a face will produce activity throughout the entire circuit.

This characteristic of being activated whenever an object is viewed also holds for the nodes of the circuits underpinning perceiving and knowing about “tools.” The current evidence suggests that the circuitry underpinning processing in this domain includes two regions in the posterior temporal lobe, one situated in the more medial extent of the posterior

versus inanimate. Going from left to right, the first image is a coronal slice showing bilateral activity in the lateral fusiform gyrus. The next coronal slice shows the location of activity in the STS, the third depicts activity in the left amygdala, and the last shows activations located in the medial prefrontal and posterior cingulate cortices. (Adapted from Wheatley, Milleville, & Martin, 2007.) (C) Activity in the macaque brain when listening to species-specific calls. Shown are PET scans obtained from a single animal. Going from left to right, the first image shows a coronal slice through ventral regions TEO/TE, the next coronal slice shows activity in the STS, the third slice shows activation in the amygdala, and the fourth slice shows an activation located in Area 32 on the medial surface of the brain. (Adapted from Gil-da-Costa et al., 2004.) (See color plate 85.)

fusiform gyrus, the other located in the left posterior portion of the middle temporal gyrus. These regions have been linked to representing the visual form and visual motion associated with these objects (e.g., Beauchamp, Lee, Haxby, & Martin, 2002, 2003). The other two nodes in this circuit, both strongly lateralized to the left hemisphere, are in posterior parietal cortex (in the intraparietal sulcus and often also including a more anterior region in the inferior parietal lobule) and in ventral premotor cortices. These regions have

been linked to the representation of goal-directed action associated with an object's function (for recent reviews and discussion see Beauchamp & Martin, 2007; Frey, 2007; Lewis, 2006). As with the animacy circuitry discussed earlier, the circuitry underpinning perceiving and knowing about "tools" is engaged whenever these objects are viewed (e.g., Chao et al., 1999; Chao & Martin, 2000; Handy, Grafton, Sheroff, Ketay, & Gazzaniga, 2003) (see Mahon et al., 2007, for neuroimaging and neuropsychological evidence supporting the specificity of this circuitry for "tools" relative to other manmade, manipulable objects).

Activity in domain-specific neural circuitry transcends stimulus features

These findings suggest that the brain contains property-based, domain-specific neural circuits for perceiving and knowing about specific object categories. A case was made that one of these circuits developed for representing animate things, another for "tools." It was also suggested that these circuits are active whenever objects from these broad categories are perceived. However, this fact alone says nothing about the relationship between these circuits and conceptual processes. To make that link requires showing that activity in these circuits is associated with the *interpretation* of a stimulus, rather than its physical characteristics. There is now considerable evidence to support this claim. For example, the lateral region of the fusiform gyrus that has been linked to representing the visual form of animate entities responds to animate entities as represented by pictures and written names of animals (Chao et al., 1999; Devlin, Rushworth, & Mathews, 2005; Mechelli, Sartori, Orlandi, & Price, 2006; Okada et al., 2000; Price, Noppeney, Phillips, & Devlin, 2003; Rogers, Hocking, Mechelli, Patterson, & Price, 2005; Wheatley, Weisberg, Beauchamp, & Martin, 2005), human voices (von Kriegstein, Kleinschmidt, Sterzer, & Giraud, 2005), point-light displays of human bodies in motion (Beauchamp et al., 2003; Grossman & Blake, 2001, 2002; Peelen, Wiggett, & Downing, 2006), and humanlike stick figures (Peelen & Downing, 2005). In contrast, the more medial aspect of the fusiform associated with representing the visual form of "tools" has been reported in response to pictures and written names of tools (Chao et al.; Chao, Weisberg, & Martin, 2002; Devlin et al.; Mechelli et al.; Whatmough, Chertkow, Murtha, & Hanratty, 2002), the spoken names of tools (Noppeney, Price, Penny, & Friston, 2006), and point-light displays depicting tools in motion (Beauchamp et al.).

Perhaps even more convincingly, activity throughout the animacy circuit has even been observed when participants view abstract representations of social situations as illustrated by the interactions among simple geometric shapes in motion (Heider & Simmel, 1944). For example, the lateral

fusiform gyrus responds to animations suggesting social interactions such as hide-and-peek (Schultz et al., 2003), mocking and bluffing (Castelli, Happe, Frith, & Frith, 2000; Castelli, Frith, Happe, & Frith, 2002), and sharing (Martin & Weisberg, 2003). These studies also reported activity in other nodes of the animacy circuit including pSTS, the amygdala, and ventromedial prefrontal cortices. In contrast, activity in the temporal lobe regions associated with the visual form and motion of "tools" (medial fusiform and left middle temporal gyrus, respectively) has been observed when animations composed of simple geometric shapes were interpreted as depicting mechanical interactions (Martin & Weisberg, 2003).

Wheatley and colleagues have recently provided even more compelling evidence that activity in these circuits is linked to the interpretation of a stimulus rather than its physical features (Wheatley, Milleville, & Martin, 2007). In that study, different background settings were used to bias the interpretation of a simple geometric shape in motion as depicting either an animate entity or an inanimate object. All the previously mentioned regions in the animacy circuit (lateral portion of the fusiform gyrus, STS, medial prefrontal cortex, posterior cingulate, amygdala) were active when the objects were interpreted as animate, relative to when that same form and motion were interpreted as depicting an inanimate object. Moreover, these regions were also active when subjects were asked to imagine the object they had previously seen based on viewing the backgrounds alone (figure 71.3B; see Wheatley et al., 2007, for details). Thus activation in this domain-specific, property-related circuit was not due to particular stimulus features, but rather appeared to be directly related to conceptual representation.

Several other studies have provided data to support this claim. Each of these studies used a learning paradigm to show that acquiring new information about novel objects changes the brain's response to those objects. Moreover, the locations of these responses were directly related to the type of information acquired. For example, Weisberg, van Turenout, and Martin (2007) asked subjects to perform a simple visual matching task on photographs of novel objects. After scanning, the subjects were given extensive training manually manipulating the objects to perform specific tool-like functional tasks. After training, the subjects were again scanned while performing the visual matching task. Comparison of the data collected prior to training with those collected after training revealed that experience using the objects as tools led to predictable changes in how these objects were now represented in the brain. Whereas prior to training visual matching of the novel objects elicited only broad activity in ventral occipitotemporal cortex, after training ventral temporal activity was largely restricted to the medial aspect of the fusiform gyrus, the same region previously implicated in representing the visual shape or form of

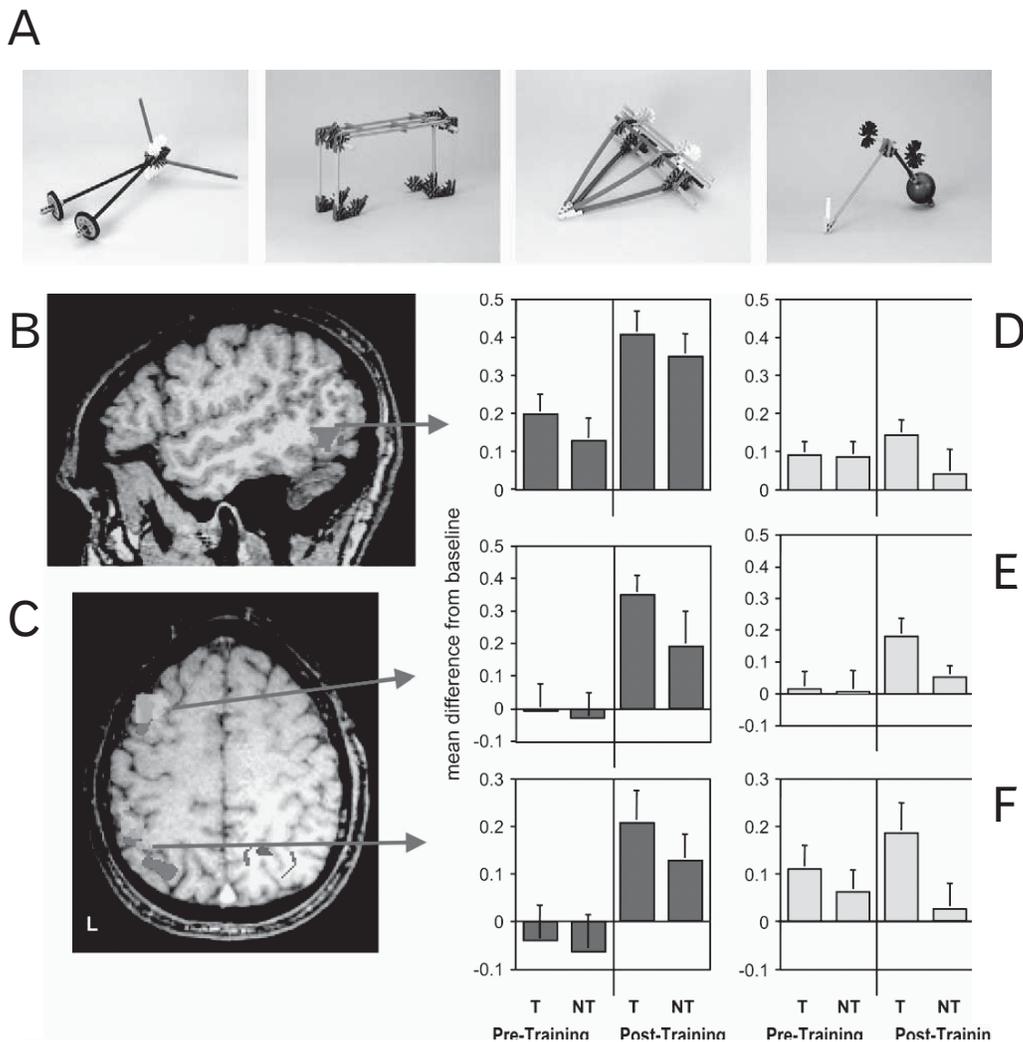

FIGURE 71.4 (A) Examples of novel objects designed to perform specific toollike functions. (B) Sagittal section showing the location of learning-related activity in the left middle temporal gyrus. Regions in red were more active after training than before training. Regions in yellow, which overlap with regions in red, were more active for trained (*T*) objects than for not-trained (*NT*) objects. (C) Axial section showing the location of learning-related activity in the left premotor/prefrontal cortex and intraparietal cortices. (D, E, F)

Histograms showing the difference between novel-object-matching and scrambled-image-matching baseline task in the middle temporal gyrus, left premotor, and intraparietal regions, respectively. Red bars represent brain regions that showed increased activity for object matching after but not prior to training; yellow bars represent regions that demonstrated greater activity for trained objects than not-trained objects after but not prior to training. (Adapted from Weisberg, van Turenout, & Martin, 2007.) (See color plate 86.)

“tools.” Similarly, new activations emerged after training in other regions of the circuitry associated with perceiving and knowing about “tools,” including the left posterior region of the middle temporal gyrus (linked to nonbiological motion perception; Beauchamp et al., 2002, 2003), left intraparietal sulcus, and left premotor cortex (goal-directed manipulation related to object function) (figure 71.4).

Learning effects have also been observed for animate entities. It has been well documented that viewing point-light displays of human forms in motion elicits activity in lateral fusiform and pSTS (Beauchamp et al., 2003; Grossman & Blake, 2001, 2002). Grossman, Blake, and Kim (2004) trained subjects to perceive human forms in point-light dis-

plays that were embedded within visual noise. After training, not only were the subjects better at indicating when a human form was present in a noisy visual display, but they also exhibited greater fusiform and pSTS activity in response to detecting those forms, and the amount of activity in both regions was positively correlated with a subject’s behavioral performance.

Finally, in addition to visual learning paradigms, it has been demonstrated that a verbal learning procedure can be used to demonstrate the development of property-based circuitry (T. James & Gauthier, 2003). Prior to scanning, subjects learned verbally presented information about the auditory and motor-related properties of different families

of novel animate-like entities (“greebles”). For example, subjects were trained that a particular family of greebles were associated with an auditory property (e.g., roars or squeaks), whereas other types of greebles had action properties (e.g., hops or jumps). After training, subjects underwent fMRI while performing a visual matching task that did not require retrieval of these learned associations. The results showed that viewing greebles associated with auditory properties produced activity in auditory cortex (as defined by an auditory functional localizer) and viewing greebles associated with action properties produced activity in the biological-motion-sensitive region of the pSTS (as localized by moving point-light displays). These findings, along with the findings of Weisberg et al. (2007), demonstrate that experience with novel objects leads to the development of activity in domain-specific property circuits. Simply seeing an object from the training set elicited activity in specific regions of the previously described circuits, even though that information was not necessary for successfully performing the task and not present in the stimuli. Subjects learned that, for example, a particular object was associated with a particular type of movement (e.g., hopping). Having acquired that knowledge, a region in pSTS that is active when viewing biological motion became active when that object was viewed, even though the subject’s task did not require retrieving that information. The posterior region of the STS was activated automatically when the object was seen again.

A mechanism that allows us to quickly and effortlessly form inferences about objects in the world has obvious survival value. As a result we would expect that the ability to infer properties would be preserved across primate species. Recent evidence suggests that this may be the case with regard to the circuitry supporting perception of animate entities. Using PET to study perception of species-specific calls in the macaque, Gil-da-Costa and colleagues (2004) showed that the calls elicited activity in area TE/TEO, a presumed monkey homologue of human fusiform gyrus, and in the pSTS, relative to acoustically similar controls (figure 71.3C). In addition, calls known to carry emotional connotations activated the amygdala and medial prefrontal cortices over and above calls presumed to connote more neutral associations (see Gil-da-Costa et al. for details). While strong claims cannot be made about the meaning of these calls for the macaques, it should be safe to conclude, at the very least, that the calls were interpreted as indicating the presence of another monkey. Thus, as with humans, when monkeys process information about animate entities, activation occurs across a distributed circuit. The nodes of this circuitry are presumed to represent the salient properties of those entities, including what they look like and how they move, even when those properties are not present in the stimulus, and therefore must be inferred.

Additional architectural considerations: The role of the anterior regions of the temporal lobes

Clearly, these circuits do not operate in isolation. For one thing, information must be selected and retrieved, and much work has established that the left inferior prefrontal cortex plays a prominent role in performing these functions (Badre, Poldrack, Pare-Blagoev, Insler, & Wagner, 2005; for review see Thompson-Schill, Bedny, & Goldberg, 2005). Object-property information must also be integrated, and this requirement raises a form of the binding problem on the level of conceptual representation. One potential mechanism for achieving an integration of information stored in different locations is through their interaction. In that scenario, each node would represent the information it was specialized for, as well as reflecting or re-representing other types of information stored elsewhere (see Konen & Kastner, 2008, and Schwarzlose, Swisher, Dang, & Kanwisher, 2008, for neuroimaging data consistent with this view). Another possibility is that information from all circuits is integrated in a specific region. Several candidates have been proposed for this “hub” architecture, including posterior regions of left lateral temporal cortex (Hickok & Poeppel, 2000), left prefrontal cortex (reviewed in Thompson-Schill et al.), and thalamus (Kraut et al., 2002).

More recently, a highly influential version of a hub architecture has been proposed that locates this mechanism in the most anterior portion of the temporal lobes (Lambon Ralph, Lowe, & Rogers, 2007; McClelland & Rogers, 2003; Patterson et al., 2007; also see McClelland et al., chapter 72 in this volume). As argued by Patterson and colleagues (2007) in order to operate in the service of semantic cognition, property-based circuits require that all stored information about objects be integrated at a single location (Patterson et al.). Under this view, a central hub is needed because a distributed architecture alone cannot account for one of the central defining characteristics of a conceptual system; the ability to generalize across exemplars belonging to the same category (e.g., telephone) when the specific exemplars in this category can have very different physical features (desk phones, cellular phones) (see Patterson et al. for details of this argument). Moreover, according to this view, the ability to generalize requires amodal conceptual representations, as opposed to the modality-based representations described here. Amodal representations require a central hub (Patterson et al.; also see McClelland & Rogers, 2003).

A hub of this type may in fact be necessary on computational grounds, and that possibility will not be disputed here. It should be stressed, however, that arguments about the need for a conceptual hub and the physical location of that hub in the brain are independent. It is this later claim, specifically the claim that the hub is located in the most anterior part of the temporal lobes, that I will address here.

The anterior temporal lobes include a number of distinct anatomical divisions, including the temporal pole, amygdala, and entorhinal and perirhinal cortices, as well as the anterior extents of the fusiform, inferior, middle, and superior temporal gyri. Therefore it should not be surprising that there are currently several different but non-mutually-exclusive views of anterior temporal lobe function. One view, and one that has the most support from neuroimaging and neuropsychological investigation, is that the anterior regions of the temporal lobe are involved in social and emotional processing (see Olson et al., 2007, for a recent review). Another view, also supported by neuroimaging (Gorno-Tempini & Price, 2001; Grabowski et al., 2001) and neuropsychological investigation (e.g., Tranel, Damasio, & Damasio, 1997; Damasio 1989), is that the anterior temporal lobes are involved in representing unique entities (i.e., famous people and places). A third view is that anterior temporal regions play a role in modulating access to distributed modality-specific information stored elsewhere, but are not involved in integrating this information (Martin & Chao, 2001). Finally, a fourth position is that the anterior temporal lobes are the location of the conceptual hub. Support for this claim comes primarily from study of patients with semantic dementia, a progressive disorder that is associated with pathology with a proclivity for attacking the temporal lobes, especially the more anterior portion where the damage often appears to originate (McClelland & Rogers, 2003; Patterson et al., 2007).

Several points are in order. First, studies using voxel-based morphometry to measure the extent of atrophy associated with semantic dementia indicate that pathology in these patients is not limited to the anterior temporal lobes. Rather, these studies uniformly show that the pathology often extends to the more posterior regions of the temporal lobes engaged in many of the neuroimaging studies reviewed previously. Moreover, the semantic deficits in these patients are nearly as strongly related to atrophy in posterior temporal cortex as with atrophy in anterior temporal cortex (G. Williams, Nestor, & Hodges, 2005). Semantic dementia is a progressive disorder. As symptoms increase in severity, pathology gets more widespread throughout the temporal lobes. Thus the discrepancy between the findings with semantic dementia patients and the neuroimaging literature may not be nearly as strong as some have suggested (Patterson et al., 2007). It is probably also noteworthy that these patients often have pathology outside the temporal lobes, most prominently in frontal cortex. Thus it is not at all clear that the devastating impairments in semantic cognition that characterize these patients can be attributed solely to anterior temporal lobe pathology (Lambon Ralph et al., 2007). The available evidence suggests that the anterior regions of the temporal lobes likely support multiple functions. It is more than likely that one of these functions involves conceptual

and semantic processing. The exact nature of this role, however, and, in particular, whether the anterior temporal lobes are necessary for creating amodal representations, remains to be determined.

Summary and concluding comments

The evidence discussed in this chapter indicates that the information about salient object properties—such as how they look, move, and are used, along with our affective associations to them—is stored in the neural systems that support perceiving, acting, and feeling. It is in this sense that conceptual knowledge is argued to be grounded and embodied. The evidence further suggests that this information is not stored in every part of our sensory and motor systems. The circuits for sensing, perceiving, and knowing are partially, not fully, overlapping.

These architectural constraints, however, say nothing about the nature or format of this information. It has been assumed that information stored in discrete regions of the fusiform gyrus represents the visual form of objects. This assumption has been made because this region is part of the ventral visual object-processing stream known to underpin object identification. Yet it appears that these same regions respond in a categorical manner in the blind when palpating objects (Pietrini et al., 2004). This finding is consistent with the idea that this region codes for object shape or form, but it also suggests that the way shape is represented may be quite abstract. Information about object shape may be stored in the ventral stream, even when that shape information was obtained through a different modality, in this case touch rather than vision. This finding, in turn, challenges us to specify the sense in which the information grounded in perceptual and action systems should be considered modality specific or sensory or motor in nature.

The evidence reviewed here also suggests that object-property-based information is organized into broadly defined domain-specific circuits. These circuits appear to be remarkably stable in the sense that the spatial arrangement among their defining nodes seem to be consistent from one individual to another. This stability is most apparent when considering the spatial arrangement of regions in ventral temporal cortex purported to support identification of words (McCandliss, Cohen, & Dehaene, 2003), faces (Yovel & Kanwisher, 2004), animals (Chao et al., 1999), tools (Chao et al., 2002), and environmental scenes (Epstein, 2008). Although discussion of this important issue is outside the scope of this chapter, several suggestions have been offered to explain this fact (Op de Beeck, Haushoffer, & Kanwisher, 2008; Martin, 2006; Mahon et al., 2007).

The evidence also suggests that activation of these circuits is dependent on how a stimulus or event is interpreted, not on the physical features of the stimuli impinging on our

senses. These findings indicated that while different regions of the cortex are specialized for processing and storing information about specific properties (e.g., biological motion), these same regions can be reactivated in top-down fashion based on the interpretation applied to a stimulus, even when that critical property is not physically present (Wheatley et al., 2007).

This type of finding raises important questions about the function played by these activated regions. In the Wheatley and colleagues (2007) study, the task was simply to indicate whether the depicted object represented an animate thing. Nevertheless, animacy identification led to activation of a suite of regions that, based on other data, support a range of complex higher-order social processes (e.g., theory of mind, making self-other similarity judgments; Mitchell, 2008). In fact, as illustrated in figure 71.3A, this entire circuit becomes active when simply viewing photographs of the human face. Clearly, activation in ventromedial prefrontal cortex or in the amygdala is not necessary to perceive faces. Thus a major challenge for future studies is to specify what role these activations play in these tasks. One possibility, and I believe the most likely explanation, is that these activations reflect the automatic generation of inferences that are a central part of what we mean by a conceptual representation. In this sense, these activations may serve to prime the conceptual system for future action. That is, they are predictive of future events. Seeing a hammer activates the dorsal stream because hammers are objects likely to be grasped and used to perform some function. Seeing other individuals activates a broad circuit of regions so we are prepared to interpret their state of mind and actions. Our ability to sort out the role played by these regions in the context of different tasks will require investigations that combine functional neuroimaging and lesion approaches. Investigations of this type have just begun, but they have already yielded tantalizing clues (Calder, Keane, Manes, Antoun, & Young, 2000; Mahon et al., 2007).

NOTE

1. It should be stressed that the overlap observed in this and in other studies of this type does not necessarily mean that the *same neurons* are involved in both perceiving and knowing. Support for that claim would require single-unit recordings from the human brain. Functional neuroimaging evidence consistent with this claim could be obtained by showing that the amplitude of the BOLD signal in a region of cortex was reduced when verbally retrieving information about a property, for example, color, following activity produced by viewing that color (i.e., by showing an across-task repetition suppression effect. For a discussion of the logic behind this approach see Grill-Spector & Malach, 2001; Henson, 2003). Nevertheless, the embodiment view proposed here does not require that perceiving and knowing be coded in the same neurons. It does, however,

require that these processes be carried out in the same brain region, strictly defined. For example, the embodied view would hold if the neurons involved in visual perception and those involved in information storage were found to be interdigitated in the same tightly constrained space.

72 Semantic Cognition: Its Nature, Its Development, and Its Neural Basis

JAMES L. McCLELLAND, TIMOTHY T. ROGERS, KARALYN PATTERSON,
KATIA DILKINA, AND MATTHEW LAMBON RALPH

ABSTRACT We consider parallels in the development of conceptual knowledge and its disintegration in a neurological disorder. During development, children's concepts become more differentiated. Developing children make striking errors, attributing properties to objects that they do not have and over-extending frequent category labels to other objects. Patients with semantic dementia (SD), a progressive condition affecting the anterior temporal lobes, show a loss of differentiation of concepts. Like developing children, they attribute properties to objects that they do not have and over-extend frequent category labels. Such patients may draw four legs on a duck, or call an elephant a horse. We present a theoretical framework and computational models that explain these parallel phenomena. We also consider the disintegration of lexical knowledge, which parallels the deterioration of semantics in SD patients. We present a model that simulates these findings within a single system that processes and represents both lexical and semantic information.

Interest in the nature of conceptual knowledge extends back at least to the ancient Greek philosophers. In recent years, there has been a wide range of different approaches to understanding the nature of conceptual knowledge, its development, and its neural basis. In most other work, however, these issues are not all treated together. Instead, workers in philosophy, adult experimental psychology, child development, and cognitive neuroscience have pursued related questions in relative ignorance of each other's efforts. Even within cognitive neuroscience, there has been until recently a relative separation between approaches taken by neuropsychologists, who study the effects of brain disease on cognition in patients, and researchers who study the neural

basis of conceptual knowledge in neurologically intact populations, using functional imaging and related methods.

We have sought to develop an integrative perspective on these matters. Our effort is facilitated by our theoretical framework, which lends itself to implementation in computational models that capture both the ability to learn gradually from experience, in order to model development, and the tendency to degrade in a graded fashion, in order to capture the partial nature of the deficits resulting from brain injury. We begin with an overview of the theoretical framework and its application to three developmental phenomena. We then show how the framework also addresses parallel phenomena that arise in the striking neuropsychological condition called semantic dementia. We review evidence that the disorder affects knowledge of words as well as knowledge of things, motivating an extension of our theory in which knowledge of things and words is fully integrated, contra most other approaches. A final section describes imaging and magnetic stimulation studies in normals that test predictions arising from the theory; this section also considers evidence from disorders other than semantic dementia that indicates how the theory might be extended to address the flexible use of semantic knowledge in complex task situations.

The PDP framework and its application to development

The parallel distributed processing (PDP) approach (Rumelhart, McClelland, & the PDP Research Group, 1986) provides the starting point for our theory of semantic cognition. The fundamental tenets of the approach are as follows:

- Cognitive activities emerge from the interactions of large numbers of simple processing units and are distributed over populations of such units both within and across brain areas.
- Active representations in this framework—the representation someone may have when, for example, he brings to

mind a particular dog, who may be greeting him by jumping up and down, barking, and licking at his face—are likewise distributed, involving activity of many contributing units in each of many disparate brain areas that contain neurons representing the shape, color, odor, movement, and sounds made by the dog being imagined.

- The ability of one kind of information (say the sight of a particular dog, or its bark, or simply the word “dog”) to bring this information to mind depends on knowledge stored in the patterns of strengths or “weights” on the connections among the participating neurons.

- The patterns of connection weights are gradually acquired through experience. This process takes place over developmental time (i.e., years), gradually affecting the details of the representations we are able to bring to mind from particular inputs, and thus shaping gradual change in our behavior in cognitive tasks.

- The units and the connections are the substrate we use to understand not only normal cognitive functions and their development, but also the effects of brain damage and brain diseases on these functions. In particular, we assume that damage or disease results in the loss or disruption of the units and/or connections.

Within this theory, the effects of experience on connection weights explain many aspects of conceptual development; and the effects of damage and disease on the units and connections explain the disintegration of these functions in conceptual disorders such as semantic dementia.

It should be noted that our theory posits two complementary learning systems, only one of which—the neocortical one—is the focus here. We also propose that there is a second, fast-learning system based in the medial temporal lobes, allowing rapid learning of new, arbitrary information (McClelland, McNaughton, & O’Reilly, 1995). Normally, new semantic learning depends on both systems working together, but semantic knowledge is thought to gradually become independent of the fast-learning system, as evidenced by patients with profound amnesia for new information who nevertheless retain their semantic knowledge and abilities (Squire, 1992).

SOME PHENOMENA IN CONCEPTUAL DEVELOPMENT As children develop, their conceptual knowledge gradually changes, in a way that appears to reflect aspects of experience. Three key features of this process are the following:

- Progressive differentiation of conceptual knowledge in development
- A tendency to overgeneralize names of frequently occurring objects
- A tendency to produce “illusory correlations” in attributing properties to objects

Differentiation in development has been explored in several contexts. In one investigation, Keil (1979) asked children what kinds of attributions or “predications” could apply to particular objects. For example, he asked children if it was “ok” or “silly” to say that something (say, a movie or a chair) “is sorry” or “is an hour long.” Using their responses, he constructed, for each of many children at each of several ages, a “predicability tree” like the ones shown in figure 72.1. Here we see trees for representative children at progressively older ages. Clearly, these trees indicate conceptual differentiation. As children grow older, they cease to lump together concepts that older children (and adults) pull apart. Similar conclusions arise from work on infants using nonverbal methods (e.g., Mandler & McDonough, 1993; Pauen, 2002).

Overgeneralization of frequently encountered names is also well documented. Such behavior is striking since it often represents an error that first emerges and then subsequently disappears—a classic “U-shaped” trend in development. As Mervis (1987) has investigated in detail, one common case of such overgeneralization is the extension of the word “dog” as a name for a wide variety of different animals, particularly other four-legged animals, by children in the early childhood years.

The developmental phenomenon of “illusory correlations” has been treated by many investigators as a sign that young children have acquired domain-specific causal theories that lead them to overapply properties attested in these theories to other objects (Keil, 1991). One such illusory correlation was observed by Gelman and Williams (1998). They showed pictures of objects to young children and asked if the objects could go up and down a hill by themselves. Children usually answered yes if the pictured object appeared to be an animal. When asked to explain their answers, children often attributed feet to the pictured animals, even in cases where no feet were in evidence in the pictures. While in some cases (e.g., an animal called an echidna, which appeared as a small furry ball) such attributions were justified; in other cases (e.g., a snake) they would clearly be “illusory correlations”—perceived correlations of movement properties with physical properties of objects that are often, but not always, valid. Such overattributions are not by any means restricted to young children, but also occur in adult cognition. For example, people in the United States have a tendency to perceive an innocuous object as a weapon when it is in the hands of an African American (Eberhart, Goff, Purdie, & Davies, 2004).

APPLICATION OF THE THEORY TO DEVELOPMENT: THE RUMELHART MODEL Our application of our theory to conceptual development grew out of earlier work by Hinton (1981, 1989) and Rumelhart (1990). Rumelhart wished to

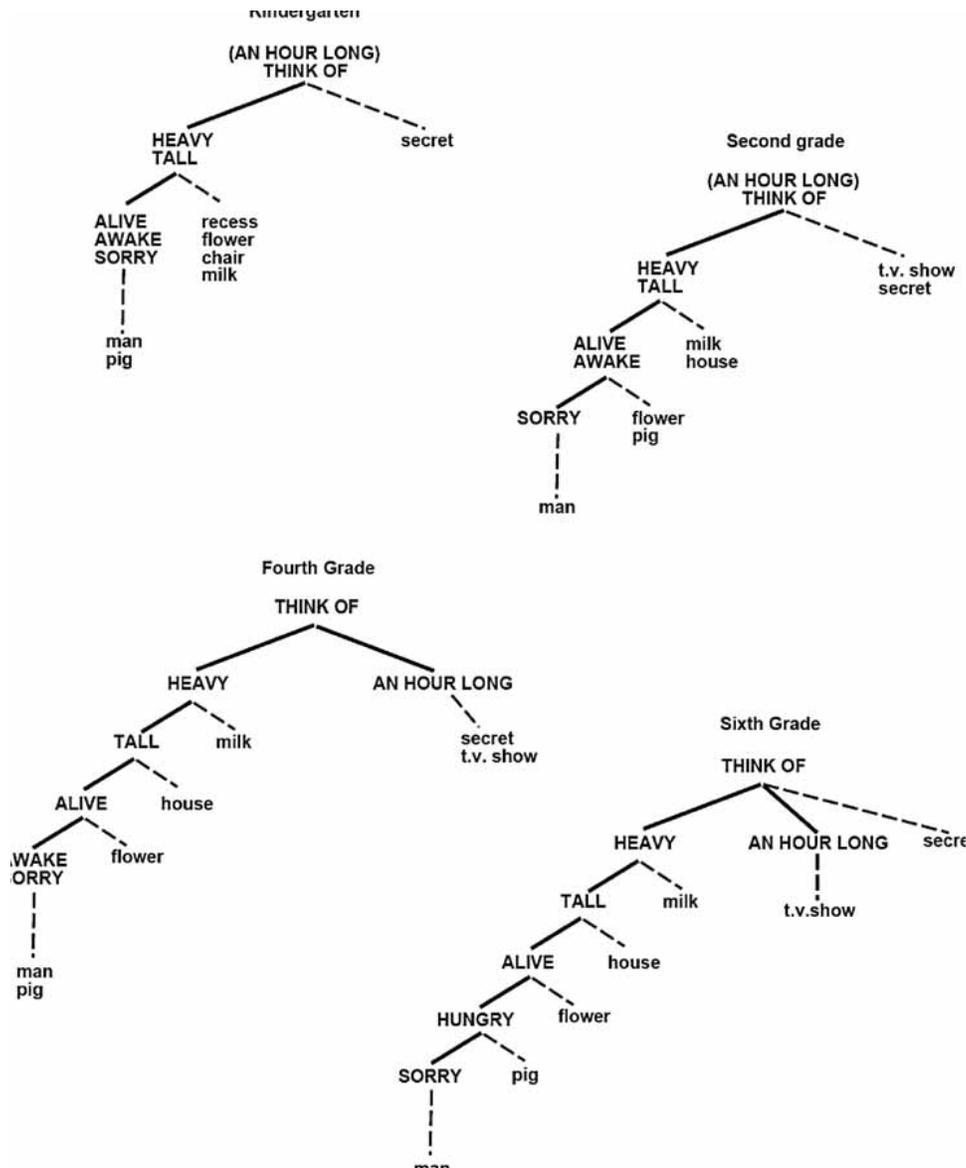

FIGURE 72.1 Examples of the predicability trees constructed by Keil (1979), from four individual children in different age groups. The trees indicate which of several predicate terms are accepted by the individual children as being applicable to various concepts; concepts accepting the same set of predicates are grouped

together at the same branch of the tree. (Reprinted with permission from Rogers & McClelland, 2004, figure 1.3, p. 10, based on appendices A3, A17, A37, and A54 from Keil, 1979, pp. 181, 183, 185, and 187.)

articulate an alternative to prior ways of thinking about conceptual knowledge and chose the domain of living things as his example. Instead of storing knowledge explicitly as a network of linked propositions, as shown in figure 72.2, he proposed it might be stored in connections among simple processing units, as in the network shown in figure 72.3. In this network, called the *Rumelhart network*, the knowledge, say, that a robin can grow, can move, and can fly is not stored in explicit propositions, but instead arises from a pattern-completion process. We query the network to tell us what a robin can do by activating units for “robin” and “can” on

the input side of the network, and propagating activation forward through intermediate layers to the output layer. The network is simplified in many ways relative to our overall theory, but it provides a useful ground for explaining the patterns we have discussed that arise in development.

When it is first initialized, the network’s connection weights are both small and random, so that a query produces very neutral and undifferentiated patterns of activation at all levels of the network forward from the item and context inputs. However, the network is trained with repeated exposure to the information in figure 72.2. Each input consists of

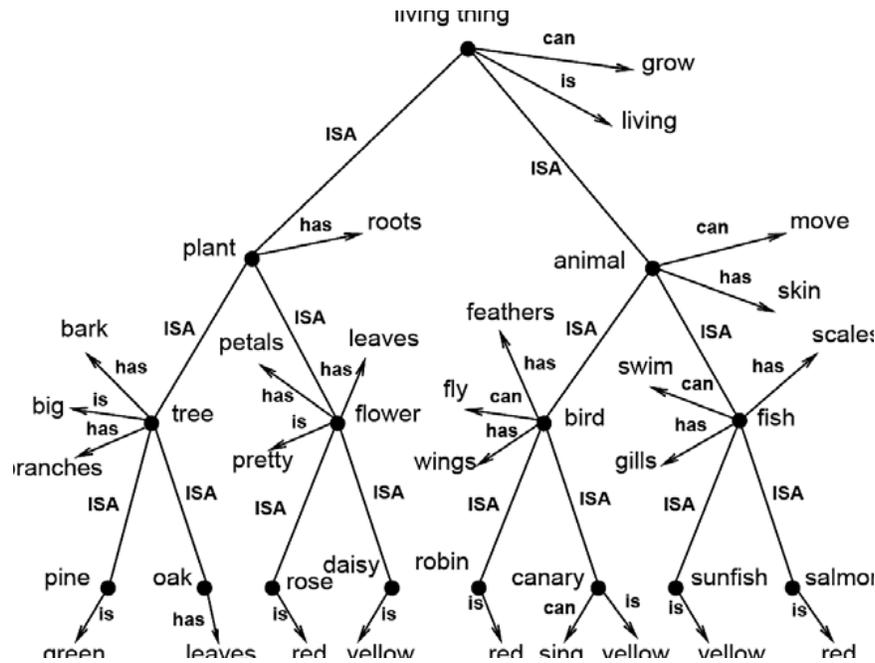

FIGURE 72.2 A taxonomic hierarchy of the type used by Quillian (1968) in his propositional model of the organization of knowledge in memory. ISA links may be followed up the tree to infer proper-

ties not explicitly connected to items below. (Reprinted with permission from Rogers & McClelland, 2004, figure 1.2, p. 6.)

an item (one of the eight items at the bottom of the figure) in each of four relational contexts (called “is” for appearance properties, “ISA” for the categories to which it belongs, “can” for things it can do, and “has” for specifying its parts). Activity propagates forward through the network and is then compared to the correct completion provided by the environment. Note that we do not envision this as an explicit instruction process, but simply a matter of anticipating future inputs from current inputs. It is the mismatch between what the network anticipates and what is provided by the environment that drives the adjustment of connections. In this case, the target pattern specifies the correct set of completions of the item-context pair provided as input. We treat the model as a proxy for the learning children do both from explicit (verbal) propositions provided by others in their environment and from actual experiences with objects in different contexts. For example, the child watching a robin on a branch may not anticipate at first that it will fly away as a cat creeps up upon it. Witnessing that the bird does fly away provides a signal that does not match expectations, and it is the difference between the (null) expectation and the witnessed action that then drives connection-based learning.

The details of the learning process are described in Rogers and McClelland (2004). The process is described as “back-propagation of error,” and its biological plausibility has been much maligned, but it has repeatedly been shown how the necessary error information can be derived from temporal differences in activation in networks with bidirectional con-

nections (e.g., O’Reilly, 1996). What is important for our purposes is that all the connections in the network are affected by this process. Some of these connections serve to change how patterns of activation inside the system affect the output units. Others serve to influence how external inputs (on the left in the diagram) are internally represented. The changing structure in these representations is crucial for the patterns of change that we see in development.

Figure 72.4 presents the patterns of activation seen in the “representation” layer of the network in figure 72.3 at three points during learning. Each histogram bar in the left panel of the figure represents the activation of one of the units in the representation layer of the network for a particular item at a particular time. The set of eight such bars for a particular item at a particular time constitutes that item’s internal representation. We can see that initially each unit takes a middling activation value for all items, so that the patterns are not well differentiated. The small differences at this stage largely reflect the initial random noise in the connection weights. In contrast, at the last time point (right column of figure 72.4) it is clear that the patterns have become quite differentiated. Hierarchical clustering analysis (not shown) reveals what can also be seen by eye. The network treats the two different types of fish as very similar, but as quite distinct from the two types of birds; all these are very different from all of the plants. Among the plants, the two trees are very similar and so are the two flowers. The trees and flowers are somewhat differentiated from each other, though not as much so as the birds are from the fish.

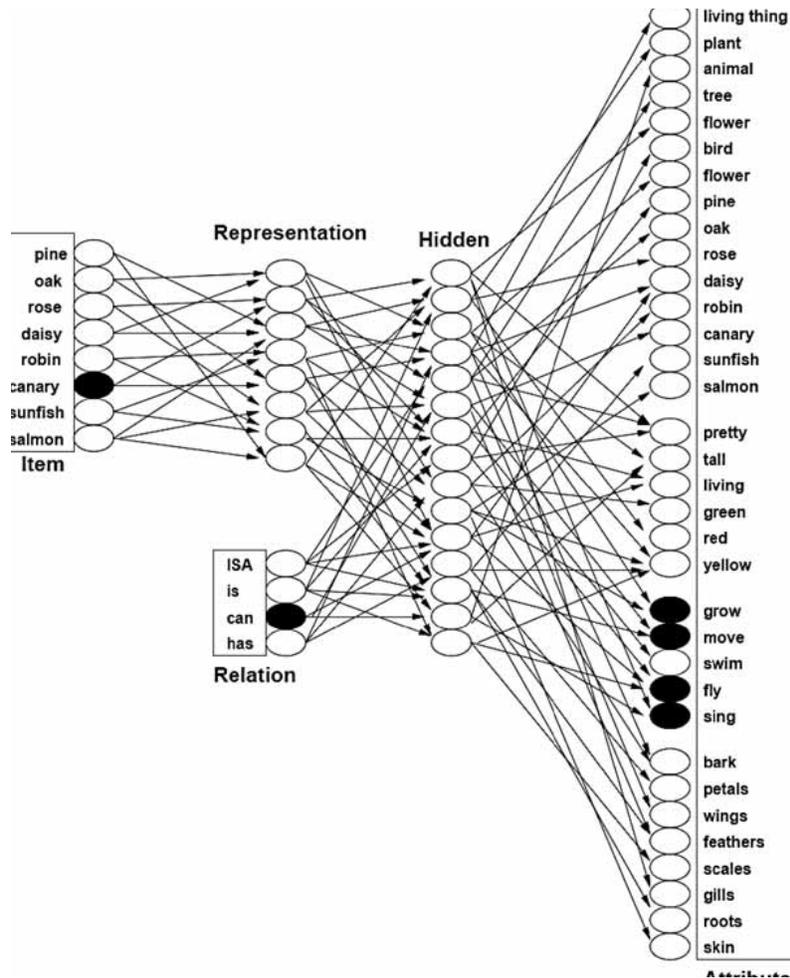

FIGURE 72.3 The connectionist model of semantic memory used in the developmental simulations, adapted from Rumelhart (1990; Rumelhart & Todd, 1993). The entire set of units used in the network is shown. Input units are shown on the left, and activation propagates from the left to the right. Where connections are indicated, every unit in the pool on the left is connected to every unit in the pool to the right. Each unit in the *Item* layer corresponds to an individual item in the environment. Each unit in the *Relation*

layer represents contextual constraints on the kind of information to be retrieved. Thus the input pair *canary can* corresponds to a situation in which the network is shown a picture of a canary and asked what it can do. The network is trained to turn on all the units that represent correct completions of the input query and to turn off all other units. In the example shown, the correct units to activate are *grow*, *move*, *fly*, and *sing*. (Reprinted with permission from Rogers & McClelland, 2004, figure 2.2, p. 56.)

What is particularly interesting for our purposes is the fact that the representations undergo a progressive differentiation. Specifically, at the intermediate time point shown, the network has successfully differentiated the plants from the animals before it further differentiates these two superordinate categories into their particular intermediate-level types. The full trajectory of this process is illustrated in a two-dimensional projection in figure 72.5. An animated version of this figure best captures the progressive differentiation of the network's representations over time. The animation at <http://psychology.stanford.edu/~jlm/Presentations/Differentiation.mpg> illustrates that the progressive differentiation process is highly stagelike in character, as seen in many aspects of children's cognitive development (McClelland, 1989). In the animation, we can see that all the patterns are

initially undifferentiated; they first divide into the plants on the one hand and the animals on the other; then the mammals diverge from the birds; then the trees from the flowers; then the different individuals differentiate from one another.

OVERGENERALIZATION OF NAMES AND ILLUSORY CORRELATIONS The overgeneralization of frequent names and the presence of illusory correlations both arise from the progressive differentiation process. Simulations illustrating the transitory developmental emergence of both these effects are shown in figures 72.6 and 72.7. In figure 72.6 we see what happens in a simulation in which there were four trees, four flowers, four fish, four birds, and five four-legged animals. Among the latter, one—the dog—occurred ten times more frequently than the others, including the goat

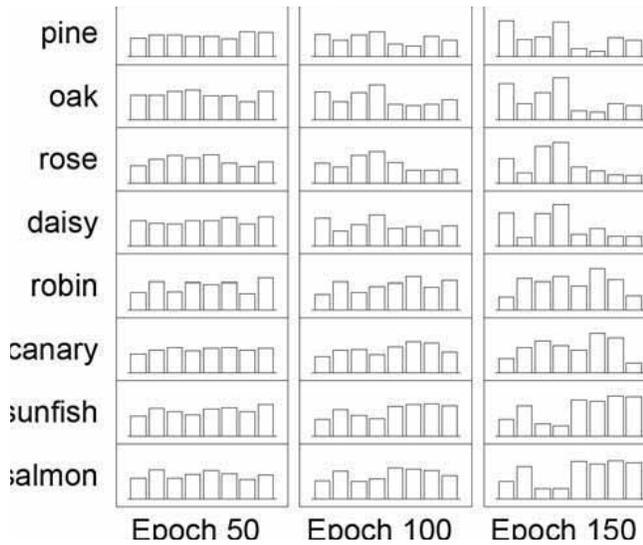

FIGURE 72.4 The process of differentiation of conceptual representations as seen in the Rumelhart model. Learned internal representations of eight items at three points during learning, using the network shown in figure 72.3. The height of each vertical bar indicates the degree of activation for one of the eight units in the network's *Representation* layer, in response to the activation of a single *Item* unit in the model's input. Early in learning (50 Epochs), the pattern of activation across these units is similar for all eight objects. After 100 epochs of training, patterns have begun to differentiate at the superordinate level (plants versus animals) but not at the intermediate level (trees versus flowers, birds versus fish). This further differentiation is apparent after 150 epochs, and continues down to the subordinate level as training continues. (Reprinted with permission from Rogers & McClelland, 2004, figure 3.1, p. 86.)

(consistent with input children receive, Rogers & McClelland, 2004, chapter 5). In this case, the network had a tendency, at a certain point in its development, to activate the name “dog,” not only for the dog but also for the other four-legged animals, including the goat. This tendency arises at a time when the four-legged animals are differentiated from the other animals but are not yet well differentiated from each other, and falls away again as the different land animals pull apart. This tendency makes sense from an optimal inference point of view, if we consider the conditional probability of hearing the label “dog” when experiencing the internal representation shared by the land animals (this probability is $10/(10 + 1 + 1 + 1 + 1)$ or about 0.7). Thus when the network has only one shared internal representation for all land animals, its best guess is to call them all “dog.” Once the representations differentiate, however, the conditional probability of each label given each item's representation changes dramatically, leading the network no longer to overgeneralize.

In figure 72.7, we see the tendency for the network to activate the property “has leaves” for the pine tree. For the network, this is an illusory correlation; although all other

plants have leaves, the pine tree does not in the network's training environment. There is a phase, relatively early in the network's development, where it attributes leaves to all things with a middling activation value (this value represents the proportion of all objects that have leaves). When the plants begin to differentiate from the animals, however, the network attributes leaves more strongly to all the plants, including the pine tree. Only as it comes to differentiate the pine from the other plants does it reverse this illusory correlation. Once again, this pattern makes sense from an optimal inference point of view. At the point in development where the representation of the pine tree is identical to the representation of the other plants, the conditional probability of “leaves” is very high. Again, once the representation of the pine differentiates from the representation of each of the other plants, the conditional probabilities change. Now, the network can learn the conditional probability of leaves for pine is actually 0.

SENSITIVITY TO COHERENT COVARIATION AND ITS DEPENDENCE ON THE ARCHITECTURE OF THE NETWORK In Rogers and McClelland (2004) the reasons why these three phenomena occur in the network are extensively explored. The essential point of this analysis is the observation that the connection weights from the item units to the representation units—and in consequence, the patterns of activation assigned to each concept on the representation layer—are sensitive to the pattern of coherent covariation of properties across the items presented to the network. The fact that all the animals share one set of properties that none of the plants have, while the plants share another set of properties that none of the animals have, is responsible for the first wave of differentiation. The error signals reaching the representation layer (and therefore driving the connection weights) tend to push the representations in a similar direction for all the animals—a direction that is different from the direction in which the error signals push the representations of all the plants. The subsequent differentiation of the different types of animals is also driven by the fact that each type of animal shares a set of properties that none of the other types possess, and similarly for the differentiation of the different types of plants. Now, it is the connections forward from the representation layer to the output layer that determine what output the network generates when a given pattern is present on the representation units. During the phase of development when the network is essentially representing the dog and all the other land animals as the same, but different from the plants and from the other types of animals, the correct name response when this shared representation is present over the representation layer is usually “dog,” because the dog occurs more frequently than any of the other land animals. The error-correcting learning process thus pushes the weights forward from this representation layer to activate the name

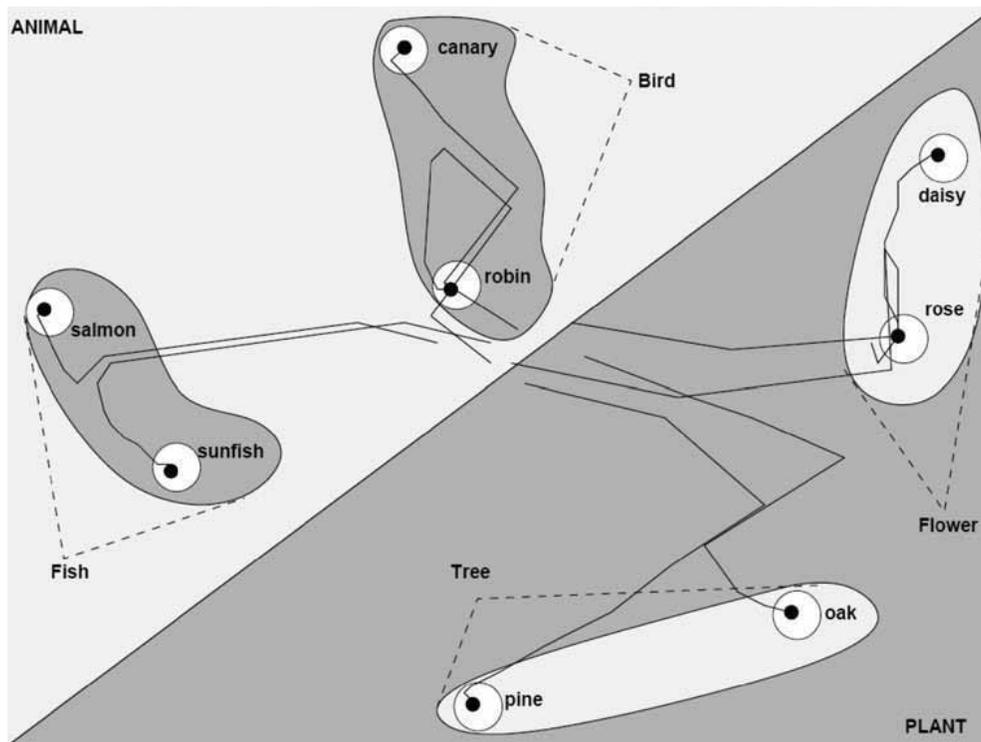

FIGURE 72.5 Trajectories of item representations (lines fanning from center of space) and their ultimate positions in the Rumelhart network's semantic representational space. Shaded regions around the final points indicate the approximate size of regions

associated with subordinate, intermediate, and superordinate levels as indicated. When an item has higher frequency, the region associated with that item and its properties is increased. (Reprinted with permission from Rogers & McClelland, 2004, figure 3.9, p. 112.)

“dog” more often than any other name, thereby accounting for the tendency for all land animals to be called “dog” at this stage of development. In the case of attributing leaves to the pine tree, the situation is similar. As long as the representation of the pine tree is similar to the representation of all other plants, the network tends to attribute “has leaves” to it as it does to the other plants. Thus both overgeneralization of frequent names and illusory correlations arise as a consequence of the sensitivity of the representations in the network to coherent covariation.

It is important to see that the network's tendency to be sensitive to coherent covariation, and thus to exhibit differentiation, name overextension, and illusory correlations, is a feature of its architecture (figure 72.8). In the extreme, if each item-context pair projected to its own distinct representation unit, which in turn projected forward to the appropriate properties for the object (as in figure 72.8B), there would be no sensitivity to coherent covariation at all. The error signals driving learning of each property of each item would be completely segregated from those relevant to every other property. In our actual architecture (figure 72.8A), something very different happens. Because the error signals for each property of each object in each context are projected on the same set of representation units, and because different concepts share these representation units, what is

learned about an object in one context tends to be shared both across objects and across contexts. In short, a key observation from our theory is this:

Sensitivity to coherent covariation, a tendency central to explaining many aspects of conceptual development, requires the use of a shared representation layer mediating all aspects of conceptual knowledge of all different kinds of things.

The particular architecture of the Rumelhart network is only one architecture with this property; in the rest of this article we will be considering networks with slightly different architectures that still make use of a single shared representation mediating all kinds of knowledge of all kinds of things.

Disintegration of conceptual knowledge in semantic dementia

Although the network discussed so far is quite abstract, the simulations do suggest an important hypothesis about the architecture of the cortical semantic network: that there must exist some place in the network where all different kinds of information *converge*, so that different items and events, regardless of the modality of input or the particular semantic domain, get processed through the same set of

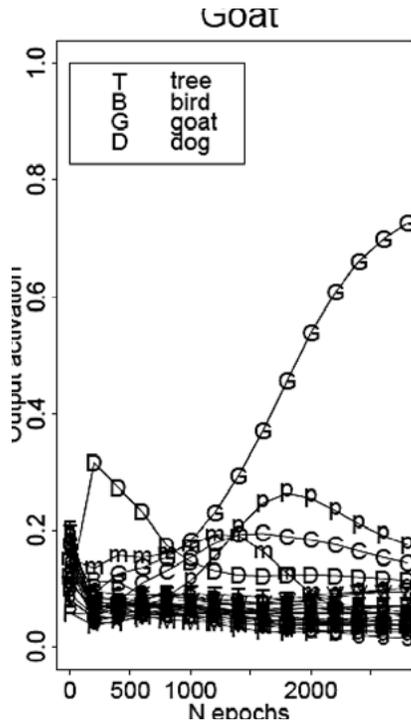

FIGURE 72.6 Activation of all the name units when the model is probed for its knowledge of basic names, in a network trained with dog patterns eight times as frequently as other mammal patterns in the environment. Early in learning, the network tends to inappropriately activate the name “dog,” especially for related objects. (Reprinted with permission from Rogers & McClelland, 2004, figure 5.1, p. 214.)

neurons and synapses. It is precisely this convergence of information that promotes sensitivity to coherent covariation in this network. This same convergence can explain the striking pattern of semantic deficits seen in patients with a rare neurological disorder, semantic dementia.

CHARACTERISTICS OF THE DISORDER Semantic dementia (SD) is a progressive deterioration of conceptual knowledge in the context of otherwise greatly preserved cognitive function (Snowden, Goulding, & Neary, 1989; Hodges, Patterson, Oxbury, & Funnell, 1992). Patients show serious deficits in any task requiring them to access knowledge about any type of thing from any form of input (Bozeat, Lambon Ralph, Patterson Garrard, & Hodges, 2000). Thus patients are impaired at both comprehending and producing speech, recognizing words and line drawings of common objects, indicating the correct color for black-and-white drawings of familiar items, choosing which of a set of items makes a particular sound, matching objects on the basis of shared function or use, demonstrating the use of everyday objects, and even recognizing common odors. These impairments affect knowledge for all different kinds of concepts—living and nonliving, abstract and concrete, verbs and nouns—and are apparent regardless of the modality of reception or

expression tapped by a particular test. Despite these serious disabilities, patients with SD perform normally or near-normally in tests of basic perception, episodic and working memory, executive function, problem solving, and attention; and, apart from word-finding difficulties arising from their conceptual deficits, they produce fluent and grammatical speech. Such patients thus appear to exhibit a pure and progressive cross-modal and domain-general impairment of semantic or conceptual knowledge (Patterson, Nestor, & Rogers, 2007; Lambon Ralph & Patterson, 2008).

As notable as the syndrome itself is the remarkable anatomical specificity of the cortical atrophy observed in the disease, which without exception affects anterolateral regions of the temporal lobes. Bilateral degeneration is the norm, though pathology is usually asymmetrical and patients with left-predominant atrophy present at about double the rate of right-predominant cases. The typical pattern on structural MRI is well-defined atrophy of both anterior temporal lobes that is maximal at the temporal pole and on the adjacent rostral-inferior surface (Hodges & Patterson, 2007; Patterson et al., 2007).

The pattern of semantic dysfunction together with the anatomical specificity of the atrophy provide strong evidence that the cortical semantic network adheres to the “convergence principle” suggested by the modeling work discussed earlier. Specifically, the findings from SD suggest that semantic knowledge for all kinds of concepts, across all modalities of reception and expression, depends upon a relatively circumscribed region of the anterior temporal lobes. Perhaps, then, these regions play a functional role similar to that of the *representation* layer of the Rumelhart network: by processing information about all kinds of items in many different situations and contexts, perhaps these regions form learned internal representations of inputs that capture the semantic similarity among items.

MODELING SEMANTIC DEMENTIA Rogers, Lambon Ralph, Garrard, and colleagues (2004) investigated this hypothesis using a PDP model based on the architecture shown in figure 72.9. Here, different kinds of sensory, motor, and linguistic information are represented in different pools of units, with each pool dedicated to a particular kind of information. These *surface* representations receive direct input from the corresponding sensory systems so that, whenever a given stimulus is encountered, the units that code its directly observed properties are activated. Like many other researchers, we believe the different surface representations to be subserved by different brain areas, organized predominantly by modality, and situated near the sensory channels from which they receive input (Martin & Chao, 2001). Also in common with other researchers, the function of the semantic system in this framework is to mediate learned associations among the various different surface

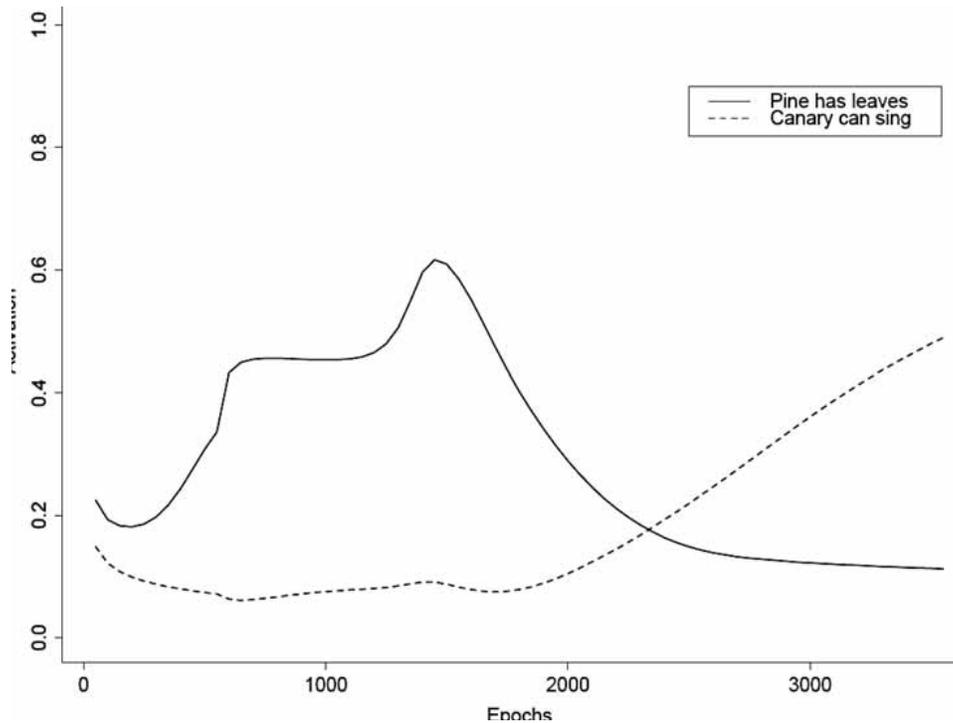

FIGURE 72.7 The activation of the “has leaves” and “can sing” output units across the first 5000 epochs of training, when the network is probed with the inputs *pine has* and *canary can*, respectively. At epoch 1500, the network has been trained 150 times to turn off the “has leaves” unit in response to the input *pine has*, and

to turn on the unit “can sing” in response to the input *canary can*. Nevertheless, the network still activates the “has leaves” unit for the pine tree, and fails to activate the “can sing” unit for the canary. (Reprinted with permission from Rogers & McClelland, 2004, figure 6.6, p. 254.)

representations—so that, for instance, when a line drawing of a pencil is observed, representations of associated attributes in other modalities, such as the appropriate color (yellow), name (“pencil”), and action (writing), will also become activated in the appropriate modality-specific brain areas.

Our framework differs from some others in proposing that the associations between all different forms of surface representations are mediated by a central “hub” in the anterior temporal lobes. The hub itself receives no direct input from sensory systems, but receives connections from and sends connections to the surface representations that code representations of particular sensory, motor, and linguistic attributes. The hub, illustrated in figure 72.9, is similar to the *item representation* layer in the Rumelhart network in that the representations there are a consequence of the learning process that shapes the weights projecting into and out from the layer. The surface representations in figure 72.9 are analogous to the *attribute* output units in the Rumelhart model, in that they explicitly encode observable characteristics of items in the environment. Because processing is recurrent in this model—activation flows both from the surface representations to the hub and from the hub back to the surface—there is no need to have separate “input” and “output” layers. Instead, any given input can be specified as a distributed pattern of activation across corresponding units

in the surface layers of the model. These inputs will propagate activation up to the hub of the anterior temporal lobes, which will then feed activation back to the surface representations to activate other properties of the item that have not been directly observed.

This framework also provides a natural paradigm for learning. The top-down activation of surface attributes may be viewed as the generation of an implicit expectation about the item’s unobserved properties. If these expectations are contradicted by a subsequent observation, the discrepancy can be used as an error signal to drive weight changes throughout the network, so that the system comes to generate increasingly accurate expectations.

Rogers, Lambon Ralph, Garrard, and colleagues (2004) used a model implementing these ideas to assess whether the theory could account for patterns of semantic impairment observed in SD. The model consisted of a *Visual* layer in which each unit coded a visually apparent property of an object; a *Verbal* layer, in which each unit coded a predicate (e.g., “has wings”) that might appear in a verbal description of an object, including names and other descriptors; and a *Semantic* layer that mediated interactions between these. Visual perception of an object was simulated by directly activating the object’s properties in the Visual layer and allowing activation to propagate through Semantic units to

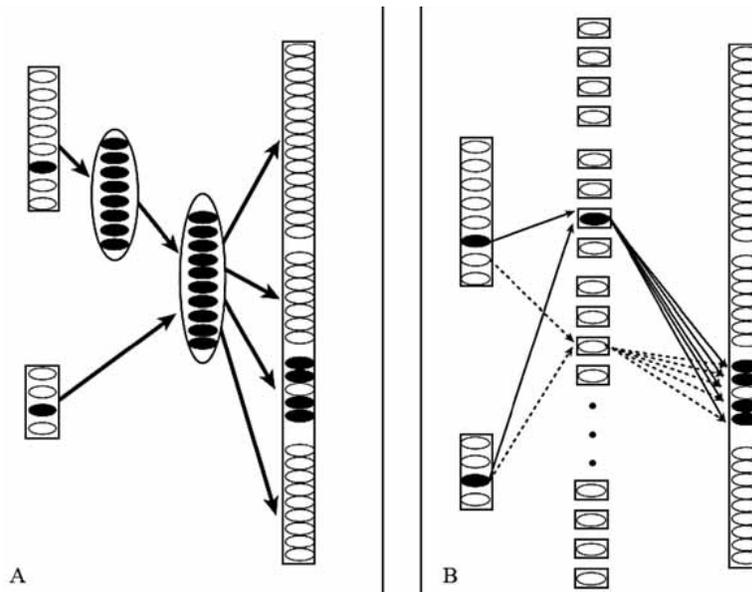

FIGURE 72.8 Two alternative feedforward architectures for mapping from localist *Item* and *Context* inputs to sets of output properties. Thick arrows in *A* indicate full connectivity among units in the sending layer to those in the receiving layer; thin arrows in *B* indicate individual connections. The shading of units indicates how activation spreads forward given the input *canary can*. (*A*) The Rumelhart network architecture, in which all items first map to a single context-independent hidden layer and then converge with context inputs in a second hidden layer. The first layer of hidden units receives error signals that are filtered through the second,

convergent representation; hence the architecture constrains the network to find context-independent representations of individual items that are sensitive to coherent covariation of properties across different contexts. (*B*) Separate localist representations for every possible conjunction of item and context. Only connections for *canary can* (solid arrows) and *salmon can* (dotted arrows) are shown. In this case the model will not generalize and will not be sensitive to coherent covariation. (Adapted with permission from Rogers & McClelland, 2004, figure 9.1, p. 357.)

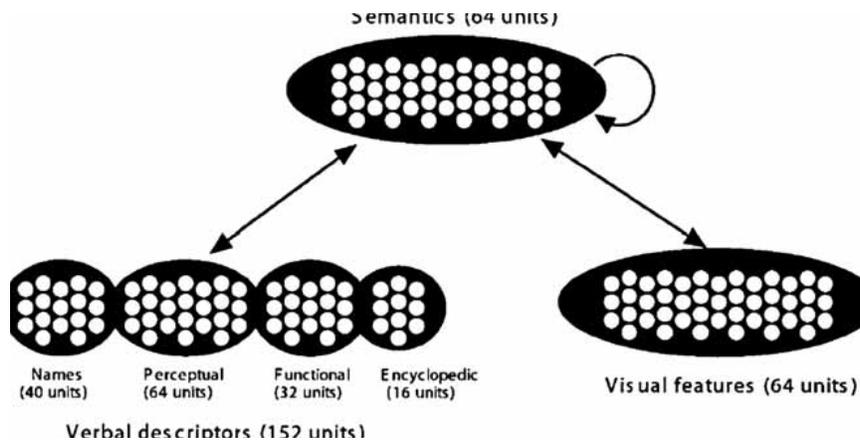

FIGURE 72.9 Architecture of the model used to simulate semantic dementia. (Reprinted with permission from Rogers, Lambon Ralph, Garrard et al., 2004, figure 1, p. 207.)

Verbal units. Presentation of an object name was simulated by directly activating the single unit representing the name in the Verbal layer; and presentation of a verbal description of an object was simulated by activating the subset of units representing the presented predicates. The model was then trained with backpropagation to produce the correct visual pattern, verbal pattern, or name when provided with one of these representations as input. Representations on the

Semantic layer were not specified but, as in the Rumelhart network, emerged as a consequence of learning. Once trained, the model permitted simulation of the most basic tasks used to assess semantic memory in patients with SD, including visual object naming, drawing-to-name, delayed-copy drawing, word-to-picture matching, sorting words and pictures, and so on. The patterns used to train the model were constructed to capture important aspects of similarity

structure apparent in both verbal attribute-listing studies and drawings of common objects. In both cases, superordinate category structure was clearly apparent—items from the same superordinate category (e.g., animals, manmade objects, and plants) tended to share many verbal descriptors and also to have similar visible parts in their drawings. There was also some more specific structure, especially among the set of animals; for example, different birds were more similar to each other than they were to other types of animals.

After training, the model represented each individual item—whether accessed by means of a single name, a verbal description, or a visual pattern—with its own domain-general pattern of activation across Semantic units. Just as with the Rumelhart network, these patterns captured similarity relations, with semantically related items represented by similar patterns of activation.

The deficit in semantic dementia was simulated by removing an increasing proportion of the connection weights projecting into or out from the intermediating hidden layer; the model was then tested on analogs of the semantic tasks used with patients. Comparable results are obtained by deleting individual units rather than individual connections.

The model naturally captures both the cross-modal and cross-category nature of the semantic impairment in SD. Semantic task performance was compromised both for visual semantic tasks like delayed-copy drawing—where the participant must draw a previously viewed item from memory after a short delay—and for cross-modal tasks like object naming; and the magnitude of impairment was roughly equivalent for animals and manmade objects (Lambon Ralph, Lowe, & Rogers, 2007). These aspects of model performance follow from the fact that it respects the convergence constraint identified in the previous section. When these weights were lesioned, performance for all tasks and semantic domains was affected.

PARALLELS BETWEEN DEVELOPMENT AND DISINTEGRATION

The model also offers a clear explanation of what for us is one of the key features of semantic dementia: loss of differentiating details about particular concepts together with spared knowledge of more general information. This loss of differentiating detail was first documented in the initial report of semantic dementia by Warrington (1975). Warrington also pointed out the parallelism between this finding and the lack of differentiation in early stages of conceptual development. Warrington demonstrated that knowledge of an item's properties that characterize broad semantic categories—for instance, the fact that tigers have fur—is much more robust than knowledge of item-specific properties, such as the fact that tigers have stripes. Knowledge about properties that characterize very specific classes—for instance, particular breeds of dog—is much more vulnerable to early impairment,

as is knowledge about less frequent and less prototypical items. So, when categorizing familiar objects, patients with very mild impairment will usually fail at naming objects at subordinate levels such as “robin” or “BMW,” but can seem unimpaired at more general levels such as “bird” or “car”; and even very semantically impaired individuals can succeed as well as controls at very general categories such as “animal” or “vehicle” (Rogers & Patterson, 2007).

In the model described by Rogers, Lambon Ralph, Garrard, and colleagues (2004), this erosion of knowledge about the individuating details of specific concepts arises as a consequence of the similarity structure of the distributed representation acquired in the semantic layer. To see this point, consider how the healthy model retrieves a fact specific to a particular subordinate concept, such as that a robin has a red breast. Even though Rogers and colleagues used the architecture shown in figure 72.9, the situation is still well reflected in figure 72.5, which shows the situation arising in the simpler training environment used in the Rumelhart network. What we see in this figure is a graphical depiction of the fact that the models learn to treat the robin as quite similar to all the other birds (in this case, the only other bird is the canary); yet none of these other birds has a red breast like the robin. Therefore, to correctly activate the “red breast” units in either the Visual or Verbal layer, the Hidden layer must instantiate the pattern of activation corresponding to the robin almost exactly—if this pattern is just a little different, then it may become more similar to another individual bird that does not have a red breast, and the system will fail to activate the correct property in the periphery. Thus relatively small distortions to the correct representation will prevent the model from strongly activating properties that are unique to very specific categories.

Now consider a property that the robin shares with other birds, like “has wings.” In this case, the model need not instantiate precisely the right representation to retrieve the property, since it is common to all of the birds and hence will be activated by all of the patterns that are somewhat similar to the correct pattern. If the robin representation is distorted so that it more closely resembles the canary representation, this distortion will not disrupt activation of the “has wings” units in the Visual and Verbal layers, because the canary has wings just like the robin (as do all of the other birds). Thus even with a relatively severe distortion to the representation the system can still generate the correct outputs for category-typical properties. The same argument suggests why still more general properties—like the fact that animals have eyes—are even more robust. If the robin representation is, as a consequence of brain damage, so degraded that it becomes less distinguishable from the various mammals as well as from the other birds, the system will still continue to correctly activate properties held in common between birds and mammals.

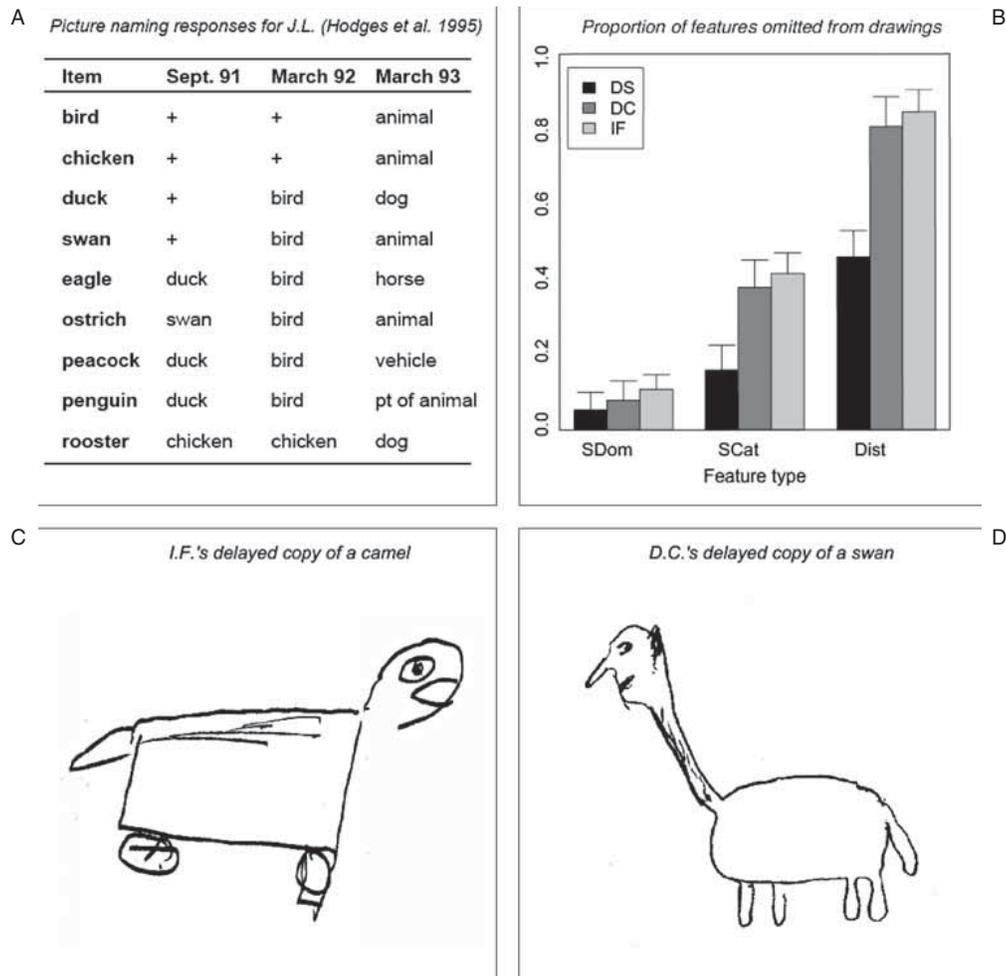

FIGURE 72.10 Evidence of conceptual disintegration in semantic dementia. (A) Naming responses given by patient JL to pictures of birds (drawn from a set of line drawings for which control subjects consistently provide the name given in the left column) at three times during the progression of his illness (+ indicates correct responses). (B) Proportion of features of different types omitted from drawings by three other semantic dementia patients. Patients were shown a picture of the object including all the tested properties and were asked to copy the picture from memory after a 10-second delay. All copied the picture accurately while it remained in view, but had difficulty in reproducing the distinctive but not the domain-general properties of the pictured objects after a delay. SDom: Properties shared by typical members of the general domain (e.g.,

eyes, shared by animals) of the test item. SCat: Properties shared by typical members of the superordinate category (e.g., wings, shared by birds). Dist: Distinctive features of the test item itself (e.g., stripes, distinctive attribute of tiger). (C) Delayed copy of a camel; no hump is evident. (D) Delayed copy of a swan. A long neck is present, indicating some preserved representation of specific information but there are four legs, illustrating the tendency these patients have to fill in properties that are generally present in items within the overall domain (animals) even if not present in the specific item (swan) or even its immediate superordinate (bird). (Redrawn with permission from McClelland & Rogers, 2003, figure 2, p. 312. Panel A excerpted from the appendix of Hodges, Graham, & Patterson, 1995, p. 490.)

The gradual loss of idiosyncratic detail coupled with the preservation of information shared among members of a category creates progressive dedifferentiation of semantic knowledge, paralleling the progressive differentiation seen in development. Hand in hand with this progressive dedifferentiation are two other phenomena that parallel those seen in development: (1) overgeneralization of names of frequently occurring objects and (2) illusory correlations, or the attribution of category- or domain-general properties to objects that lack these properties. Evidence of these aspects of SD is shown in figure 72.10. In figure 72.10A, we present

picture-naming data from patient JL at different stages of his progressive deterioration (Hodges, Graham, & Patterson, 1995). Here we see that, as his impairment becomes progressively worse, he shows an increasing tendency to overapply names of the more common animals (e.g., duck) to less common animals (eagle, peacock). In figure 72.10C and 72.10D, we present delayed copies made by two patients of a swan and a camel. In the latter case, the differentiating detail of the camel's hump is lost; more strikingly, in the former, a property typical of the broad class of animals—that of having four legs—is added to the swan, making it far

more like other animals. These phenomena are not idiosyncratic to particular objects or patients (figure 72.10B). There is a general tendency to produce names of more frequent category coordinates in object naming (Woolams, Cooper-Pye, Hodges, & Patterson, 2008) and a general tendency to both omit differentiating details and to incorrectly incorporate domain-general properties in patient's delayed copying (Bozeat et al., 2003).

The reasons for overgeneralization of frequent names and illusory correlations can again be understood with reference to figure 72.5. As illustrated in the figure, the points in representational space associated with specific items are a function of the item's frequency. A very small region surrounding a very specific point is associated with the idiosyncratic properties of individual objects, including their names, whereas a much larger region is associated with the properties of frequent objects (such as a dog) or the shared properties of many objects (such as having four legs). As a result, any distortion of the representation of a particular, relatively uncommon item will tend to result in the network's representation landing in a part of the space associated with more common objects and more typical properties. Indeed, the model shown in figure 72.9 was able to simulate closely the proportions of category coordinate naming errors seen in SD, as well as the proportion of item-specific omissions and category-general overgeneralization errors made by such patients (Rogers, Lambon Ralph, Garrard, et al., 2004).

In summary, just as the Rumelhart model explains the progressive differentiation of conceptual knowledge over development, the model of Rogers, Lambon Ralph, Garrard, and colleagues (2004) explains the apparent reversion of this process in SD: the gradual erosion of knowledge about the details that individuate concepts, beginning with very specific concepts and progressing to more and more general concepts. All these phenomena arise from the same general principles: that semantic knowledge is acquired through domain-general mechanisms, in a system that learns mappings among various different "kinds" of sensory, motor, and linguistic information and that stores these mappings within a convergent architecture in which all kinds of information for all kinds of concepts are processed through the same neurons and synapses.

Nonsemantic deficits in semantic dementia

The previous section demonstrates how the essential principle of convergence from widely distributed modality-specific brain regions can help us to understand the *semantic* deficits observed in semantic dementia (SD). This section addresses a *further* set of deficits observed in SD. These deficits are important because the abilities affected are ones that have been thought by many to operate *without* reference to seman-

tic knowledge. If SD constitutes a semantic impairment, why should these abilities be affected? One possibility is that the nonsemantic impairments are simply additional independent deficits that arise because of abnormalities in other, nonsemantic regions. However, these additional deficits both (1) occur consistently with the semantic deficit and (2) are similar in nature to the semantic deficit. From these observations, we have argued that they are a part of the core deficit itself (e.g., Patterson et al., 2006). We concentrate here on "nonsemantic" SD deficits in four tasks using words, though similar deficits occur with other kinds of stimuli. Nearly all SD patients had abnormal performance on each of the four tests: (1) lexical decision, in which the participant must judge whether each of a series of letter strings is a real word or must choose the real word when items are presented in pairs; (2) oral reading of single printed words; (3) written spelling of single spoken words; and (4) oral production of the past tense from present tense (stem) forms of verbs (Benedet, Patterson, Gomez-Pastor, & de la Rocha, 2006; Funnell, 1996; Graham, Patterson, & Hodges, 2000; Hodges et al., 1995; Patterson & Hodges, 1992; Patterson, Lambon Ralph, Hodges, & McClelland, 2001; Rogers, Lambon Ralph, Hodges, & Patterson, 2004; Ward, Stott, & Parkin, 2000). The basis for performing three of these tasks (reading, spelling, and past tense formation) is traditionally considered to be a joint function of a system of rules and a system of lexical entries; the rules and lexical entries are often considered separate from each other and also separate from semantic knowledge (e.g., Caramazza, 1997; Coltheart, Rastle, Perry, Langdon, & Ziegler, 2001; Levelt, 1989; Pinker, 1991). Lexical decision is often thought to depend only on lexical entries, although the presence of typicality effects in this task might be taken to suggest that some other system of knowledge, perhaps a system of rules, would be needed here, too.

Within the PDP framework, performance on all these tasks is thought to rely on a single integrated processing system that contains neither rules nor lexical entries but, like the semantic system, is sensitive both to properties that items share with each other and to idiosyncratic, item-specific information (Rumelhart & McClelland, 1986; Plaut, McClelland, Seidenberg, & Patterson, 1996). Words, like objects, tend to have properties that they share with others. Tigers have fur like other animals, but they also have their idiosyncratic stripes. Similarly, the word *pint* has correspondences it shares with many other words in the pronunciation of most of its letters, but it has an idiosyncratic correspondence in the pronunciation of the vowel; and the irregular verb *keep* forms its past tense like regular words in most respects. In regular verbs, a /t/ would be added to the stem (cf. *bake–baked*, pronounced /be:kt/). The same is true with *keep–kept*, but in addition there is an idiosyncratic vowel adjustment.

Semantic dementia patients have difficulty in all of these tasks in ways that parallel the deficits they show in semantic tasks. As their semantic disorder progresses, they make progressively more errors on words that are of low typicality, especially when they are also of low frequency. Also, the nature of the patients' errors mirrors precisely the "illusory correlations" discussed earlier with reference to knowledge of the properties of objects. Semantic dementia patients apply to atypical words the correspondences that the words would have if they were more typical. Asked to read the word *sew*, they often say "sue" using the typical correspondence in *crew*, *few*, *new*, and so on; asked to spell "cough," they write *coff*, using the typical spelling for /f/ as in *off*, *scoff*, *fluff*, *cuff*, and so on. Asked to put the sentence "Every day I fight with my brother" into the past tense, they will often say, "Yesterday I fought with my brother." A typicality effect is also seen in lexical decision. Asked which of the two letter strings *seize* and *seese* is a real word, severe SD patients actually prefer the incorrect but more typical spelling *seese*. The effect is strictly analogous to an effect seen in an object-decision task (Rogers, Lambon Ralph, Hodges, & Patterson, 2004). Asked to choose between a real elephant with large floppy ears of the kind that one only sees on elephants and an otherwise identical elephant with smaller, more typical ears taken from a monkey, severe SD patients will tend to choose the pseudoelephant over the real one.

A SINGLE SYSTEM FOR KNOWLEDGE OF BOTH OBJECTS AND WORDS Clearly, semantic dementia patients show a conjunction of semantic and lexical deficits. These deficits not only correlate (Graham et al., 2000; Patterson et al.,

2006; Woollams, Lambon Ralph, Plaut, & Patterson, 2007) but also exhibit similar characteristics. In semantic tasks, the patients tend to lose knowledge of specific and idiosyncratic properties of objects while retaining and overextending knowledge of general and typical properties. Similarly, in lexical tasks such as word reading, word spelling, and lexical decision, they tend to lose knowledge of atypical items and mappings while retaining and overextending knowledge of the typical (as regularization errors). The strong correlation of these deficits and the similarity of their nature suggest that the tasks all depend on the same set of processing structures that also underlie semantic processing. On this view, it is damage to these structures that produces both the semantic deficits and the parallel deficits in lexical tasks seen in SD patients.

Dilkina, McClelland, and Plaut (2008) developed a connectionist model implementing just such a single-system approach to semantic and lexical processing and showed that it could reproduce the convergent pattern of semantic and lexical deficits seen in SD. The simulation focused primarily on one "semantic" task—picture naming—and one "lexical" task, word reading. The model builds on the one used by Rogers, Lambon Ralph, Garrard, and colleagues (2004). In place of individual units to represent printed or spoken words, Dilkina and colleagues used patterns of activation over orthographic (letter) and phonological (sound) units for the spellings and sounds of words, respectively (figure 72.11). Like Rogers and colleagues, the model uses a single cross-modal level of representation that integrates all types of information about both words and objects and thus corresponds to the convergent semantic representations of the

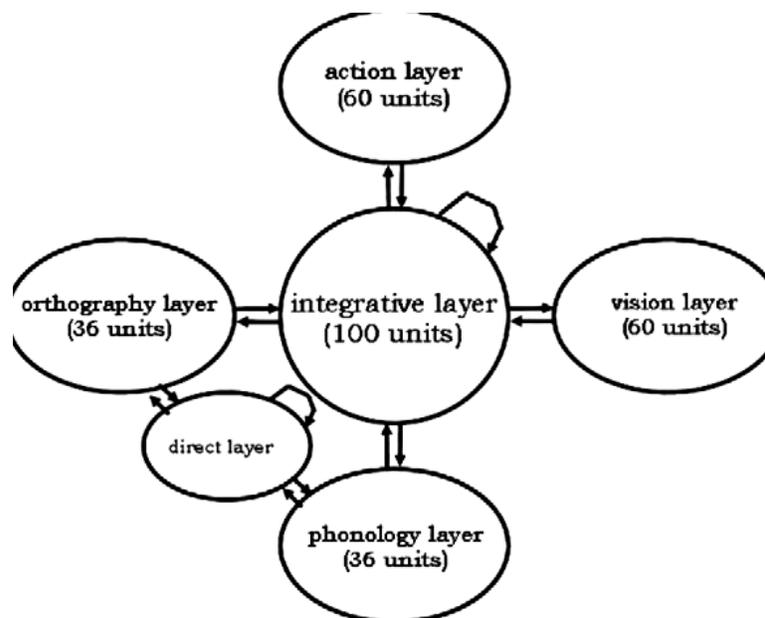

FIGURE 72.11 Network architecture used to simulate a single integrative system for semantic and lexical processing. (Reprinted with permission from Dilkina, McClelland, & Plaut, 2008, figure 3, p. 143.)

earlier model. The model also builds on earlier work (Plaut et al., 1996; Seidenberg & McClelland, 1989) by including a “direct” route between spelling and sound, in addition to bidirectional connections between both spelling and sound and the semantic layer. Although the direct route tends to specialize in capturing typical spelling-to-sound correspondences whereas the pathway through the integrative layer tends to specialize in idiosyncratic word-specific information, the partitioning is not absolute, and neither pathway corresponds to a strict rule system or a strictly lexical system.

The model was trained to map among four surface representations: (1) visual representations of what entities (objects and animals) look like; (2) action representations of how one may interact with these entities; (3) phonological representations of their names; and (4) orthographic representations of these names. The visual and action representations were binary vectors based on probabilistic category prototypes similar to those used in Rogers, Lambon Ralph, Garrard, and colleagues (2004). The name representations were simple onset-vowel-coda patterns that approximate English spelling-sound consistencies. After the network was trained to map from either visual or orthographic input to produce all four surface patterns, the semantic layer was progressively damaged to simulate semantic dementia.

The model exhibited the overall characteristic performance of SD patients—strong frequency effects in both tasks, and a frequency-by-typicality interaction in reading, as well as a high correlation between naming and reading of irregular words. In addition, the model was applied to the specific pattern of deficit seen in five patients tested with the same set of materials, including the case of an SD patient (patient EM; Blazely, Coltheart, & Casey, 2005) who showed spared reading of low-frequency exception words in spite of a fairly profound impairment in standard semantic tasks. The model was able to fit the specific pattern of reading and naming data observed in all five patients, including patient EM.

Patients like EM and others with similar deficits (Cipolotti & Warrington, 1995) have been used to argue against the single-system account, and thus it is important to understand how the model was able to address this patient, while at the same time addressing the other four, more typical, cases. The basis for this approach lies in incorporating the assumption that there are both premorbid and postmorbid *individual differences* that can contribute to the detailed pattern of performance seen in individual SD patients. Dilkina and colleagues (2008) focused on three such factors—premorbid experience with reading, premorbid capacity of the neural substrate mapping visual word form to phonological word form, and the spatial distribution of the lesion. Each of these factors was motivated by previous literature strongly suggesting that people indeed vary along these dimensions. The three factors were independently manipulated in the model.

Each of them significantly and independently affected the relative robustness of naming and reading. Notably, the model was able to successfully fit the SD dissociation case EM by manipulations that made reading relatively more robust to damage than naming. Notably, an experience manipulation alone was sufficient. Even though the model posits that naming and reading involve a single underlying system, greater premorbid experience with reading makes this system’s reading performance more robust under damage. In such cases, while naming declines quickly, the decline in reading may be delayed. Similar effects occur with other manipulations that increase reading robustness or that distribute the lesion toward connections from visual more than orthographic input. The account predicts that, as patients like EM progress in their illness, the deficit will eventually affect reading in all cases. Where data are available to test this prediction, it has held up to date (Woolams et al., 2007).

In summary, Dilkina and colleagues (2008) provide a theoretical and a computational account of how semantic and lexical deficits arise within a single system, and how they may appear to dissociate in some cases. While this work does not rule out a separate-system account, it shows that it is not necessary to postulate two systems to explain a handful of dissociation cases. Moreover, a single-system approach seems much more suitable in light of the large body of evidence showing a highly consistent SD profile where semantic and lexical abilities decline together, where there is a distinct frequency-by-typicality interaction in both domains, and where compromised performance results in homologous types of errors.

Roles of the ATL and other brain areas in semantic cognition

As noted throughout this chapter, our approach to understanding the nature and neural basis of conceptual knowledge has deliberately spanned a wide range of approaches and sources of data. In the preceding sections we reviewed a selection of these, including our overarching theoretical framework for considering conceptual knowledge and how this has been implemented in various PDP models addressing two core sources of empirical data—namely, the development of concepts in children and the structured degradation of concepts observed in semantic dementia. In this final section we review other sources of evidence bearing on our hypothesis that the anterior temporal lobes (ATLs) provide a hub over which conceptual knowledge is represented. First we review convergent evidence for the notion that the ATL is a critical part of the wider brain network that supports semantic cognition. Then we broaden the theoretical canvas to include the role of other brain regions. This allows us to consider a wider range of brain mechanisms that contribute

to semantic cognition, construed broadly as the task-modulated use of semantic knowledge to guide behavior.

CONVERGENT EVIDENCE FOR THE ROLE OF THE ATL IN SEMANTIC MEMORY There is considerable debate about the putative role of different brain regions in tasks requiring use of semantic knowledge (Hickok & Poeppel, 2007; Martin, 2007; Patterson et al., 2007; Wise, 2003). As noted earlier, in SD a selective semantic impairment is paired with relatively circumscribed atrophy of the anterior, inferolateral temporal lobes, bilaterally. Thus, as already articulated, the simplest and most obvious hypothesis is that the ATL areas are critical for semantic memory (Lambon Ralph & Patterson, 2008; Patterson et al., 2007; Rogers, Lambon Ralph, Garrard, et al., 2004). Given that SD is a neurodegenerative condition, there is no absolute boundary to the damage, and there is always the possibility that subthreshold damage or dysfunction due to invading pathology occurs elsewhere and that it is this more subtle, widespread damage that is the root of the patients' semantic impairment (Martin, 2007). It is critically important, therefore, to derive convergent evidence about the putative role of ATL regions in conceptual knowledge.

Converging evidence comes in three forms: other patient groups, functional neuroimaging, and transcranial magnetic stimulation (TMS). Other neurological conditions do produce semantic impairment when damage affects the same bilateral temporal lobe regions as semantic dementia. These include Alzheimer's disease (Hodges, Salmon, & Butters, 1992) and herpes simplex virus encephalitis (Lambon Ralph et al., 2007; Noppeney et al., 2007), although the more widespread brain damage associated with these neurological diseases leads to additional cognitive and memory impairments (Lambon Ralph & Patterson, 2008). The functional neuroimaging literature provides a slightly complex picture. If one primarily looks at the fMRI literature, there is a distinct lack of evidence for our hypothesis: fMRI studies of semantic memory or comprehension rarely find activation in anterior temporal lobe regions (Devlin et al., 2000; Garavan, Ross, Li, & Stein, 2000). While there may be important task design issues in some of these studies, the failure to find anterior temporal lobe activation reflects, at least in part, fMRI signal loss and distortion that is particularly pronounced in orbitofrontal cortex and the inferior and polar aspects of the temporal lobes (Devlin et al.; Wise, 2003). Functional neuroimaging that utilizes PET does detect semantically related activation in the anterior temporal lobes, even when the same experiment conducted in fMRI does not (Devlin et al.). Likewise, semantic-related processing in the ATL has been observed in normal participants by using MEG, irrespective of whether the stimulus is presented in the auditory or visual modality (Marinkovic et al., 2003), matching findings from early PET-based studies

based on pictorial or verbal input (Vandenberghe, Price, Wise, Josephs, & Frackowiak, 1996).

Of course, the areas differentially activated in imaging studies do not imply a *necessary* role (Price & Friston, 2002). Given the potential doubt over the neuropsychological data, we have recently initiated a new line of investigation that uses off-line, repetitive transcranial magnetic stimulation (rTMS) to probe the role of ATL in neurologically intact participants (Lambon Ralph, Pobric, & Jefferies, 2009; Pobric, Jefferies, & Lambon Ralph, 2007). By using timed versions of the semantic tasks used in SD studies, we have been able to compare the pattern observed in the patients with that seen in normal participants post rTMS. The results closely mirror the characteristics of semantic dementia. For example, ATL rTMS produces a temporary slowing of responses on semantically related tasks (e.g., synonym judgment) but not other cognitive tasks matched for overall difficulty (e.g., number judgment). The same stimulation also affects expressive tasks (picture naming but not number reading is slowed). Intriguingly, like the SD patients, a greater effect was observed for identifying concepts at a specific level (e.g., *golden retriever*) than at a basic level (e.g., *dog*). The relative role of the left versus the right ATL can also be probed using this rTMS method. In one study we compared left versus right ATL rTMS on the same synonym judgment task. A comparable slowing of semantic decision times was observed, indicating that both left and right ATL support semantic memory (Lambon Ralph et al., 2009). This pattern was replicated in a further study on a test of semantic association (e.g., between pyramids and palm trees; Bozeat et al., 2000; Howard & Patterson, 1992). In these assessments, stimuli are presented either as pictures or as written words. Repetitive TMS to either left or right ATL produced equivalent slowing on both the verbal and nonverbal versions of the task (Pobric, Jefferies, & Lambon Ralph, submitted).

These convergent results are all in keeping with our hypothesis that the ATL lobes jointly provide an amodal hub for semantic knowledge. However, there are still some puzzling data. Perhaps the most striking results come from patients with ATL resection for intractable epilepsy, who are not clinically associated with a postsurgical semantic impairment, at least not to the same degree as SD patients (Hermann, Davies, Foley, & Bell, 1999). Future studies of semantic memory that directly compare SD and TLE-resection patients are required to understand if the TLE data are truly inconsistent with our hypothesis. Most of the literature on the sequelae of temporal lobe resection is focused upon episodic memory impairment and anomia (which might itself reflect subtle semantic impairment; Lambon Ralph, McClelland, Patterson, Galton, & Hodges, 2001), and semantic memory is rarely formally tested (Giovagnoli, Erbetta, Villani, & Avanzini, 2005). Where semantic perfor-

mance has been assessed, studies have found subtle multimodal impairments both in unoperated TLE patients (Giovagnoli et al., 2005) and in patients after temporal lobe resection (Wilkins & Moscovitch, 1978). Furthermore, temporal lobe resection is a unilateral procedure, but SD patients have bilateral temporal lobe atrophy; it may be that bilateral damage is required to produce significant semantic impairment. It must also be noted that localization of function is complicated in these patients because long-standing epilepsy might lead to changes in neural organization. Indeed, recent imaging studies have shown that white matter connectivity and neurotransmitter function are significantly altered in this condition (Hammers et al., 2003; Powell et al., 2007). In addition, there might be some postsurgical reorganization that is less likely in neurodegenerative conditions when the brain is subjected to constant brain injury (Welbourne & Lambon Ralph, 2005). Consistent with this hypothesis, Wilkins and Moscovitch (1978) found a negative correlation between the severity of semantic impairment and time postsurgery.

BEYOND THE ATL: THE ROLE OF OTHER BRAIN REGIONS IN SEMANTIC COGNITION As articulated previously, our theoretical framework proposes one hypothesis about the way in which semantic knowledge is acquired through development and how it breaks down to produce the multimodal semantic impairments observed in semantic dementia and other ATL-focused neurological diseases. However, full-fledged semantic cognition—defined here as the adequate use of semantic knowledge to guide complex behavior—requires not only the ability to activate stored information from all modalities. It also requires the ability to shape or regulate the activation of task- and time-relevant information in order to produce flexible and appropriate behavior. Some kind of regulatory process is critical: we store a wealth of information about the meanings of words and objects, but frequently only a subset of this knowledge is required for a task—indeed, other aspects of knowledge may actually be inappropriate and unhelpful. As an example, consider the radically different uses of the same knife in making a sandwich: these can include piercing a package, slicing bread, meat, or cheese; scooping and spreading mustard or mayonnaise on the sandwich; and so on. Specific aspects of the knife's properties (and ways of holding and manipulating it) must be brought to the fore, one by one, while the most commonly listed property of cutting has to be inhibited in many of these activities. Indeed, in the case of scooping, the canonical function of the knife has to be disregarded altogether and replaced by a substituted function in place of another object (spoon). In sum, in addition to the acquisition and activation of conceptual knowledge, the ability to regulate and shape is critical to any complete account of semantic cognition.

The distinction between semantic representations and control processes that regulate processes acting on these representations helps to resolve a puzzle highlighted by a comparison of different, semantically impaired patient groups (i.e., patients who fail both verbal and nonverbal semantic tasks). Patients with ATL damage are not the only ones to exhibit poor semantic performance across different modalities. Indeed, it is possible to find a subset of aphasic patients who have multimodal semantic impairments (Chertkow, Bub, Deaudon, & Whitehead, 1997; Jefferies & Lambon Ralph, 2006) arising from temporoparietal or prefrontal damage rather than ATL damage. We refer to this pattern as *semantic aphasia* (SA) (Jefferies, Patterson, & Lambon Ralph, 2008). By directly comparing semantic aphasia and semantic dementia, we have been able to demonstrate that each group's failure on semantic tasks is qualitatively different and that they should not be considered as the same type of impairment.

We have hypothesized that the patient groups reflect two of the primary ingredients in semantic cognition: semantic dementia reflects a degradation of the core conceptual knowledge, whereas semantic aphasia arises from a deficit in the regulation of semantic cognition. We find that SD patients are highly consistent across different semantic tasks: patients who retained knowledge of an item in one task were typically able to demonstrate this knowledge in all other tasks. In contrast, SA patients show significant correlations/consistency only between different versions of the same semantic task (e.g., judgments of semantic association for words and pictures). Unlike SD, the SA patients' ability to retrieve information is inconsistent when tested across tasks with different semantic control demands (e.g., judgments of semantic association versus word-picture matching). Moreover, SA patients' ability to make semantic judgments can be predicted by how readily the relevant semantic dimension can be discerned and competitors rejected. For such patients, cues or constraints provided by the examiner can boost their performance considerably. The patients' errors in picture naming provide a further basis for differentiating the groups. The SD patients make frequent coordinate and superordinate semantic errors (such as saying "dog" or "animal" for goat). The SA patients also make associative errors (e.g., producing the response "nuts" for squirrel); these responses are virtually never seen in SD. These errors suggest that the SA patients retain a considerable amount of knowledge about unnamed targets (in order to be able to generate such errors) and suggest that their difficulty lies in directing activation toward the correct name and away from irrelevant associations.

These patient studies provide a direct convergence with fMRI studies of semantic processing in normal participants. These studies consistently implicate prefrontal cortex and the temporoparietal junction in tasks requiring controlled

semantic processing—for example, when a particular aspect of meaning must be selected or when there is strong competition from alternative responses (Thompson-Schill, Desposito, Aguirre, & Farah, 1997; Wagner, Pare-Blagoev, Clark, & Poldrack, 2001). It is possible that the relevant control or shaping processes may underpin executive/attentional functions more generally, as these same regions are commonly activated in a variety of tasks requiring cognitive control (Garavan et al., 2000; Peers et al., 2005). In keeping with this hypothesis, the SA patients tend to fail executive/attentional tasks even when they do not involve semantic information (Jefferies & Lambon Ralph, 2006).

Conclusion

This article has reviewed research spanning a wide range of research approaches. Behavioral investigations of developing children and neuropsychological patients, computational modeling investigations, and investigations of brain activity in healthy human volunteers using noninvasive imaging methods and TMS have all been used to support an overall account of the nature of semantic knowledge, its development and disintegration, and its instantiation in networks of interconnected areas of the brain. The approach has had some success in linking research from all these different methods under a common theoretical framework based on the principles of parallel distributed processing and in providing the stimulus for a considerable body of ongoing research. More work needs to be done to flesh out the theory and to better understand how activation of semantic and other forms of knowledge thought to depend on the anterior temporal lobes is influenced by activations in other brain areas.

73 Two Views of Brain Function

MARCUS E. RAICHLER

ABSTRACT In this chapter I encourage a broader discussion of how we view brain function. Traditionally, experiments of those studying brain functions have largely focused on the manner in which it responds to the momentary demands of the environment. By their very nature such experiments encourage a primarily reflexive view of brain function. Although such an approach has been remarkably productive, it ignores the alternative possibility that the brain's operations are mainly intrinsic, involving the maintenance of information for interpreting, responding to, and even predicting environmental demands. Here I will argue that it is the latter view that best characterizes the nature of brain function.

Since the 19th century and possibly longer, two views of brain function have existed (for a brief historical review see chapter 1 in Llinas, 2001). One view posits that the brain is primarily reflexive, driven by the momentary demands of the environment. The other view is that the brain's operations are mainly intrinsic, involving the maintenance of information for interpreting, responding to, and even predicting environmental demands. The former has motivated most neuroscience research, including that with functional neuroimaging. This is likely the case because experiments designed to measure brain responses to controlled stimuli and carefully designed tasks can be rigorously controlled, whereas evaluating the behavioral relevance of intrinsic brain activity can be an elusive enterprise. I believe the successes in studying evoked activity have caused us to ignore the possibility that our experiments reveal only a small fraction of the actual functional activity performed by our brain. This has certainly been the case in cognitive neuroscience until quite recently.

It was the concept of a default mode of brain function (Gusnard & Raichle, 2001; Raichle & Snyder, 2007; Raichle et al., 2001), which resulted from our desire to understand activity decreases from a resting state during task performance, that caused us to take seriously the notion that intrinsic activity likely plays an important role in brain function. Two other observations reinforced this belief. First was the demonstration that "noise" in the fMRI BOLD signal, first noted by Bharat Biswal and colleagues (Biswal, Yetkin, Haughton, & Hyde, 1995) and now actively being studied by many investigators (for a recent review see M. Fox &

Raichle, 2007), actually represents ongoing (intrinsic), spatially coherent activity within brain systems including the default mode network (Greicius, Krasnow, Reiss, & Menon, 2003). The second observation was that intrinsic functional activity accounts for the overwhelming majority of the brain's enormous energy budget (Raichle, 2006; Raichle & Mintun, 2006). In this chapter I review how these observations converged to underscore the importance of the brain's intrinsic activity for me.

The origins of an idea

By the early 1980s, positron emission tomography (PET) began to receive serious attention as a potential functional neuroimaging device in human subjects. (For a detailed historical account see Raichle, 2000.) The study of human cognition with neuroimaging was aided greatly in the 1980s by the involvement of cognitive psychologists whose experimental strategies for dissecting human behaviors fit well with the emerging capabilities of functional brain imaging (Posner & Raichle, 1994). Subtracting functional images acquired in a task state from ones acquired in a control state was a natural extension of mental chronometry (Posner, 1986), in which one measures the time required to complete specific mental operations isolated by the careful selection of task and control states. This approach, in various forms, has dominated the cognitive neuroscience agenda ever since with remarkably productive results.

For the better part of a decade following the introduction of subtractive methodology to neuroimaging, the vast majority of changes reported in the literature were activity increases, or *activations*, as they were almost universally called. Activity increases but not decreases are expected in subtractions of a control condition from a task condition as long as the *assumption of pure insertion* is valid. To illustrate, using an example based on mental chronometry, say that one's control task requires a key press to a simple stimulus such as the appearance of a point of light in the visual field, whereas the task state of interest requires a decision about the color of the light prior to the key press. Assuming pure insertion, the response latency difference between conditions is interpretable as the time needed to perform color discrimination. However, the time needed to press a key might be affected by the nature of the decision process itself, violating the assumption of pure insertion. More generally, the brain state

MARCUS E. RAICHLER Washington University School of Medicine, St. Louis, Missouri

underlying any action could have been altered by the introduction of an additional process. Interestingly, functional neuroimaging helped address the question of pure insertion by employing the device of *reverse subtraction*. Thus in certain circumstances subtracting task-state data from control-state data revealed negative responses, or *task-specific deactivations* (for examples and further discussion of this interesting issue see S. Petersen, van Mier, Fiez, & Raichle, 1998; Raichle, 1998; Raichle et al., 1994). It was clearly shown, just as psychologists had suspected, that processes active in a control state could be modified when paired with a particular task. However, none of this work prepared us for nor anticipated “the problem.”

“The problem,” as we now think of it, arose unexpectedly when we noted, quite by accident, that activity decreases were present in our subtraction images even when the control state was either visual fixation or eyes-closed rest. What particularly caught our attention was the fact that, regardless of the task under investigation, the activity decreases almost always included the posterior cingulate and adjacent precuneus, a region we nicknamed MMPA for “medial mystery parietal area.”

The first formal characterization of task-induced activity decreases was a large meta-analysis of published PET data from our group (G. Shulman et al., 1997). This study generated a set of iconic images, now generally referred to as the *default mode network* (figure 73.1A) after our later paper on the subject (Raichle et al., 2001). The unique identity of this network was amply confirmed in later meta-analyses by Jeffery Binder and colleagues at the Medical College of Wisconsin (Binder et al., 1999) and Bernard Mazoyer and his colleagues (Mazoyer et al., 2001) in France. Similar observations are now an everyday occurrence in laboratories throughout the world, leaving little doubt that a specific set of brain areas decrease their activity across a remarkably wide array of task conditions when compared to a passive control condition such as visual fixation.

The finding of a network of brain areas frequently seen to decrease its activity during goal-directed tasks (figure 73.1A) was both surprising and challenging. Surprising because the areas involved had not previously been recognized as a system in the same way we might think of the motor or visual system. And challenging because initially it was unclear how to characterize their activity in a passive or resting condition.

For us the issue of characterizing activity decreases came to a head in 1998 when a paper we were attempting to publish was rejected because of the way in which we characterized activity changes of the type seen in figure 73.1A. One of the referees wrote, “This is the most controversial aspect of this paper as it (1) cannot be ruled out that these signal changes are actual activations in the so-called resting state and (2) the physiological mechanisms underpinning

a genuine BOLD signal decrease remain a matter of speculation.”

It was clear that we needed a way to determine whether or not task-induced activity decreases were simply “activations” present in the absence of an externally directed task and why they should appear in both PET and fMRI functional neuroimaging studies. In pursuing this question we employed quantitative PET measurements of regional brain blood flow and oxygen consumption to define a physiologic baseline. The details of this work have been recounted on several occasions (Gusnard & Raichle, 2001; Raichle & Snyder, 2007; Raichle et al., 2001; Raichle & Mintun, 2006), including the third edition of *The Cognitive Neurosciences* (Gusnard & Raichle, 2004), and thus will not be repeated here. Suffice to say that this work allowed moving forward on the assumption that activity within the default mode network did not represent conventional activations in the resting state.

Having arrived at the view that the brain has a default mode of function through our analysis of activity decreases, we began to take seriously claims that there was likely much more to brain function than that revealed by momentary demands of the environment. Two bodies of information have been especially persuasive.

The cost of intrinsic activity

One of the challenges we face is trying to adjudicate the relative importance of intrinsic and evoked activity. For me the most persuasive approach has been to consider their relative costs. Let us turn then to a brief discussion of the budgeting of brain energy consumption.

In the average adult human, the brain represents about 2% of the total body weight but about 20% of the energy consumed (Clark & Sokoloff, 1999), 10 times that predicted by its weight alone. Relative to this very high rate of ongoing or “basal” metabolism (usually measured while resting quietly awake with eyes closed), the amount dedicated to regional imaging signals is remarkably small.

The regional increases in absolute blood flow associated with imaging signals as measured with PET are usually no more than 5–10% of the resting blood flow of the brain. These are modest modulations in ongoing circulatory activity that rarely affect the overall rate of brain blood flow during even the most arousing perceptual and vigorous motor activity (P. Fox, Burton, & Raichle, 1987; Friston et al., 1990; Lennox, 1931; Madsen et al., 1995; Roland, Eriksson, Stone-Elander, & Widen, 1987; Sokoloff, Mangold, Wechsler, Kennedy, & Kety, 1955).

The modest nature of these task-induced increases in blood flow is further underscored when one considers the increase in energy consumption they represent. Recall that the average resting metabolic activity of the brain is sup-

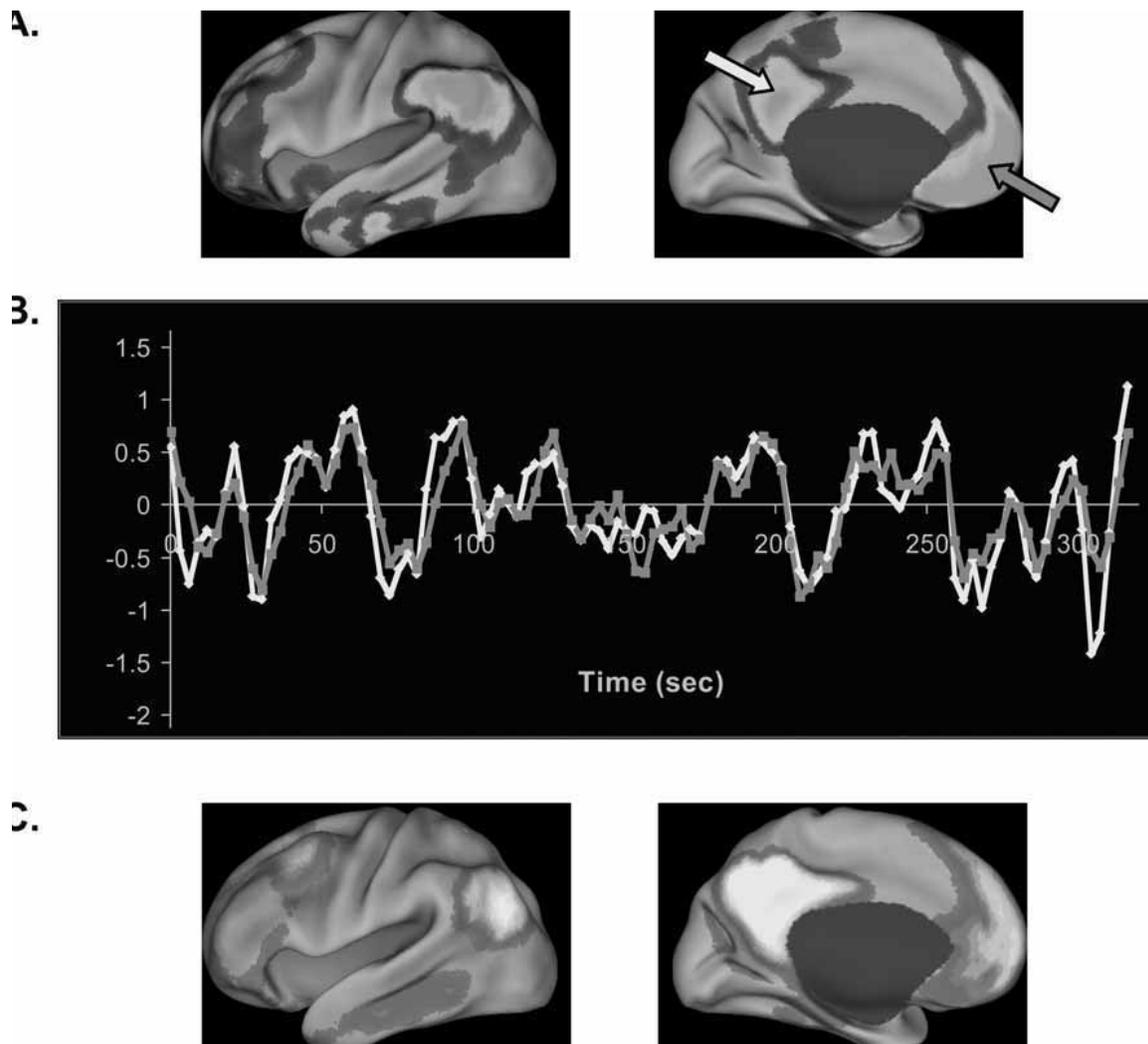

FIGURE 73.1 Performance of a wide variety of tasks has called attention to a group of brain areas (*A*) that decrease their activity during task performance (data adapted from G. Shulman et al., 1997). These areas are often referred to as the brain's default mode network after our initial work on them (Raichle et al., 2001). If one records the spontaneous fMRI BOLD signal activity in these areas in the resting state (arrows, *A*) what emerges is a remarkable similarity in the behavior of the signals between areas (*B*), a phenomenon originally described by Biswal and colleagues (1995) in the somato-motor cortex and later in the default mode network by Greicius

and colleagues (2003). Using these fluctuations to analyze the network as a whole (M. Fox et al., 2005; Vincent et al., 2006) reveals a level of functional organization (*C*) that parallels that seen in the task-related activity decreases. These data provide a dramatic demonstration that the ongoing organization of the human brain likely provides a critical context for all human behaviors. (These data were adapted from our earlier published work: M. Fox et al., 2005; Gusnard & Raichle, 2001; Raichle et al., 2001; G. Shulman et al., 1997.) (See color plate 87.)

ported by the nearly complete (>90%) oxidation of glucose to carbon dioxide and water, producing approximately 32 moles of ATP per mole of glucose consumed (Siesjö, 1978). Imaging signal activations, however, are associated with increases in glucose utilization that are not accompanied by a proportionate increase in oxygen consumption (Blomqvist et al., 1994; P. Fox, Raichle, Mintun, & Dence, 1988; Madsen et al., 1995), resulting in the production of only 2 moles of ATP per mole of glucose consumed, typical of glycolysis. Estimates of the actual increases in oxygen consumption vary somewhat (P. Fox & Raichle, 1986; P. Fox et al.,

1988; Fujita, Kuwahara, Reutens, & Gjedde, 1999; Mintun, Vlassenko, Shulman, & Snyder, 2002; Roland, Eriksson, Widen, & Stone-Elander, 1989) but are always less than that predicted by the increase in blood flow. From knowledge of these relationships, one can estimate that if blood flow and glucose utilization increase by 10%, but oxygen consumption does not, the local energy consumption increase due to a typical task-related response could be as little as 1%. It becomes clear, then, that the brain continuously expends a considerable amount of energy even in the absence of a particular task (i.e., when a subject is awake and at "rest").

What is the nature of this intrinsic activity present even at rest that commands such a large amount of the brain's energy resources?

It is tempting to assume that this intrinsic or resting-state energy utilization reflects simple housekeeping functions such as neuronal repair or protein trafficking. However, the preponderance of evidence suggests that such functions consume a relatively small fraction of the brain's energy budget. Measurements of brain energy metabolism using magnetic resonance spectroscopy (R. Shulman, Hyder, & Rothman, 2001; R. Shulman, Rothman, Behar, & Hyder, 2004; Sibson et al., 1997, 1998) in a variety of experimental settings have indicated that up to 80% of the entire energy consumption of the brain at rest is devoted to glutamate cycling and, hence, neural signaling processes. Complementary analyses using extant anatomic, physiologic, and metabolic data (Ames, 2000; Attwell & Laughlin, 2001; Lennie, 2003; Wong-Riley, 1989) to assess the cost of different components of excitatory signaling in the gray matter have arrived at similar conclusions. Such estimates leave for future consideration the demands placed on the brain's energy budget by the functional activity of inhibitory interneurons (Ackerman, Finch, Babb, & Engel, 1984; Buzsaki, Kaila, & Raichle, 2007; Chatton, Pellerin, & Magistretti, 2003; McCasland & Hibbard, 1997; Patel et al., 2005; Waldvogel et al., 2000). That evidence notwithstanding, it is likely to remain the case that a significant fraction of the energy consumed by the brain (quite possibly the majority) is due to functionally significant intrinsic neuronal activity.

From this cost-based analysis of brain functional activity it seems reasonable to conclude that intrinsic activity may be as significant as, if not more than, evoked activity in terms of overall brain function. Taking this position converts one's view of the brain as a system primarily responding to changing contingencies to one operating on its own, intrinsically, with sensory information interacting with rather than determining the operation of the system. This view has historical (Llinas, 1988) and recent theoretical (Olshausen & Field, 2005), as well as experimental, support (Arieli, Sterkin, Grinvald, & Aertsent, 1996; Fiser, Chiu, & Weliky, 2004; Kenet, Bibitchkov, Tsodyks, Grinvald, & Arieli, 2003). It seems highly likely that ultimate constraints on the behaviors we study with neuroimaging or any other technique will be significantly determined by this intrinsic activity.

The organization of intrinsic activity

A second body of evidence that persuades us to take seriously the importance of intrinsic activity is its remarkable degree of organization. For us this organization was first revealed in the activity decreases we and others observed in our studies with functional neuroimaging (figure 73.14). More

striking, however, have been the patterns of activity revealed in the analysis of the "noise" in the fMRI BOLD signal when subjects are resting quietly in the scanner with their eyes closed or simply maintaining visual fixation.

A prominent feature of fMRI is that the unaveraged signal is quite noisy (figure 73.1B), prompting researchers to average their data to reduce this "noise" and increase the signals they seek. As first shown by Biswal, Hudetz, Yetkin, Haughton, and Hyde (1997), a considerable fraction of the variance in the BOLD signal in the frequency range below 0.1 Hz appears to reflect spontaneous fluctuating neuronal activity that exhibits striking patterns of coherence within known brain systems (figure 73.1C), even in the absence of observable behaviors associated with those systems (for a recent review of this rapidly expanding literature see M. Fox & Raichle, 2007). Additionally, these patterns of coherence are remarkably consistent among individuals as well as across subject groups. The value of studying these resting-state BOLD fluctuations has been well articulated (Buckner & Vincent, 2007). But what does intrinsic activity represent?

One possibility is that intrinsic activity simply represents unconstrained, spontaneous cognition—our daydreams or, more technically, stimulus-independent thoughts (SITs; Antrobus, 1968; Mason et al., 2007; McGuire, Paulesu, Frackowiak, & Frith, 1996). But from a cost perspective SITs are highly unlikely to account for more energy consumption than that elicited by responding to controlled stimuli, which accounts for a very small fraction of total brain activity (Raichle & Mintun, 2006). Most telling is the recent observations that spatially coherent, spontaneous BOLD activity is present under general anesthesia (Vincent et al., 2007) and during sleep (Fukunaga et al., 2006). These two important observations suggest that intrinsic activity cannot simply be a reflection of conscious mental activity. Rather, it likely reflects a more fundamental property of brain functional organization.

Among the possible functions of this intrinsic activity is the regulation of neuronal responsiveness. Neurons continuously receive both excitatory and inhibitory inputs. The "balance" of these stimuli determines the responsiveness (or gain) of neurons to correlated inputs and, in so doing, potentially sculpts communication pathways in the brain (Abbott & Chance, 2005; Haider, Duque, Hasenstaub, & McCormick, 2006; Laughlin & Sejnowski, 2003; Salinas & Sejnowski, 2001). Balance also manifests at a large-systems level. For example, neurologists know that strokes damaging cortical centers controlling eye movements lead to deviation of the eyes toward the side of the lesion, implying the pre-existing presence of "balance." Another well-known example first demonstrated in the visual system of the cat is the "Sprague effect" (Sprague, 1966). It may be that in the normal brain, a balance of opposing forces enhances

the precision of a wide range of processes. Thus “balance” might be viewed as a necessary enabling, but costly, element of brain function.

A more expanded view is that intrinsic activity instantiates, in ways yet to be fully understood, the maintenance of information for interpreting, responding to, and even *predicting* environmental demands. In this regard, a useful conceptual framework from theoretical neuroscience posits that the brain operates as a Bayesian inference engine designed to generate predictions about the future (Kersten, Mamassian, & Yuille, 2004; Knill & Pouget, 2004; Olshausen, 2003). Beginning with a set of “advance” predictions at birth, the brain is then sculpted by worldly experience to represent intrinsically a “best guess” (“priors” in Bayesian parlance) about the environment and, in the case of humans at least, to make predictions about the future. This is a theme precisely enunciated many years ago by the late David Ingvar in his memorable essay “Memory of the Future” (Ingvar, 1985).

An important question for future research is how to incorporate studies of intrinsic brain activity into an already busy program of work devoted to evoked activity. Some, of course, will elect not to do so. However, limiting one’s approach in this way will eventually limit its potential if it is not nourished by a broader consideration and understanding of such relevant neurobiology. What is required is an expanded framework upon which to base one’s research agenda. Neuroscience and the behavioral sciences *together* must provide that framework, which is one that we heartily endorse.

Cognitive neuroscientists for their part will need to become more familiar with a broad range of approaches to the study of spontaneous activity of neurons (Arieli et al., 1996; Buzsaki & Draguhn, 2004; Foster & Wilson, 2006; Kay, 2005; Kenet et al., 2003; Leopold, Murayama, & Logothetis, 2003), which can include work in humans (He, Snyder, Zempel, Smyth, & Raichle, 2008). In this regard, descriptions of slow fluctuations (nominally, <0.1 Hz) in neuronal membrane polarization—so-called up and down states—are intriguing (Hahn, Sakmann, & Mehta, 2006; Isomura et al., 2006; Luczak, Bartho, Marguet, Buzsaki, & Harris, 2006; C. Petersen, Hahn, Mehta, Grinvald, & Sakmann, 2003). Not only does their temporal frequency approach that of the spontaneous fluctuations in the fMRI BOLD signal along with other low-frequency fluctuations (He et al.), but their functional consequences may be relevant to an understanding of the variability in task-evoked brain activity (Arieli et al.; M. Fox, Snyder, Zacks, & Raichle, 2006), as well as behavioral variability in human performance (M. Fox, Snyder, Vincent, & Raichle, 2007; Gilden, Thornton, & Mallon, 1995). Neuroscientists for their part need to be aware of the expanded view of intrinsic activity afforded by neuroimaging and the potential to relate this not only to

their own work at the cellular level but also to the behavior we all seek to understand that is instantiated in the large-scale organization of the brain’s intrinsic activity.

74 The Neuroeconomics of Simple Goal-Directed Choice (Circa 2008)

ANTONIO RANGEL

ABSTRACT This paper reviews what is known about the computational and neurobiological basis of simple goal-directed choice. Two features define this type of choice. First, individuals make decisions between stimuli that are associated with different outcomes or rewards. Second, the brain solves the decision problem by (1) computing the distribution of outcomes associated with each stimulus, (2) assigning a value to each stimulus equal to the expected reward generated by those outcomes, and (3) selecting the stimulus with the highest computed value. A typical example of simple goal-directed choice is given by the problem of choosing a meal from a buffet table.

Neuroeconomics studies the computational and neurobiological basis of animal and human decision making. Its goal is to understand how the brain solves the multitude of choice problems that organisms face every moment of their existence. One important complication in addressing these problems is that decision-making situations come in many different flavors, and it is likely that the brain uses different computations and systems to solve them. Compare, for example, the problem of a lion chasing a gazelle with the problem of a typical consumer deciding which of two cereal boxes to purchase. Both organisms are engaged in decision making, but their problems are very different. The problem of the lion is to select a direction of movement every instant to increase the probability of catching the gazelle. This entails a simple goal (“catch the gazelle”), but a series of action choices. In contrast, the consumer faces a complicated choice between goals (“which cereal box has the best taste-health-price combination?”), but once that decision has been made, the choice over actions is trivial (“pick the motor plan that grabs the chosen cereal box”). Given this complexity, an important task for neuroeconomics is the construction of a neurally relevant taxonomy of choice tasks that can be used to guide the research and to organize the findings.

Another difficulty in neuroeconomics is that there does not seem to be a simple one-to-one mapping between

decision-making situations and the neural processes used to make choices. Instead, a sizable and rapidly growing body of animal and human evidence suggests that there are at least three conceptually and neurally separable behavioral controllers at work in most decision-making situations: a Pavlovian system, a habitual system, and a goal-directed system (Balleine, Daw, & O’Doherty, 2008; Daw, Niv, & Dayan, 2005; Dayan, 2008; Dickinson & Balleine, 2002; Rangel, Camerer, & Montague, 2008). Although this topic is just beginning to be explored, the existing evidence suggests that the relative importance of the systems changes with the details of the decision-making situation. Given these two complications, it is unlikely that we will find a simple neuroeconomic theory of decision making that covers all types of choice situations.

In order to deal with these two complications, research in neuroeconomics typically focuses its attention on a subset of the behavioral controllers and a well-defined subclass of choice problems. In this chapter we review what is known about a class of problems that has received considerable attention in neuroeconomics and behavioral neuroscience: How does the goal-directed system make choices among sets of stimuli associated with different rewards? We refer to this problem as simple goal-directed choice. The decision-making situations of interest resemble the example of the consumer who has to choose one type of cereal among several options. The consumer cares about which choice he makes because the different stimuli are associated with different combinations of outcomes (or rewards). For example, one cereal box might be tastier and cheaper than another. It is important to emphasize that animals also engage in this type of choice. As an example, consider the problem of a rat that has to press a left or a right lever on a Skinner box in order to obtain one of two rewards, or the problem of a hungry lion confronted with several gazelles.

The review has several goals. First, we show that several choice tasks that have been used in the neuroscience and animal learning literatures are special cases of simple goal-directed choice. Second, we provide a mathematical description of the computations that define the goal-directed system. Third, we use the computational framework as a way to organize what is known about the neurobiology of

ANTONIO RANGEL Humanities and Social Sciences, Computational and Neural Systems, California Institute of Technology, Pasadena, California

the goal-directed system and what are some of the most important open questions.

Simple binary stimulus choice: A behavioral paradigm to study simple goal-directed choice

In a simple binary stimulus-choice task, individuals make repeated choices between pairs of stimuli that are presented to them, one on the left and one on the right. Individuals care about their choice because the stimuli are associated with different outcomes (or rewards) that affect their well-being. They indicate their choice by executing one of two different actions associated with each of the stimuli (e.g., a left or a right button push, a left or a right saccade, etc.). The actions are such that the costs and effort required to execute them are as similar as possible.

A typical example of such a task is depicted in figure 74.1A (Karjibich, Armel, & Rangel, under review). Individuals are shown pairs of high-resolution pictures of familiar snack-food items in a computer monitor and have to choose which one they would like to consume at the end of the experiment by pressing either a left or a right button. There are 70 different such stimuli that are randomly assigned into pairs in 100 different trials. At the end of the experiment, one of the trials is selected at random, and the subject eats the food depicted in the picture that he chose in that trial. Another example is shown in figure 74.1B (Baxter & Murray, 2002). During an initial training phase, monkeys are exposed to 120 objects of different shape and color, two at a time. Importantly, 60 of the objects are associated with a food reward (half with a cherry and half with a peanut) that is placed below the object, whereas the other 60 objects are associated with no such reward. The goal of this phase is for animals to learn to associate the 30 cherry objects with the consumption of a cherry and the 30 peanut objects with the consumption of a peanut. During a second training phase, the animals are repeatedly presented with one cherry object and one peanut object, and are taught to make a choice by lifting only one of the objects and grabbing the reward underneath. The location of the objects is fully randomized. After the animals are fully trained, they are tested in one of three conditions: (1) sessions that are preceded by feeding to satiety with cherries, (2) sessions that are preceded by feeding to satiety with peanuts, and (3) sessions with no prefeeding.

Note some of the central elements of the simple binary stimulus-choice task. First, there are at least 2 stimuli that the subjects choose from, although the set may be much larger. For later reference, let S denote the set of stimuli and s denote a typical element. Second, each stimulus is associated with a probability over outcomes. Let O denote the set of potential outcomes, o denote a typical outcome, and $p(o|s)$ denote the probability that the subject gets outcome o if stimulus s is chosen. The outcomes can be appetitive (e.g.,

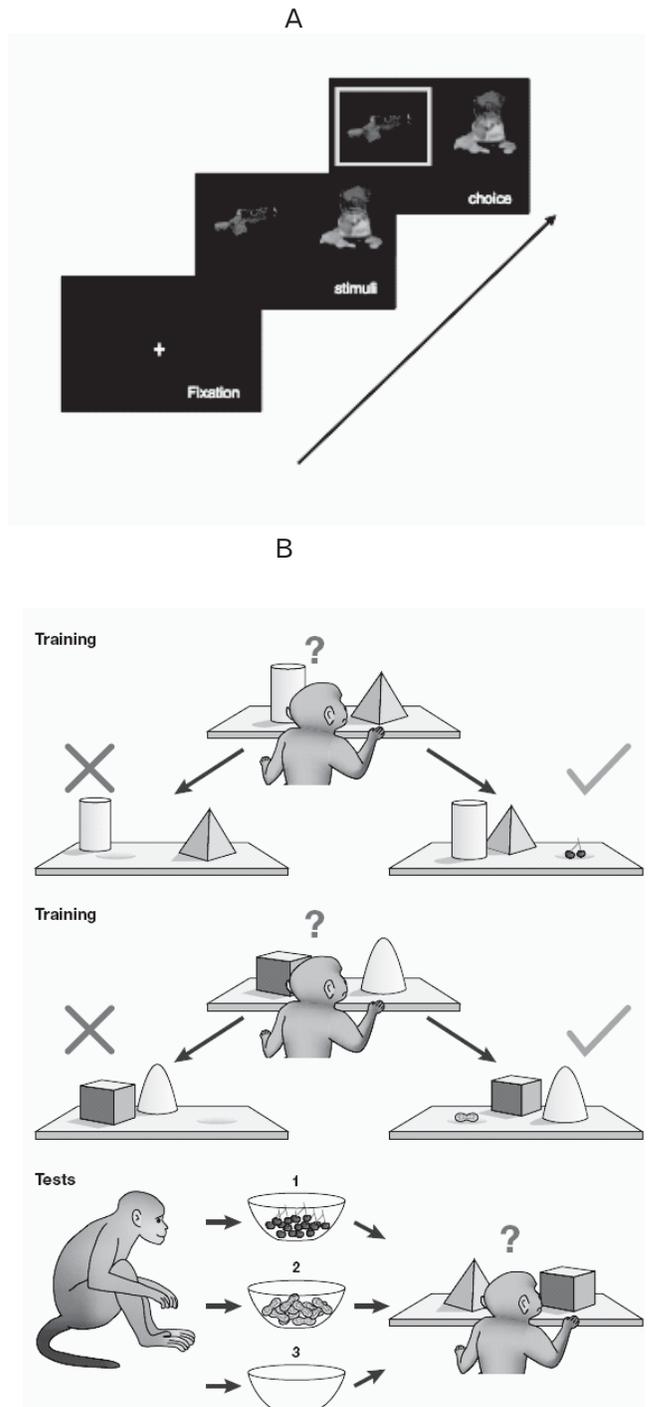

FIGURE 74.1 Examples of simple binary stimulus choice tasks. (A) Binary food choice from Karjibich, Armel, and Rangel (under review). (B) Devaluation choice task from Izquierdo, Suda, and Murray (2004). (With permission from Baxter & Murray, 2002.) (See color plate 88.)

food) or aversive (e.g., a shock). A stimulus might be paired with multiple outcomes. In the simple tasks we have described, the stimulus-outcome associations are degenerate and time-invariant probability distributions, but we need the more general notation to accommodate other tasks of

interest. For example, in reversal-learning tasks the stimulus-outcome associations change with time, and thus we have to write $p(o|s)$. Third, the mapping from stimuli to action, denoted by $a'(s)$, changes from trial to trial. As a result, there is not a fixed mapping between actions and stimuli, or actions and outcomes. This approach captures the fact that in the real world the actions required to obtain a particular stimulus often change over time. Fourth, all the actions required to make or implement the choice entail approximately the same costs to the individual. An example would be a Skinner box with two levers that have equal tension, symmetric location, and so on. The property would be violated if one of the levers is more difficult to pull. Note that in order to keep things simple we make an explicit distinction between the potential aversive outcomes associated with a stimulus (which occur at the time of outcome consumption) and the costs associated with taking the action necessary to obtain the stimulus (which occur at the time of choice).

Another important feature of the binary stimulus-choice task is previous experience consuming all the possible outcomes in all the states of the world that might be induced by the experimenter. To understand why this is important, consider the devaluation experiment depicted in figure 74.1B. Here monkeys are asked to make choices among stimuli in three different states of the world: a cherries-satiation condition, a peanut-satiation condition, and a no-satiation condition. To qualify as a simple binary stimulus-choice task, monkeys must have had extensive experience consuming the cherries and peanuts in the three states of the world prior to the actual experiment. As we will see, the choices made by the goal-directed system will depend on how it values the outcomes associated with each stimulus *given the state of the world*. If the subjects have not had experience consuming the outcomes in a particular state, they might need to learn how to evaluate them, a phenomenon that Balleine has called incentive learning (Balleine & Dickinson, 1998). This might result in unstable choices across the experiment. The simple binary stimulus-choice paradigm removes this complication by requiring that subjects have extensive prior experience with all the outcomes in all the relevant states of the world.

The other details of the task are not important and can take many different forms. For example, the stimuli could be pictures on a computer screen, or physical objects with different shape and color, or cards with printed photographs or verbal descriptions of rewards, or even real exposure to the actual outcomes. Subjects might get a reward after every decision, or might get rewarded only for a random subset of the choices that they made at the end of the trial. There are also no constraints on the actions associated with choosing a stimulus, as long as they satisfy the equal-cost property. Thus subjects might indicate their choice through an eye

movement and then get the chosen liquid delivered to their mouths, or they may indicate their choice through the act of reaching for one of the stimuli in order to consume it.

The binary stimulus-choice paradigm outlined here covers as special cases several tasks that have been used in the neuroscience and animal learning literatures. First are the type of simple binary choices described in figure 74.1A (Kable & Glimcher, 2007; Karjbich et al., under review; Padoa-Schioppa & Assad, 2006, 2008; Tom, Fox, Trepel, & Poldrack, 2007; Wallis & Miller, 2003). Second are the devaluation choice tasks described in figure 74.1B (Izquierdo, Suda, & Murray, 2004; Wellman, Gale, & Malkova, 2005). The main differences from the previous set of tasks are that subjects indicate their choice by lifting an object, instead of pressing a button or executing a saccade, and that the value of the outcomes is manipulated by feeding the subject to satiation on some of the foods. Third are reward preference tasks (Izquierdo et al.). The key difference from the previous task is that subjects are exposed to the actual rewards, instead of stimuli associated with them, and they indicate their choice by reaching for the chosen outcome. Fourth are reversal learning tasks (Hampton, Bossaerts, & O'Doherty, 2006). In a typical version of these tasks there are two stimuli and one potential outcome. In every trial the probability of obtaining the outcome is high for one of the stimuli and low for the other, and it evolves over time either through an exogenously specified process or as a function of the history of choices.

It is important to emphasize that, as general as it is, this behavioral paradigm does not cover many decision situations that have also been used in the literature to study the goal-directed system. It rules out the case of multistimulus (nonbinary) choice. It also rules out a popular odor discrimination task from the rat literature (Schoenbaum, Chiba, & Gallagher, 1998) in which rats decide whether or not to drink a liquid from a single location based on the odor that they receive in an odor port (some odors predict rewards like sugar, others punishers like quinine). Note that instead of a choice between stimuli, this task entails choice between motor plans with fixed state-dependent action-outcome relationships. More generally, the paradigm also rules out any tasks in which there is a constant mapping between actions and stimuli or outcomes at each state of the world. It also rules out instrumental paradigms in which animals engage in free rates of responding, even if they have a choice among multiple responses (Balleine & Dickinson, 1998; Dayan & Balleine, 2002). This last class of decision tasks is substantially more complicated as animals need to decide not only what to choose, but also about when to take action. In contrast, in the binary stimulus-choice paradigm the timing of decision making is controlled by the experimenter.

Multiple behavioral controllers: What is goal-directed choice?

As mentioned at the beginning of the chapter, a growing body of evidence suggests that the brain might deploy different behavioral controllers in parallel in many decision-making situations. In this section we provide a brief review of the computational differences among the three main systems that have been identified: a habitual, a goal-directed, and a Pavlovian system. For more detailed reviews see Balleine and colleagues (2008), Dayan (2008), and Rangel and colleagues (2008).

GOAL-DIRECTED SYSTEM The defining feature of the goal-directed system is that it makes choices over stimuli using model-based computations of value. These are carried out in two steps. First, a value is assigned to each stimulus by identifying the distribution of outcomes associated with it and computing the expected values of those outcomes in the current state of the world. Second, the computed values are compared in order to select one of the stimuli.

Note several key properties of this system. First, its goal is to make choices over stimuli, not actions. Second, it assigns value to stimuli by anticipating the outcomes to which they might lead and then computing their expected reward. Third, this computation is based on stimulus-outcome associations and beliefs about the reward that those outcomes are likely to generate in the current state of the world. It follows that the computation is model based (sometimes called forward looking) and is not based on the historical level of payoff generated by the different stimuli. This last property gives enormous flexibility to the system, since it allows it to rapidly update the value that it assigns to stimuli based on either a change on the stimulus-outcome associations or a change in the state of the world that affects their expected value. Fourth, this flexibility comes at the cost of computational complexity. The brain needs to store or compute stimulus-outcome associations and state-dependent value functions, and then needs to carry out expected value computations online.

HABITUAL SYSTEM The defining feature of the habit system is that it makes choices over actions based on the historical level of rewards that they have generated. This is also done in two steps. First, a value for each of the available actions is retrieved from memory. Second, the retrieved values are compared in order to select one of the stimuli.

Note several key properties of this system. First, choice is made over actions, not over stimuli. Second, the values used to make choices are retrieved from memory, not computed online. Third, the values assigned to actions depend on the level of rewards that they have generated in the past.

Multiple studies have shown that relatively simple reinforcement learning algorithms approximate well the process of value learning for this system (Montague, Dayan, & Sejnowski, 1996; Niv & Montague, 2008; Schultz, Dayan, & Montague, 1997; Sutton & Barto, 1998). Fourth, the fact that the learning can be state sensitive leads to the use of state-dependent action values by the habit system. Fifth, the computations made by the habitual system at the time of choice are simpler than those of the goal-directed system, since values are retrieved from memory instead of computed online. Sixth, this computational simplicity comes at the cost of some behavioral flexibility. Although with enough experience the habitual system is able to make optimal decisions in environments that are sufficiently stable, it cannot do so when the action-outcome contingencies are rapidly changing (as, for example, in the simple experiment described in figure 74.1A).

PAVLOVIAN SYSTEM In contrast to the previous two systems, which are able to assign values to any stimulus or action, the Pavlovian system assigns values to a small set of actions that are evolutionarily appropriate responses to particular environmental stimuli. Typical examples include preparatory behaviors (such as approaching cues that predict the delivery of food) and consummatory responses to a reward (such as pecking at a food magazine).

Although many Pavlovian behaviors are “hardwired” responses to specific predetermined stimuli, with sufficient experience animals can also learn to deploy them in response to other stimuli. For example, rats and pigeons learn to approach lights that predict the delivery of food. At first glance, Pavlovian behaviors look like automatic, stimulus-triggered responses, and not like instances of value-based choice processes. However, since Pavlovian responses can be interrupted, they must be assigned something akin to a “value” so that they can compete with the actions that are favored by the other valuation systems.

The computational and neurobiological basis of the Pavlovian system is much less well understood than that of the habitual and the goal-directed systems. For recent reviews see Dayan and Seymour (2008) and Rangel and colleagues (2008). This lack of understanding is due, in part, to the fact that there might be multiple Pavlovian controllers, some responsible for triggering outcome-specific responses (e.g., pecking at food or licking at water) and others responsible for triggering more general valence-dependent responses (e.g., approaching positive outcomes and withdrawing from negative ones). Nevertheless, since a wide range of human behaviors with important economic consequences might be controlled by the Pavlovian system (from overeating to the harvesting of immediate smaller rewards at the expense of larger delayed rewards), a detailed

understanding of this system is an important open question for neuroeconomics.

COEXISTING AND COMPETING VALUATION SYSTEMS All these behavioral controllers can potentially be active at the same time even in the case of simple binary stimulus choice. Consider, for example, the experiment in figure 74.1B. Since some of the stimuli covering the food rewards have been associated with appetitive outcomes, they might trigger Pavlovian approach responses that could influence which of the two objects the monkey lifts first. Similarly, since the execution of the choice entails two constant motor actions (reach for the left object or reach for the right object) and the monkeys receive extensive experience in the task, the habitual system might use historical action values to influence the choice that is made. Finally, the goal-directed system could also bias the monkey's actions by assigning a higher value to the actions associated with the higher-value stimulus. This possibility leads to a very important open question in neuroeconomics about which next to nothing is known: How does the brain assign control to the three different systems? Although some simple computational models have been proposed (Daw et al., 2005; Dayan, Niv, Seymour, & Daw, 2006), to date no experiments have been performed to study how the systems interact and compete at the neural level in simple binary stimulus choice.

In this review we focus on the computations of the goal-directed system during the simple binary stimulus-choice task. We do so not because the effects of the other systems in this type of situations are unimportant, but because much more is known about the role of the goal-directed system. We emphasize, however, that a full understanding of simple stimulus choice will require the study of how the other two systems are deployed in this type of task and of how the allocation of control is resolved.

Computational basis of goal-directed choice in the simple binary stimulus-choice paradigm

In this section we provide a mathematical description of the computations that the goal-directed system needs to make in simple binary stimulus-choice situations.

REPRESENTATION OF THE CHOICE PROBLEM The first problem that the system needs to solve is to identify the parameters of the decision-making problem: What are the potential stimuli that could be chosen? What are the actions required to obtain each stimulus? What external and internal state variables might affect the desirability of the different stimuli and actions? Let e be a summary of the internal and external variables determining the state of the world.

This part of the choice process is often ignored in decision-making models by implicitly assuming that the brain always computes these variables correctly. But given the complexity of the world, it is likely that the brain relies on computational shortcuts. Consider, for example, the problem of a shopper in a modern supermarket aisle that contains thousands of different products. When confronted with such complexity, the brain only evaluates and compares a small subset of the possible items. Since an item is chosen only if it is considered, the representation step has a large impact on the choice that is eventually made. Given the large number of external and internal variables that can impact the choice situation, similar issues are likely to arise in the identification of the relevant states of the world. The algorithms and neural processes at work, as well as the limitations on choice performance to which they lead, are just beginning to be understood (Reutsckaja, Pulst-Korenhberg, Nagel, Camerer, & Rangel, under review). Basic open questions include the following: How does the brain determine which actions to assign values to and which actions to ignore? Is there a limit to the number of options that animals can consider at a time? How are internal and external states computed?

STIMULUS VALUATION As we saw before, the goal-directed system makes choices by assigning values to the different stimuli based on the expected value of the outcomes associated with them. Let $V(s|e)$ denote the value of stimulus s given the state of the world e . In order to compute this value, the system needs two pieces of information: (1) the stimulus-outcome associations, which are summarized by the function $q(o|s)$ specifying the probability that every potential outcome o occurs as a function of the stimulus s , and (2) the value function $v(o|e)$ specifying the value of each outcome given the state of the world.

Note several things about this notation. First, there is a difference between the $p(o|s)$ function that describes the objective mapping between stimulus and outcomes and the $q(o|s)$ function that describes the beliefs of the subject about that relationship. Second, by assumption, the stimulus-outcome associations do not depend on the state of the world, and, for simplicity, we assume that the subjects always know this fact. Third, the value function $v(o|e)$ is the goal-directed system's belief about the reward that it will experience if the outcome occurs, which is a different signal than the level of reward that actually occurs at the time of consumption. Fourth, the value function $v(o|e)$ does not depend on the stimulus. The reason is that there is a conceptual distinction between the (positive or negative) outcomes generated by a stimulus and the costs of taking the action necessary to get that stimulus.

The value assigned to a stimulus is simply the expected value of the outcomes to which it might lead. This is given by

$$V(s|e) = \sum_{o \in O} p(o|s)v(o|e)$$

STIMULUS CHOICE The brain uses the net-value information to make a choice between the stimuli. A sizable amount of behavioral evidence suggests that the maximization process is stochastic and well approximated by a *soft-max* process in which the probability of choosing stimulus s is given by

$$\frac{e^{\tau V(s|e)}}{\sum_{t \in S} e^{\tau V(t|e)}}$$

where τ is a coefficient measuring the sensitivity of the choices to the stimulus values (when $\tau = 0$ each alternative is chosen with equal probability regardless of the values, and for sufficiently large τ almost all of the probability falls on the item with the highest value).

The soft-max model is a reduced-form model of limited use for neuroeconomics, since it describes how the probability of making a choice changes with the net values, but not how the choice is actually made. A large research effort is devoted to this problem (for recent reviews see Bogacz,

2007; Busemeyer & Johnson, 2004; Ditterich, 2006; Gold & Shadlen, 2007; Rangel, 2008). Most of the models that have been proposed are versions of a race-to-barrier diffusion process. A simple version of the model for the case of two alternatives is depicted in figure 74.2A. The model has several components. First, there are circuits that compute the value of each of the items. The value assigned to the items is assumed to fluctuate stochastically from instant to instant. Every instant, the two value signals are subtracted to produce a relative-value signal that is then fed to an integrator circuit that computes the value of item 1 minus the value of item 2, thus keeping track of the accumulated relative signal. A decision is made when this relative-value signal becomes sufficiently large (“choose item 1”) or sufficiently negative (“choose item 2”).

This class of models has several attractive features. First, they predict a logistic choice function similar to the one generated by the soft-max model. Second, they predict that the time required to make a choice should be larger when items have similar values than when the values are far apart.

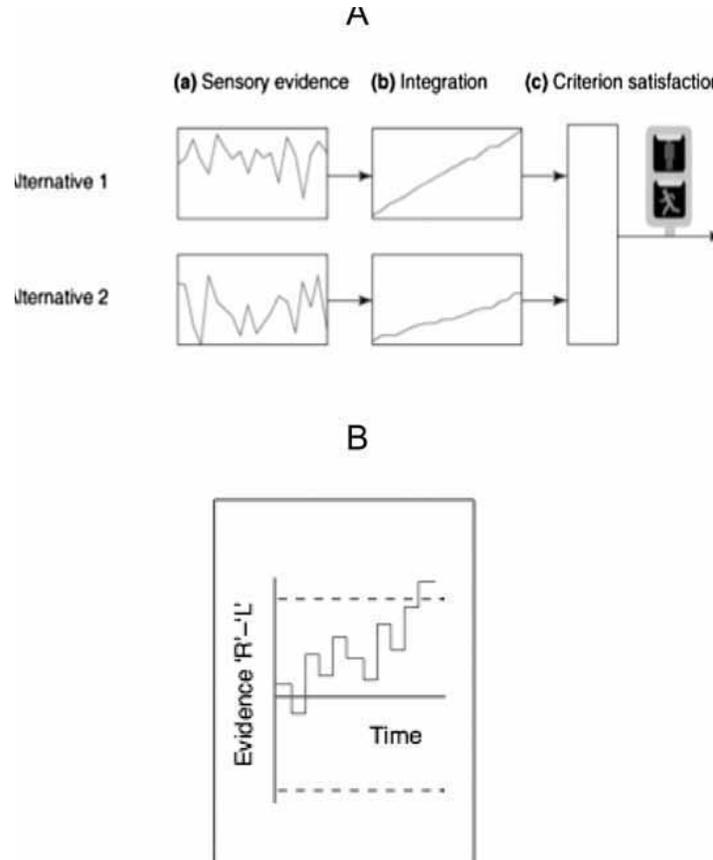

FIGURE 74.2 Models of the value comparison process. (A) Illustration of the main components of the race-to-barrier models. (Adapted with permission from Bogacz, 2007.) (B) A typical run of the random walk model. The step function represents the accumulated relative value of the “right” target. The process starts at a middle point and stops the first time this variable crosses one of the thresholds (depicted by the bracketed horizontal lines). “Right” is chosen

when it crosses the upper threshold; “left” is chosen when it crosses the lower one. Time advances in discrete steps. The size of every step is given by a Gaussian distribution with a mean that is proportional to the true direction of motion. This noise is meant to capture the variability in the valuation processes. (See color plate 89.)

Both predictions are consistent with a large body of behavioral data. Finally, the model makes useful predictions about which kind of computations should be implemented by the brain: there should be circuits computing the value of each stimulus, circuits computing relative values, an integrator circuit, and a circuit that triggers a choice when a barrier is crossed.

These models assume that a choice is first made over stimuli and that the choice is then implemented by deploying the action that leads to that stimulus. We refer to these types of models as *stimulus-based choice*. Another a priori equally plausible theory (Glimcher, Dorris, & Bayer, 2005) specifies that the brain uses the stimulus values to assign a value to every feasible action, and that it then makes the choice through a process of competition over action plans. We refer to this possibility as *action-based choice*. It is difficult to compare these two views on theoretical grounds, since the race-to-barrier models apply well to both types of choice. Thus novel experiments are needed to address this issue. The question is important because the neural systems involved in making the choice are likely to be different in the case of stimulus- and action-based choice.

LEARNING In some versions of the simple binary stimulus-choice paradigm, subjects receive an outcome after every choice. This provides them with feedback that can be used to update their estimate of the stimulus-outcome associations. Here we propose a simple algorithm that subjects can use to carry out this type of learning.

We assume that the experimental task is structured as follows. Every experimental trial t begins with the revelation of the current state of the world (e). A stimulus s^t is then chosen that leads to the set of outcomes O and a level of reward r^t .

We assume that learning takes place in two stages. In the first stage a prediction error is computed for every possible outcome in the set O . These prediction errors are given by

$$\delta^t(o) = I_o - q^t(o|s^t)$$

where I_o is an indicator function taking a value of 1 if the outcome in question occurs and a value of zero otherwise. Note that positive prediction errors measure the degree to which the occurrence of an outcome was surprising, and negative prediction errors measure the extent to which the nonoccurrence of the other outcomes was surprising. In the second stage the prediction errors are used to update the state-outcome probability function for that stimulus by

$$q^{t+1}(o|s^t) = q^t(o|s^t) + \lambda \delta^t(o)$$

where λ is a learning rate between 0 and 1 that affects the speed of learning.

Note that this formulation assumes that only the beliefs for the stimulus that was chosen are updated. This approach assumes a very strong form of discrete learning, an assumption

which is plausible in environments where there are a small number of highly dissimilar stimuli but not in domains in which “similar” stimuli have “similar” stimulus-outcome associations. In the later case, the outcome in one state can provide information about the stimulus-outcome associations for other states. The extent to which the goal-directed system engages in this type of generalization is largely unknown.

Neurobiological basis of goal-directed choice in the simple binary stimulus-choice paradigm

In this section we review some of what is known about how the brain implements the computations described in the previous section and highlight some important open questions. For alternative recent reviews see Balleine and colleagues (2008), Rangel (2008), Rangel and colleagues (2008), and Wallis (2007).

REPRESENTATION Unfortunately, next to nothing is known about this important step in the decision-making process. Open questions of particular interest include the following. How does the brain know when to activate the goal-directed evaluation and comparison circuitry? How does the brain decide which stimuli to evaluate at any given moment? Which aspects of the state of the world are measured, and how are they encoded by the goal-directed evaluation circuitry? The first question is important because organisms are exposed to potential choice stimuli continuously, but the goal-directed choice might only engage in the process of choice sporadically. The second question is important because often there are many potential stimuli and the system might not have the capacity to evaluate all of them fully. Think, for example, of a consumer in a modern supermarket aisle.

STIMULUS VALUATION Several papers have found neural correlates of the stimulus-value signal ($V(s|e)$). Plassmann, O’Doherty, and Rangel (2007) investigated the neural correlates of stimulus valuation by the goal-directed system in humans using fMRI. They showed pictures of desirable snacks to hungry subjects who had to place bids for the right to eat them at the end of the experiment. The size of the bids was a measure of the value assigned by the brain to each stimulus at the time of choice and positively correlated with BOLD activity in the mOFC and the dorsolateral prefrontal cortex (DLPFC). (For related fMRI findings see Arana et al., 2003; Erk, Spitzer, Wunderlich, Galley, & Walter, 2002; Hare, O’Doherty, Camerer, Schultz, & Rangel, 2008; Paulus & Frank, 2003; Tom et al., 2007; Valentin, Dickinson, & O’Doherty, 2007).

A related study used single-unit electrophysiology in non-human primates to look for activity in the orbitofrontal cortex that correlates with stimulus values (Padoa-Schioppa

& Assad, 2006, 2008). Every trial, thirsty animals were given a choice between two stimuli associated with small magnitudes of two different juices. After a period of deliberation, the animals indicated their choice with a left- or right-eye movement. The action associated with each stimulus varied from trial to trial. The authors estimated a logistic-choice model to compute a measure of value for each juice-amount combination that was then correlated with the neural signals. They found a large population of neurons encoding the value of the stimulus associated with each juice independently of the action that it took to get it. They did not find an equivalent population encoding the value of the actions. A closely related study recorded simultaneously from monkey OFC and DLPFC and found neurons encoding for the value of stimuli in both areas, although the value signal arose in DLPFC with a delay of approximately 100 ms (Wallis & Miller, 2003).

The previous studies looked for stimulus-value signals in the case in which animals made choices between appetitive items. An important question is whether the brain uses the same networks to evaluate stimuli associated with aversive items (e.g., choosing which of two undesirable risks to take). Plassmann, O'Doherty, and Rangel (under review) used an experimental design similar to the one we have described to study this question. Subjects were shown pictures of undesirable food items (e.g., canned vegetables) and had to bid to avoid having to eat them. The bids were a measure of the extent to which they disliked the foods. Interestingly, no areas exhibited a positive and significant correlation with this measure of stimulus value. Instead, the study found that activity in the mOFC and the DLPFC were negatively correlated with the bids. This finding suggests that these two structures play a role in the valuation of both appetitive and aversive items, in the appetitive case through increased activity and in the aversive case through decreased activity.

Interestingly, given that the $V(s|e)$ function is a forecast of the actual value of consuming the objects associated with the stimuli, activity in the OFC has also been shown to be correlated with the value of expected outcomes in the absence of choice. For example, Gottfried, O'Doherty, and Dolan (2003) presented subjects with visual stimuli that were paired with different odors and used a devaluation procedure to manipulate the value of some of the odors. Using human fMRI, they found that activity in amygdala and OFC was consistent with the encoding of the expected odor value at the time of cue presentation (prior to the actual odor delivery). (For related human fMRI studies see Gottfried, O'Doherty, & Dolan, 2002; Nobre, Coull, Frith, & Mesulam, 1999; O'Doherty, Deichmann, Critchley, & Dolan, 2002). These findings, together with the ones for goal-directed choice described previously, suggest that the OFC might be involved in the computation of different types of value signals

at different stages of the choice process and in different types of tasks.

In all the previous experiments, there were no costs associated with choosing an item. Hare and colleagues (2008) studied a simple choice paradigm in which subjects had to make a decision about whether or not to buy a food snack at a given price. In this case, acquiring the stimulus entailed a cost equal to a loss of money given by the price. Consistent with the studies described before, they found that the value of the foods correlated with activity in the medial OFC, but that the price was not encoded in this area. Instead, a "consumer surplus" signal, equal to the value of the item minus its price, was found in the central OFC. These results suggest that the medial OFC might be involved in the encoding of stimulus value but is not responsive to the costs of acquiring the item.

A difficulty in identifying areas where stimulus values might be encoded is that these signals are most likely positively correlated with other signals that are not part of the goal-directed-system valuation process. Consider several examples that have caused some confusion in the literature. First, exposure to stimuli with very positive or very negative stimulus values might induce an increase in arousal in systems associated with motor preparation. If the experimental condition only includes appetitive items, the arousal and stimulus-value signals will be perfectly correlated, and thus one might misattribute one type of signal for the other. As proposed by Roesch and Olson (2004), one way of dissociating the two signals is to include both appetitive and aversive items in the experiment: neural value signals increase linearly with stimulus value, whereas arousal signals are correlated with the absolute value of the stimulus value. Using this logic in a monkey electrophysiology experiment, Roesch and Olson found that activity in OFC reflected the stimulus value, whereas activity in premotor cortex reflected an arousal-type variable. Second, similar to the case of arousal, exposure to stimuli with very positive or very negative stimulus values might induce an overall increase in attention. Third, in many choice paradigms, goal values and reward prediction errors are positively correlated (even if the design includes both appetitive and aversive items). Hare and colleagues (2008) show that prediction errors and stimulus values can be dissociated by introducing a random monetary prize in every trial that is independent of the choices made by the subjects. Using this experimental trick, they found that BOLD activity in the medial OFC, but not ventral striatum, was correlated with the stimulus values, whereas activity in the ventral striatum was most consistent with the prediction error signal.

Why is medial OFC involved in the computation of stimulus values? Some authors have argued that this area of the prefrontal cortex might be in a unique position to integrate information about stimuli and states of the world into a value

(Schoenbaum, Roesch, & Stalnaker, 2006; Wallis, 2007). This favorable position is due to its multiple connections with limbic areas such as the thalamus, amygdala, and striatum (Carmichael & Price, 1996; Ongur & Price, 2000).

So far we have focused on the neural basis of the stimulus-value signal. This signal represents only the output of the valuation process. As described in the previous section, these values are constructed by either retrieving or computing stimulus-outcome associations [the $p(o|s)$ functions], by retrieving or computing the value associated with each of those outcomes in the current state of the world [the $v(o|e)$ function], and by integrating them into an expected value signal [the $V(s|e)$ stimulus value]. This analysis gives rise to the following important questions: How and where are the stimulus-outcome associations represented? How and where is the $v(o|e)$ valuation function represented, and how does the state of the world modulate its value? How and where are the two of them integrated into the stimulus value signal? The answers to these questions are largely unknown and constitute one of the most important open problems in neuroeconomics.

STIMULUS CHOICE Although several proposals have been made about how the brain compares options in simple stimulus-choice situations (Glimcher et al., 2005; Wallis, 2007), next to nothing is known about this is actually done. Understanding how the goal-directed systems compare the stimulus values to make a choice is another important open problem in neuroeconomics. Other open questions include the following: Does the brain make choices by implementing a race-to-barrier model? If so, is the choice made over actions or stimuli? How are the barriers chosen and implemented? How does the slope of the integrators relate to the strength of the stimulus-value signal encoded in medial OFC? Are there other inputs to the comparison process besides the medial OFC signal? How and where does the brain incorporate information about the cost of acquiring the different stimuli? How does the system go from stimulus choices to motor responses?

LEARNING There is a large literature in neuroeconomics showing that reward prediction errors are encoded in the ventral striatum in the context of Pavlovian (nonchoice) and habitual choice paradigms (for a comprehensive review see Niv & Montague, 2008). Unfortunately, this literature is not very informative about the learning that takes place in the goal-directed system during the simple stimulus-choice task. The reason is that the prediction errors required here measure how surprising the occurrence of individual outcomes is, as opposed to prediction errors of reward that measure the amount of unexpected reward received at the time of consumption. These are two very different types of learning and are likely to be implemented by different

networks. Understanding the computational and neurobiological basis of how the goal-directed system learns stimulus-outcome associations is another important open question for neuroeconomics.

Conclusions

The goal-directed system provides organisms with a flexible and adaptive tool to make decisions. This is based on its ability to assign values to stimuli based on beliefs about the outcomes that they are likely to generate and the value of those outcomes in the current state of the world. The system might be particularly powerful through its interactions with other higher cognitive processes that might allow it to use analytical and memory processes to improve its characterization of the stimulus-outcome associations. Given that the system is thought to play a large role in human decision making, understanding its computational and neurobiological basis is central to understanding the essence of human nature.

This review has emphasized the use of simple mathematical models to describe the computations that the goal-directed system needs to carry out in order to make a choice. These models are useful because they lay down precise descriptions of the computational nature of the problem (“what needs to be encoded”) and guide the search for the neural instantiation of the process at work. We believe that the use of these types of models is critical to the rapid advancement of the field.

75 Neuroeconomics and the Study of Valuation

PAUL W. GLIMCHER

ABSTRACT Just over a decade ago neurobiologists knew almost nothing about the neural mechanisms of voluntary choice. In contrast, economists and psychologists working at that time had well-developed frameworks for describing the many hidden processes that must underlie choice, but these frameworks had very little impact in neurobiological circles. The last decade, however, has seen a revolution in the neurobiological understanding of choice that has been driven by an integration of economics and psychology into mainstream neuroscience. Today, the basic outlines of the primate system for decision making are emerging from studies on humans and monkeys that rely on techniques ranging from single-neuron electrophysiology to functional magnetic resonance imaging (fMRI). Indeed, since the last edition of this book was published a new field for the study of decision making has emerged, *neuroeconomics*, and an edited volume has been published that surveys the field (Glimcher, Camerer, Fehr, & Poldrack, 2008). This chapter provides an outline of the primate mechanism for choice as we understand it today. In broad strokes, we now believe that choice involves a two-stage neural process. The first stage, largely resident in the frontal cortex and the basal ganglia, learns and represents the value of our actions. The second stage, largely resident in a frontoparietal network, selects the option that has the highest subjective value from among the options before us at any moment in time.

Introduction

Our existing data now suggest that when we make a choice we employ a two-step neurobiological process with some remarkable similarities to both psychological and economic process models of decision making. The first step in the neurobiological processes that guide decision making places idiosyncratic valuations on the options before a chooser. These valuations involve the activation of many frontocortical and basal ganglia circuits. The second step chooses, based on those valuations, a single action for execution. Although less well understood than the valuation processes, these choice processes involve both frontal and parietal circuits. What follows is an overview of the valuation and choice mechanisms as they are understood today. Without a doubt, this understanding is fragmentary, and some of the conclusions drawn here will be somewhat controversial, but the

PAUL W. GLIMCHER Professor of Neural Science, Economics, and Psychology; Director, Center for Neuroeconomics; New York University, New York, New York

presentation captures the state of the field today and suggests just how much has been accomplished since the third edition of this volume was published only five years ago.

The two-stage model

The neurobiological evidence for a two-stage model emerged initially from studies of decision making in awake behaving monkeys conducted throughout the 1990s by two groups of researchers. The first of these groups was concerned with understanding how animals engaged in traditional psychophysical tasks that required the evaluation of visual stimuli reached a perceptual decision (Newsome, Britten, Salzman, & Movshon, 1990; Gold & Shadlen, 2007). The second emerged from the study of movement control and was concerned with understanding how changes in the magnitude or probability of reward influenced decision making (Platt & Glimcher, 1999; Glimcher, 2002). Both groups converged, however, to the view that neurons of the posterior parietal cortex participated in the actual process of deciding (selecting one action from a finite set of alternatives) and that these neurons received inputs that encoded something about the magnitude or likelihood of future rewards (associated with each of those alternatives) that originated from signals generated elsewhere in the brain.

In Platt and Glimcher's (1999) study, the authors recorded from neurons in the posterior parietal cortex while thirsty monkeys participated in a simple forced-choice task. In that task, monkeys fixated a central yellow target while two eccentric visual stimuli (one red and one green) were coilluminated (figure 75.1). One of those targets was located within the response field of a parietal neuron under study. After a brief delay, the central target then switched color to either red or green, indicating which of the two eccentric stimuli the animal should fixate in order to receive a reward. What the authors varied, across blocks of about 100 trials, was either the magnitude of reward associated with each of the targets or the probability that the fixation target would turn red. They found that, *immediately after target onset*, if the magnitude of reward associated with the target inside the response field was increased, the firing rates of neurons encoding an eye movement to that target increased at the very beginning of

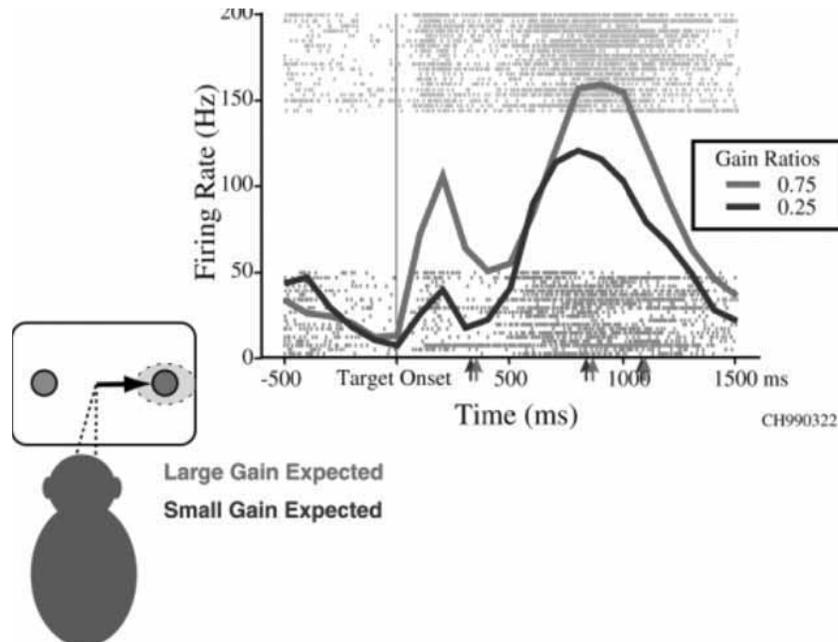

FIGURE 75.1 Same movement, different values. (From Glimcher, 2003.) (See color plate 90.)

the trial. They also showed that if the probability that an eye movement toward the response field would be reinforced was high, the units responded more strongly than if a movement toward that target was unlikely to yield a reward. *Immediately before eye movement onset*, however, the neuronal firing rate indicated whether or not the animal had chosen to produce the saccade encoded by that neuron.

In interpreting this result, they noted that all economic theories of choice predict that valuation should always be influenced by both the probability and the magnitude of reward. This theory suggested that the early activity observed in these neurons might well encode the subjective value of the eye movements to the monkeys. The late activity, in contrast, appeared to encode choice, the output of an operation performed on the set of eye movements available to the animal. The suggestion, then, was that the inputs to these parietal circuits might well encode an idiosyncratic subjective valuation of the kind described by economic theories of choice and that parietal (and related extraparietal) circuits might use these valuation inputs as part of a winner-take-all computation to choose actions for execution.

At the same time that these studies were being conducted, a number of lines of evidence began to suggest that portions of the striatum and the frontal cortex both learn and represent the values of goods and actions—a finding suggesting that these areas might serve as the source of the valuation signals identified in parietal cortex. The critical first step toward this realization was the identification of reinforcement learning mechanisms in the forebrain, and it is an understanding of these learning mechanisms that has paved the way toward a broader understanding of valuation. In the

early 1990s, Wolfram Schultz and his colleagues (e.g., Romo & Schultz, 1990; Schultz & Romo, 1990; Schultz, Apicella, & Ljungberg, 1993) demonstrated that midbrain dopaminergic neurons encode a *reward prediction error*. Montague, Dayan, and Sejnowski (1996) provided the next step when they recognized that this class of signal could be employed to construct a mechanism that learns, through trial and error, the values of actions or objects that could be used to guide choice. What followed were 10 years of work that established the existence of at least three interrelated subsystems in these brain areas that employ distinct mechanisms for learning and representing value and that interact to produce the valuations that guide choice (Dayan & Balleine, 2002; Balleine, Daw, & O'Doherty, 2008; Niv & Montague, 2008).

In a similar way, studies of the movement control systems of the brain strengthened the conviction of many that a discrete choice mechanism used these valuation signals to select and execute actions. Our current evidence indicates that the choice system involves large portions of the parietal cortex, among other areas. These parietal areas receive both direct and indirect projections from the valuation areas and project directly to the movement control areas. One issue that remains unclear, however, is how much of the frontal cortex and basal ganglia participate directly in the choice process with these parietal areas. We now know that specific neurons in the orbitofrontal cortex (Padoa-Schioppa & Assad, 2006, 2008) and the dorsal striatum (Samejima, Ueda, Doya, & Kimura, 2005; Lau & Glimcher, 2008) of the monkey also represent goods and actions that have been chosen before these choices are executed, but whether these neurons participate directly in choice is not known at this time.

This then, is a minimal working outline of the primate choice system: A valuation system that learns through repeated sampling of the environment and stores the values of actions and/or goods; a choice system that uses these values to select an action for execution; and a motor control system that executes the physical responses dictated by the choice. Of course, future experiments will enrich this description; for example, it may well be the case that perceptual systems influence the valuation systems in ways that we are just beginning to understand, but these seem to be the fundamental components of the primate architecture for choice as we understand it today.

The basic structure of the valuation system

The critical breakthrough that allowed modern studies of valuation to crystallize were insights into the function of the midbrain dopaminergic pathways. In 1993, Schultz and colleagues measured the spiking activity of single dopamine neurons while monkeys passively received rewards during a classical conditioning task. They found that *unconditioned* rewards produced a strong response in these neurons while conditioned rewards did not. This was an important finding because it revealed that the activity of dopamine neurons *could not* simply code hedonic experience but rather appeared to encode something more closely related to learning itself. This revelation led Montague, Dayan, and Sejnowski (1996) to propose that dopamine neurons encoded the difference between expected and obtained rewards: the *reward prediction error* of reinforcement learning theory. The critical idea that emerged over the next several years was that dopamine spike rates communicated to frontocortical and striatal circuits the degree to which rewards actually obtained by the subject matched previously learned predictions of reward magnitude. This explained why dopamine neurons responded to unconditioned rewards (which the animals did not expect) while remaining silent when animals received conditioned rewards (which the animals expected).

More formally, what these studies suggested was that dopamine neurons coded a term from reinforcement learning theory that had been previously developed within psychological circles. In 1972, Rescorla and Wagner had proposed that the associative strength between a stimulus and a reward during classical conditioning could be described by the rule

$$AssStr_{new} = AssStr_{old} + \alpha(Reward - AssStr_{old})$$

where *AssStr*, or “associative strength,” is thus incremented (or decremented) by the difference between the reward obtained and the reward expected (the *old* associative strength) until the prediction matches the experience and learning is thus complete. In this formulation, α is a number between 0 and 1 that controls how gradually learning shifts the predic-

tion across trials from old values to new values. (In fairness, this is not exactly the form in which Rescorla and Wagner made their proposal. Their proposal employed an additional term associated with stimulus salience and also made predictions about how two stimuli competed to predict a single reward. The form shown here is much closer to a model originally proposed in 1951 by Bush and Mosteller that served as the basis of Rescorla and Wagner’s later model.)

Subsequent studies of the dopamine neurons and many of their targets have largely validated this early conclusion of Montague’s and extended these insights into the domain of operant conditioning in animals. In 1992, Schultz and his colleagues (Ljungberg, Apicella, & Schultz, 1992) showed, for example, that even in a classical conditioning task dopamine neurons encoded a signal that closely paralleled the reward prediction error term of theory. Subsequent studies using more sophisticated computational methods (Bayer & Glimcher, 2005; Morris, Nevet, Arkadir, Vaadia, & Bergman, 2006) have also validated this hypothesis. Together, these data demonstrate unequivocally that dopamine neurons carry a signal to the striatum and frontal cortices that is sufficient to account for how animals learn the values of their actions, clear evidence that a valuation signal of some kind could be constructed and stored in these areas (or their targets) within the brains of monkeys.

Fortunately, there is also clear evidence that these dopaminergic neurons behave in the same manner in humans as they do in monkeys. Like other mammals, humans find dopaminergic drugs reinforcing. Like other mammals, humans have these same dopaminergic pathways. Like other mammals, dopaminergic drugs can be shown to bind to receptors in the terminal fields of these neurons. But the best evidence for the notion that a circumscribed learning-based valuation system associated with dopamine occurs in humans comes from fMRI studies of humans engaged in learning about rewards. In 2002, two groups (O’Doherty, Deichmann, Critchley, & Dolan, 2002; Pagnoni, Zink, Montague, & Berns, 2002) demonstrated simultaneously that activity in the dopaminergic terminal fields of the striatum and the frontal cortex during both gustatory and monetary reward tasks behaved exactly as predicted. This result indicated that there existed dopaminergic signals appropriate for value learning in humans.

Contemporary studies of these neurons continue to extend and refine these conclusions in important ways. We now have reason to believe that the actual algorithm computed by the dopamine neurons or their sources is a more refined version of the Rescorla and Wagner model known as the *temporal difference model* (Sutton & Barto, 1998). This model explains not just how expected rewards are encoded, but how a dopamine-based system could develop associations between stimuli and rewards that are separated in time. The temporal difference model, like the dopamine neurons, is able to connect the ringing of a bell with a food reward

that follows it seconds later (Schultz et al., 1993). This is an important advance, but one that lies beyond the scope of this brief review.

What remains, then, is to understand where and how these dopamine activations are used to mechanistically compute and store the values of actions. Two lines of evidence contribute to our contemporary understanding of these issues: neuronal recording studies in animals and fMRI studies in humans. The recording studies in animals have now established that the basal ganglia (and in particular the striatum) contain essentially all of the computational elements required for the execution of reinforcement learning (or more precisely *temporal difference* learning) algorithms. There are, for example, neurons within the basal ganglia that encode the magnitude of reward that an animal expects to receive for producing a particular behavioral action (Hikosaka, Takikawa, & Kawagoe, 2000; Samejima et al., 2005; Lau & Glimcher, 2008), neurons that encode the actions that have just been executed (Samejima et al.; Lau & Glimcher, 2007), and neurons with firing rates dependent on the current state of the environment (Hikosaka, 2007), among other things. These neurons are located in the striatum and project out of the basal ganglia largely through the ventrolateral nucleus of the thalamus, which projects in turn back to the frontal cortex. Single-unit recording studies in the frontal cortex have also demonstrated the existence of neurons that encode values, but this time the values of goods, not of actions (Padoa-Schioppa & Assad, 2006, 2008). Functional MRI studies in humans tell a similar story (Knutson, Westdorp, Kaiser, & Hommer, 2000; Knutson, Taylor, Kaufman, Peterson, & Glover, 2005; O'Doherty et al., 2002; O'Doherty, Buchanan, Seymour, & Dolan, 2006), suggesting that frontal and basal ganglia circuits form the core of the human mechanism for learning and representing value.

There is, however, evidence for other learning mechanisms in these same structures that interact with this well-studied Rescorla-Wagner-style learning mechanism. The details of these other learning systems are still being worked out, but in essence these studies suggest that a set of mechanisms, most if not all interacting with dopamine, provide tools for learning and representing value in the frontal cortex and the basal ganglia (Balleine et al., 2008).

For neuroeconomists, these studies constitute overwhelming evidence that a value system exists and can be functionally localized. Where, then, is the final point of convergence at which these values that guide choice, likely computed by several interaction neural circuits organized around the frontal cortex and the basal ganglia to the choice system, are acted on by the choice system that guides action?

One way to begin to answer this question is to look at the existing fMRI data and to ask, Are there a small number of areas that are actively correlated with subjective value under essentially all reward and choice conditions that have ever

been studied? Perhaps surprisingly, the answer to this question seems to be yes. The ventral striatum and the medial prefrontal cortex show up in dozens of studies under essentially all choice conditions as coding something like the values we infer humans and animals place on their own actions.

Activity in the ventral striatum has been shown to be correlated with both rewards and punishments (Delgado, Nystrom, Fissell, Noll, & Fiez, 2000), the magnitude of cumulative rewards (Elliot, Friston, & Dolan, 2000), the anticipation of reward (Knutson et al., 2000; Knutson, Fong, Bennett, Adams, & Hommer, 2003), the expectation of monetary reward (Breiter, Aharon, Kahneman, Dale, & Shizgal, 2001), the expectation of primary rewards (O'Doherty et al., 2002), the receipt of monetary rewards (Elliott, Newman, Longe, & Deakin, 2003), monetary expected values (Knutson, 2005), behavioral preference rankings among rewards (O'Doherty et al., 2006), potential gain magnitude and loss magnitude as scaled by subject-specific levels of loss aversion (Tom, Fox, Trepel, & Poldrack, 2007), and discounted reward value at delays ranging from minutes to six months (Kable & Glimcher, 2007). Single-unit recording studies in the dorsal striata of monkeys, both in the caudate (Lau & Glimcher, 2007) and the putamen (Samejima et al., 2005), tell a similar story. Neurons that clearly code action values have been identified in these areas. All these data suggest that whenever rewards are received or preferences are expressed, activity in the ventral striatum encodes the magnitudes of those rewards or preferences.

A similar correlation seems to hold in the medial prefrontal cortex. Activity in this area has been shown to be correlated with monetary reward magnitude (Knutson et al., 2001, 2003), preference ordering among primary rewards (McClure, Li, et al., 2004), the expected value of a lottery (Knutson et al., 2005), the subject-specific valuation of gains and losses (Tom et al., 2007), subject-specific discounted reward value (Kable & Glimcher, 2007), and willingness to pay (Plassmann, O'Doherty, & Rangel, 2007). Activity in this area appears to be correlated with valuation under all these conditions. These data have led to the proposal that mean activity in the medial prefrontal cortex and the ventral striatum serves as a final common path for encoding the values of actions (Glimcher, Dorris, & Bayer, 2005).

It should be noted, however, that this conclusion remains somewhat controversial. An alternative hypothesis active in the literature proposes that the valuations we infer from behavior reflect the interaction of two or more largely independent neural systems that compete to govern behavior, the so-called *multiple-self* models. These models typically propose the existence of two largely independent decision-making systems: one associated with so-called *limbic* areas of the brain and the other with so-called *rational* areas of the brain. While tremendously interesting from an economic point of view,

these models are, for the most part, at variance with most of the existing corpus of neurobiological data. Still, it is germane to ask whether the existing evidence supports a two-agent model of decision making of the type proposed by Laibson and colleagues (e.g., Laibson, 1997; McClure, Laibson, Loewenstein, & Cohen, 2004). In that model, it is argued that the basal ganglia and medial prefrontal cortex form an emotional decision-making module that interacts (additively) with a second system organized around posterior parietal cortex and the dorsolateral prefrontal cortex, which form a rational decision-making module. Anatomical considerations that weigh against this hypothesis aside, we must ask whether or not there is compelling evidence that the division of brain areas into *competing* emotional and rational subgroups can be supported by the available data. In monkeys it has now been conclusively shown that activity in the posterior parietal cortex predicts preferences under all conditions that have been studied: for immediate rewards and for delayed rewards (Janssen & Shadlen, 2005; Louie & Glimcher, 2006), for large rewards and for small rewards (Platt & Glimcher, 1999; Dorris & Glimcher, 2004), for high-probability and low-probability rewards (Shadlen & Newsome, 1996; Platt & Glimcher, 1999). The data from animals seem to be unambiguous—lateral interparietal area (LIP) activity predicts choices for both rational and emotional decision making. To take another example, let us turn to the basal ganglia. This is an area a number of neuroeconomists have argued is associated with emotional decision making, but there is almost no evidence for this claim. Diseases of the basal ganglia are only very weakly associated with emotional dysfunction. The many dopaminergic forms of learning described here, although largely mediated by the basal ganglia, do not seem to capture any clear notion of emotionality. A similar case can be made for studies of the medial prefrontal cortex. As noted previously, there is evidence that this structure encodes monetary and primary rewards, preference, expected values, and gains and losses, and at least one study reports that it encodes long-delayed monetary gains. Together, these data paint a picture of structures globally involved in valuation driven by all mental states—not a structure driven exclusively by immediacy, fear, or emotionality.

In summary then, our available evidence seems to suggest that existing multiple-self models are largely unsupported by the bulk of our existing data. Of course, emotions influence decision making, and choosers show varying levels of self-control; those conclusions are beyond doubt. The question is, How do neural circuits related to emotions influence decision making? The amygdala, to take one example, may provide an answer. The amygdala projects strongly to the ventral striatum, and there is physiological and anatomical evidence that activity in the amygdala strongly influences activity in the ventral striatum. That evidence argues that the amygdala, and thus perhaps the emotions to which it

is related, can influence valuation-related activity in this area. But it does not make a compelling case for a Freudian multiple-self model of neural decision making.

Choice

Unlike valuation, which has been extensively studied in both humans and other animals, choice has been the subject of study principally in awake behaving monkeys in neuroscience. That emphasis may reflect the fact that the temporal dynamics of choice make it difficult to study with fMRI. In any case, an understanding of choice requires an understanding of existing work in nonhuman primates.

Initial studies of choice in monkeys evolved almost simultaneously from studies of sensory-perceptual systems (e.g., Newsome, Britten, & Movshin, 1989) and movement-control studies (e.g., Glimcher & Sparks, 1992), as noted earlier. The most important of these studies examined how monkeys used noisy visual-sensory signals to identify one of two orienting eye movements, or saccades, as reinforced. They did so by leveraging an extensive preexisting literature on the structure of the visual and eye movement systems to search for the decision-making circuits that connected them in these tasks (Glimcher, 2003). Subsequent work has generalized many, but not all, of these findings to arm movement control systems and to studies of humans.

We have to begin, therefore, with a review of the basic structure of the saccadic control system (figure 75.2). The LIP in the posterior parietal cortex is one of the critical elements in this system, and it consists of a roughly topographic map both of objects in the visual world and the eye movements that would be required to align gaze with those objects (for a review see Glimcher, 2003). Thus a particular location on the map (or more precisely the neurons on the map at that location) activates when a visual stimulus appears 10 degrees to the right of fixation, *and* that region might become particularly active milliseconds before an eye movement that shifts gaze 10 degrees. This area, in turn, projects both to the frontal eye fields and the midbrain superior colliculus, two additional topographic maps that are broadly similar in function. The frontal eye fields project, as well, to the superior colliculus directly. A final note is that many of these areas are reciprocally connected (for a review of this anatomy, see Platt, Lau, & Glimcher, 2003), a fact which is probably important for understanding choice. Finally, the colliculus is connected to brain stem circuits that actually govern eye movements in real time. The connection between these brain stem systems and the colliculus are mediated by a class of collicular neurons called *burst neurons*. Burst neurons have the interesting biophysical property that they can fire action potentials in either of two states: a continuous low-frequency state in which many different firing rates are observed, and a burst state characterized by a fixed and extremely high firing rate.

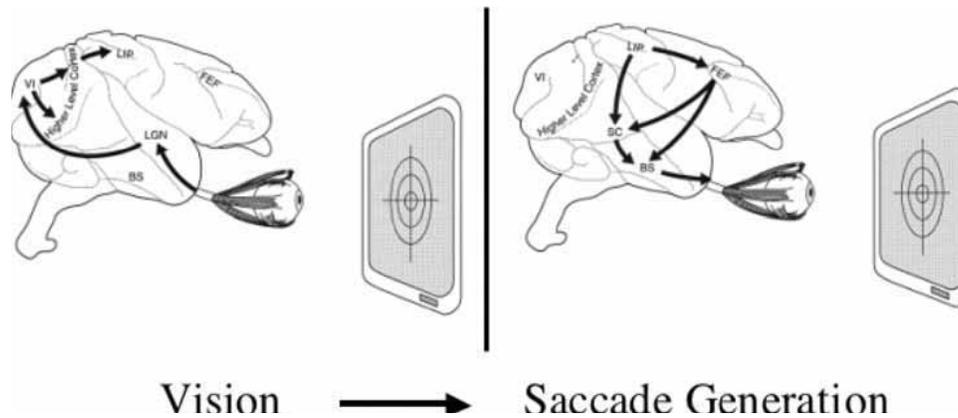

FIGURE 75.2 Saccadic control system: The visual-saccadic brain.

It is widely assumed that actual generation of a movement involves driving the collicular burst neurons above a specific firing-rate threshold, after which a burst occurs that is self-perpetuating and persists until the movement is complete. Inhibitory interconnections in the collicular map seem to preclude burstlike activity occurring at more than one location at a time, suggesting that the collicular architecture allows only a single movement to be executed at a time. Studies in area LIP, the frontal eye fields (FEF), and the superior colliculus (SC) all indicate that low-frequency firing in all three areas is related to the probability that a movement will be executed by the animal. To be more specific, if a particular movement is likely to yield a reward, then activity in all three maps at the locations associated with that movement is elevated. Of these three maps, the one that has been most studied with regard to decision is LIP. In LIP it has been shown that if the magnitude of a reward or the likelihood of a reward is systematically manipulated, then firing rates in these areas are a roughly linear function of those variables under many conditions (Dorris & Glimcher, 2004; Gold & Shadlen, 2007).

Together, these data suggest the following model for eye movement generation. At any moment in time neurons in LIP represent the instantaneous subjective value of each movement in the saccadic repertoire. Movements that have nonzero values are thus each represented by local activity on the map. One might even hypothesize that the representation of subjective value localized in the medial prefrontal cortex and the ventral striatum serves as the initial source of this signal.

In summary then, the available data suggest that all three of these areas, LIP, FEF, and SC, carry signals encoding subjective value and that movements occur when activity associated with one of the positively valued options drives its associated collicular neurons into their burst mode. A tremendous amount of work (reviewed in Glimcher, 2003; Gold & Shadlen, 2007) has examined this process of movement triggering under conditions in which animals are instructed

to make movements as quickly as possible. Less is known about how movement selection is triggered in non-reaction-time settings. One important possibility is that an input to one or more of these areas alters the inhibitory interactions within the map, forcing convergence to a single action.

The basic model proposed for selecting eye movements is thus that signals encoding subjective value project to these areas, probably through LIP. These signals propagate recursively through these networks while reflecting value inputs that may be entering the maps at many locations. An external signal then permits, or forces, convergence of the network to a single choice that occurs when the collicular neurons are driven above their burst threshold.

Two questions, however, immediately arise: How does this system achieve choice among more abstract objects that do not have specific movements associated with them? Does this model generalize to humans and non-eye-movement conditions? A limited amount of data exist that do suggest that this general class of system operates under conditions in which choices are made between more abstract objects. Gold and Shadlen (2000; see also Sugrue, Corrado, & Newsome, 2004), for example, demonstrated that when animals must choose between red and green targets that constantly interchange locations, activity in the superior colliculus reflects the instantaneous mapping between color and value even if this changes from trial to trial. This finding clearly indicates that the saccadic choice circuit has access to instantaneous mapping information relating abstract properties to actions. It cannot tell us, however, how choice is accomplished (or if it can be accomplished) in the absence of any mapping to motor circuitry of any kind.

We do, however, have some interesting hints that these choice circuits are interconnected with important valuation areas in the frontal cortex and basal ganglia. Padoa-Schioppa and Assad (2006), for example, have demonstrated the existence of neurons in the orbitofrontal cortex that encode an animal's choice before the movement expressing that choice is executed. In a similar way, Lau and Glimcher (2008) have

observed choice neurons in the dorsal striatum. At the very least, this finding suggests that the choice circuit can send information about decisions frontally, but it may also indicate that these areas participate directly in the convergence process by which choice is accomplished.

The question of whether these circuits that have been so well studied in monkeys can be generalized to other classes of movements and other species is one about which we have much less information. We do know that adjacent to area LIP are areas specialized for arm, hand, and face movements. Standard theories (Andersen & Buneo, 2002) suggest that a group of areas lining the intraparietal sulcus serve as movement control interfaces for all of the body although there are problems still being resolved with those hypotheses (cf. Levy, Schluppeck, Heeger, & Glimcher, 2007). But it does seem clear that the general theories of eye movement control advanced for the monkey do have analogs in the skeletomuscular system. Further, injuries to any of these systems in either humans or monkeys lead to permanent deficits not in the musculature but in the ability to produce movements. Finally, a small number of fMRI studies have shown value-related signals in the posterior parietal cortex, although these signals are almost always of weaker magnitude than in more frontal areas. This result of course raises the possibility that the weaker fMRI signal reflects the temporal dynamics of choice. Because subjective value is only represented until a decision is made, in these areas the magnitude of the subjective value signal, integrated over an entire trial, may be much less than in areas located more frontally where subjective value is represented throughout a trial.

Summary

What emerges from a review of the available human and animal data on decision making is evidence of a two-stage model for choice. The first, or valuation, stage learns and represents the values of both actions and goods. Within this stage at least three learning mechanisms distributed in the basal ganglia and frontal cortex contribute to the construction of what we refer to as *subjective value*. These areas are hypothesized to learn subjective values, at a biophysical level, through the well-studied process of synaptic plasticity. These learning processes operate both during choice and during the passive receipt of rewards, effecting a disassociation between choice and valuation. A network, which includes the posterior parietal cortex and a number of movement-related areas subsequent to it in the motor control stream, appears to perform a winner-take-all operation on these values that accomplishes choice itself. Let me stress that the winner-take-all choice operation must be broadly distributed and involves structures that range from the superior colliculus to the orbitofrontal cortex.

Of particular interest are several features of the model that remain unspecified. While there are many candidate pathways by which information from the medial prefrontal cortex and the ventral striatum may influence activity in the posterior parietal cortex, which of these pathways is critical for choice has not yet been determined. We also have only limited information about the systems that “decide to choose.” In some tasks, animals have to be trained to make a choice as soon as possible, and under these conditions one can observe the parietal and frontal networks converging rapidly toward choice. In other situations, however, the time courses of valuation and choice are separable. This possibility suggests the existence of a circuit that can essentially force the parietal networks toward convergence, the circuits that “decide to choose.” Such circuits almost necessarily involve cortical networks of inhibitory connections, but the features of this process that decides when to choose remain completely absent from our standard model.

Over the course of the past decade a remarkable amount of progress has been made in identifying the basic features of the primate mechanism for choice. While many critical questions remain, progress in the last decade has marked this as an exciting and innovative area in cognitive neuroscience.

76 Emotion and Decision Making

ELIZABETH A. PHELPS AND MAURICIO R. DELGADO

ABSTRACT The traditional characterization of emotion and decision making suggests that there are two opposing forces that can underlie choices: emotion, described as irrational and spontaneous, and reason, which is logical and deliberative. Although this dual-process approach is intuitively appealing, it fails to capture both the complexity of emotion and the diverse impact it has on decision processes. In this chapter, we highlight an integrative approach to understanding the relation between emotion and decision making. First, we review how two brain regions typically linked to decision making and emotion, the striatum and amygdala, both play roles in mediating value, learning, and action. Second, we review initial neuroeconomic studies that measure or manipulate specific emotion variables and examine their impact on decisions. Given that the purpose of emotion is to highlight what is relevant and important, it is not surprising that it should have a broad and critical role in decision making. However, research on the complex interaction of emotion and decision making is only beginning to emerge in neuroeconomics.

Historically, philosophical and scientific explorations of the relation between emotions and decisions have often described emotion as one system that may drive choices in contrast to reason (Dalglish & Power, 1999). The notion that there are two opposing forces that can underlie choice behavior, with emotion being irrational and spontaneous, and reason logical and deliberative, has seeped into early research on neuroeconomics (e.g., Cohen, 2005). However, in spite of the intuitive appeal of this dual-systems approach, an initial examination of the neural circuitry of emotion and decision making reveals that choices are not so clearly “led by our heart or head.” Rather, emotion is a nuanced concept that is composed of a number of overlapping and discrete processes (e.g., Scherer, 2005) that are not represented by a single neural system (LeDoux, 2000; Dalglish, 2004). At the same time, several factors, representations, and neural systems can drive decisions (see chapter 74 by Rangel and chapter 75 by Glimcher, this volume), and an understanding of how these might interact with different components of emotion is only starting to emerge.

Aside from the folk psychological concept of emotion and reason as opposing forces in decisions, there are several other factors that have led to the slow development of an

integrated understanding of the role of emotion in decision making and its underlying neural representation. First, decision science, adopting approaches from economics, has primarily investigated reward as the determinant of value in driving choice behavior. This emphasis has led to investigations of the neural systems of reward, as coded by dopamine. In cognitive neuroscience, this research has often emphasized the role of the striatum. In contrast, cognitive neuroscience research of emotion has been dominated by investigations of negative affect, specifically fear, perhaps because the characteristic physiological patterns of fear are relatively easy to investigate across species (Phelps, 2006). This research has focused on the role of the amygdala and classical fear conditioning, in which aversive values are learned, but are not tied to an action or choice (see LeDoux, this volume). Of course, choices are clearly driven by both appetitive and aversive values, and decision science will need to consider multiple reinforcer types to fully characterize decision making. Only by integrating research across the traditional disciplines of decision making and emotional learning can we begin to understand the complex relation between decisions and emotion. In the first part of this chapter, we will review the roles of the striatum and the amygdala in emotional learning, the coding of affective value, and the link to action.

A second factor that is only beginning to be addressed in studies of emotion and decision making is the complex conceptualization, organization, and measurement of emotion. Affective theorists and scientists recognize that emotion is not a unitary concept, but rather represents a class of processes, all of which are designed to signal the relevance or importance of events, situations, or information (e.g., Scherer, 2005). Although our ability to manipulate and measure emotion in the laboratory may not fully capture the range of factors outlined in theories of emotion, the suggestion that emotion has a single influence on decision making is quickly being revised (see Phelps, 2008, for a review). Along with this growing recognition of the complex psychological characterizations of emotion, affective neuroscientists have abandoned the idea that there is a single emotion “system” in the brain. This concept is the principle underlying the limbic system, which suggested that emotion is represented by a network of interacting neural structures (see Kotter & Meyer, 1992). However, in spite of years of investigations, there have yet to be definitive criteria for

ELIZABETH A. PHELPS Department of Psychology and Neural Science, New York University, New York, New York
MAURICIO R. DELGADO Department of Psychology, Rutgers University, Newark, New Jersey

inclusion in the limbic system (Kötter & Meyer, 1992), and the term has become more descriptively useful than scientifically informative (LeDoux, 2000). As a result, many affective neuroscientists have suggested that the limbic concept be abandoned, as it represents a simple but inaccurate view of emotion and the brain that might actually impede scientific progress as we try to uncover the complex neural representation of emotion (LeDoux, 2000; Phelps, 2008). In the second part of this chapter, we will briefly survey some initial findings from neuroeconomic research that have attempted to examine the complexity of emotion and isolate specific emotion variables and their influence on decisions.

The striatum and amygdala: Value, learning, and action

STRIATUM OVERVIEW Based on its connectivity and functional heterogeneity, the striatum—the primary input structure of the basal ganglia—is centrally located to influence motivated or goal-directed behavior. The striatum receives convergent projections from the prefrontal cortex, along with afferents from various other key regions implicated in emotion such as the amygdala and the midbrain dopaminergic centers, projecting back to the cortex by way of the thalamus (Alexander & Crutcher, 1990; Graybiel, Aosaki, Flaherty, & Kimmura, 1994; Middleton & Strick, 1997; Graybiel, 2000). The striatum is anatomically divided into dorsal and ventral striatum in both rodents and primates (Lynd Balta & Haber, 1994; Gerfen & Wilson, 1996; Voorn, Vanderschuren, Groenewegen, Robbins, & Pennartz, 2004). In rodents, the dorsal striatum is further divided into a more dorsomedial component (roughly equivalent to the caudate nucleus in primates) and a more dorsolateral component (roughly equivalent to the putamen in primates) (Yin & Knowlton, 2006). The ventral striatum primarily refers to the nucleus accumbens (NAcc) in rodents, although the ventral portions of the putamen and caudate are also considered parts of the ventral striatum in primates based on connectivity. Functionally, dorsal and ventral distinctions in terms of affective processing are apparent irrespective of species (e.g., Robbins & Everitt, 1992; O’Doherty, 2004), but more recent accounts propose an integrated view of the striatum where information is processed in a gradient from more medial to lateral regions as learning progresses (Voorn et al.). Although traditionally thought of as a motor structure, over the years the basal ganglia, particularly the striatum, have gained notoriety for their involvement in more cognitive (Graybiel, 1995; Packard & Knowlton, 2002) and affective processes (Robbins & Everitt, 1992; O’Doherty, 2004) that contribute to goal-directed behaviors. Of central interest to this chapter is the role of the striatum in reward-related processing, which has gained support from a rich animal literature.

Research in the striatum across species demonstrates that it is not simply involved in encoding value as it is signaled by reward, but importantly in using reward signals to learn the stimuli and actions that predict reward, thus acquiring value and reinforcing adaptive actions. For example, electrophysiological recordings in the striatum in nonhuman primates highlight its involvement in the expectation of reward (Apicella, Scarnati, Ljungberg, & Schultz, 1992; Kawagoe, Takikawa, & Hikosaka, 1998) and reward outcome processing (Hikosaka, Sakamoto, & Usui, 1989; Apicella, Ljungberg, Scarnati, & Schultz, 1991). This reward-response in the striatum is modulated according to properties of the stimulus such as the reward magnitude (Cromwell & Schultz, 2003) and individual preferences (Hassani, Cromwell, & Schultz, 2001). Similar to research in rodents, neurons in the primate dorsal striatum have been linked to the value of particular action that will lead to reward, rather than for the expected value of the outcome independent of action (Samejima, Ueda, Doya, & Kimura, 2005).

Consistent with electrophysiological data, deficits in approach or consummatory behaviors arise with lesions of the ventral and dorsal striatum, respectively (Robbins & Everitt, 1992). While the rodent ventral striatum has been implicated in simple associative reward-related learning, as exemplified by Pavlovian or classical conditioning (Ito, Dalley, Howes, Robbins, & Everitt, 2000), research suggests that the rodent dorsal striatum is more involved in learning the value of action outcomes, as exemplified by instrumental conditioning (Ito, Dalley, Robbins, & Everitt, 2002), with a potential gradient suggesting dorsomedial regions mediating initial acquisition and dorsolateral regions involved with the more habitual and automatic motor aspects of behavior with extensive learning (Yin, Knowlton, & Balleine, 2005; Yin, Ostlund, Knowlton, & Balleine, 2005).

The contributions of the striatum to reward processing have more recently been extended to the human brain, given the rapid advances in functional magnetic resonance imaging (fMRI). Many of the initial studies quickly highlighted the role of the striatum in expectation or anticipation of primary rewards such as juice (Berns, McClure, Pagnoni, & Montague, 2001; O’Doherty, Deichmann, Critchley, & Dolan, 2002), secondary more abstract rewards such as money (Knutson, Adams, Fong, & Hommer, 2001; Kirsch et al., 2003), and even processes associated with maladaptive reward expectations such as drug craving (Breiter et al., 1997). Responses to rewarding outcomes were also reported in the striatum (Delgado, Nystrom, Fissell, Noll, & Fiez, 2000), with variations in magnitude and probability of rewards (Delgado, Locke, Stenger, & Fiez, 2003; Delgado, Miller, Inati, & Phelps, 2005; Galvan et al., 2005; Nieuwenhuis et al., 2005) irrespective of whether the reward was extrinsic (e.g., monetary) or intrinsic (e.g., positive or negative feedback on cognitive tasks; Elliott, Sahakian,

Michael, Paykel, & Dolan, 1998; Poldrack et al., 2001; Seger & Cincotta, 2005). Thus early neuroimaging research was able to support and extend findings from nonhuman animals and implicate the striatum as an important structure in processing information about incentives that influence motivated behavior.

Given that one of the primary projections to the striatum is from dopaminergic neurons in the midbrain (Haber, Fudge, & McFarland, 2000) and that blood oxygenation level dependent (BOLD) responses in the striatum may reflect synaptic input activity (Logothetis, Pauls, Augath, Trinath, & Oeltermann, 2001), the human striatum hemodynamic responses were considered to reflect more than just anticipatory and consummatory signals in the brain. Rather, they were suggested to reflect a learning and valuation signal mediated by human corticostriatal circuits that underlies goal-directed or motivated behaviors (Montague & Berns, 2002; Balleine, Delgado, & Hikosaka, 2007). It was soon observed that prediction errors—the difference between expected and experienced affective outcomes thought to be coded by dopamine neurons in nonhuman primates (Schultz, Dayan, & Montague, 1997; Schultz & Dickinson, 2000; Bayer & Glimcher, 2005)—were coded in the human striatum during simple conditioning experiments with primary rewards, such as juice (Pagnoni, Zink, Montague, & Berns, 2002; McClure, Berns, & Montague, 2003; O’Doherty, Dayan, Friston, Critchley, & Dolan, 2003). The finding that prediction errors correlate with human striatal activity is widely reported with different types of paradigms and reinforcers (e.g., Schönberg, Daw, Joel, & O’Doherty, 2007; Tobler, O’Doherty, Dolan, & Schultz, 2007; Hare, O’Doherty, Camerer, Schultz, & Rangel, 2008). Additionally, in support of the animal literature, research suggested that the human striatum response to outcomes reflected reinforcement learning signals, rather than a reward per se (Tricomi, Delgado, & Fiez, 2004). Interestingly, while the human ventral striatum is involved in reward predictions irrespective of learning paradigm (e.g., classical or instrumental conditioning; O’Doherty et al., 2004), the dorsal striatum has been linked to more action-contingent learning (O’Doherty et al., 2004; Tricomi et al.; Zink, Pagnoni, Martin-Skurski, Chappelow, & Berns, 2004) with diminishing responses as learning progresses and stimuli become more predictable (Haruno et al., 2004; Delgado, Miller, et al., 2005; Seger & Cincotta, 2005).

Currently, neuroscience research on the striatum’s role in reward processing has merged with different disciplines, such as economics (Glimcher & Rustichini, 2004) and social psychology (Ochsner, 2004; Frith & Singer, 2008), to examine the different valuation calculations that contribute to motivated behavior and how such calculations are influenced by everyday social factors. Neuroeconomic investigations, for instance, have suggested that complex calculations of

expected or subjective value are integrated in the striatum during dynamic tasks that require constant representations and updating of reward contingencies, representing magnitude and probability (Knutson, Taylor, Kaufman, Peterson, & Glover, 2005), along with risk possibilities (Hsu, Blatt, Adolphs, Tranel, & Camerer, 2005; Schultz et al., 2008) and even information regarding time (McClure, Laibson, Loewenstein, & Cohen, 2004; Kable & Glimcher, 2007) and effort (Botvinick, Huffstetler, & McGuire, 2009). Although investigations with respect to losses and negative values in the striatum are in their infancy, they also have to be factored into these calculations (Becerra, Breiter, Wise, Gonzalez, & Borsook, 2001; Tom, Fox, Trepel, & Poldrack, 2007; Delgado, Li, Schiller, & Phelps, 2008; Delgado, Schotter, Ozbay, & Phelps, 2008).

Social factors also have to be taken into account when considering the role of the striatum in reward-related processing. Learning to trust someone, for instance, is a trial-and-error procedure in which feedback attained during social interaction is crucial for developing the feeling of trust. When participants develop reputations through experience in a trust game (King-Casas et al., 2005), neural signals in the striatum shift according to learning; that is, they respond to the earliest predictor of a potential reward—a pattern analogous to responses observed in dopamine models of reinforcement learning. Similarly, social signals in the trust game (such as faces of previous cooperators) can serve as approach signals for future social interactions and engage striatal circuits (Singer, Kiebel, Winston, Dolan, & Frith, 2004) that will be motivated to act in self-interest (e.g., retaliation) when trust is breached (de Quervain et al., 2004). Thus social information can modulate striatal function involved in reward processing, particularly when social expectations are violated (Delgado, Frank, et al., 2005). Overall, research on the striatum has highlighted its role in processing a wide range of rewards and the use reward signal to learn the value of stimuli and reinforce adaptive actions.

AMYGDALA OVERVIEW The amygdala is a small, almond-shaped structure in the medial temporal lobe that sits adjacent and anterior to the hippocampus and has broad connections with sensory, prefrontal, and subcortical regions (M. Young, 2002). In spite of its small size, the amygdala is a complex structure with several subnuclei, each with unique roles. The primary technique used to explore the function of these subnuclei in animal models is classical fear conditioning, in which a neutral stimulus, such as a tone, called the conditioned stimulus (CS), is paired with aversive stimulus, such as a shock, called the unconditioned stimulus (US). Through this pairing, the CS comes to elicit a range of conditioned fear responses (CR) when presented alone. Within the amygdala, the lateral nucleus is the site of sensory input from the CS and US, and is also proposed to be the

site of plasticity underlying the CS-US association (see LeDoux this volume). The LA projects to the central nucleus (CE), which in turn outputs to a range of brain regions mediating the physiological and neurohormonal expression of conditioned fear. The LA also projects to the basal nucleus (B), which projects the CE and plays a role in the contextual mediation of the expression of fear (Fanselow, 2000).

The amygdala's role in fear conditioning highlights its importance in the encoding and storage of the emotional value of stimuli and the physiological expression of fear, but this research alone does not link the amygdala to any action or choice. Although it has been proposed that the physiological expression of emotion may underlie decisions, perhaps through interactions with orbitofrontal cortex (Damasio, 1994), recent research in rodents suggests that the amygdala may mediate choice more directly. A study exploring the amygdala's role in mediating choice examined the escape from fear (EFF) paradigm. In this paradigm, the rodent first undergoes fear conditioning. In a second stage, the rodent is given the option to take an action to terminate the CS, thus reducing exposure to the fear-eliciting event. The termination of the CS becomes a conditioned reinforcer for the instrumental action. Amorapanth, LeDoux, and Nader (2000) found that diminishing fear through an action or choice relied on a circuitry within the amygdala that could be dissociated from its physiological expression. By placing lesions in the different amygdala subnuclei, it was found that although damage to the LA impairs both the physiological expression of fear and learning an action to diminish exposure to the CS, damage to the CE only disrupted the physiological expression. Rodents with lesions confined to the CE were able to learn an action to terminate the CS, even though they failed to show the typical expression of conditioned fear. In contrast, damage to B resulted in the opposite pattern of results, that is, failure to learn an action to terminate the CS but normal expression of the CR. It is suggested that B may not be the site of storage for the representation of action or choice in the EFF paradigm; rather, B projects to the striatum, which, as outlined earlier, has a broader role in motor control and reinforcement of action. In short, the pathway for fear-motivated actions is hypothesized to involve the LA, which projects to the B, which, in turn, projects to the striatum to convey the reinforcing nature of the instrumental action (see LeDoux & Gorman, 2001).

Because of technical limitations, research on the human amygdala has not yet examined the roles of specific subnuclei, but in general the function of the amygdala appears to be similar across species. Imaging studies demonstrate increased amygdala activation to a CS that is correlated with expression of the CR (LaBar, Gatenby, Gore, LeDoux, & Phelps, 1998; Buchel, Morris, Dolan, & Friston, 1998). Damage to the human amygdala impairs the physiological expression of conditioned fear (Bechara et al., 1995; LaBar,

LeDoux, Spencer, & Phelps, 1995). These results suggest that the mechanism of fear conditioning is preserved across species. However, humans have more efficient means of learning which stimuli in the environment predict potential aversive consequences than fear conditioning. Learning fears through social means does not require the aversive experience of a US. For instance, simply being told or instructed that an event or situation may lead to an aversive consequence is enough to elicit a fear response in that situation (Funayama, Grillon, Davis, & Phelps, 2001; Phelps et al., 2001). Similarly, observing another person being hurt when exposed to a stimulus is enough to elicit a fear when that stimulus is presented (Olsson, Nearing, & Phelps, 2007). Social learning of fear is more typical in humans, and learning through language is unique to humans. However, research indicates that even uniquely human, socially acquired fears also depend on the phylogenetically old amygdala for expression (see Olsson & Phelps, 2007, for a review). Finally, there is some preliminary evidence suggesting that amygdala-striatal interactions may also play a role in mediating actions that diminish exposure to fearful events in humans (Delgado, Jou, LeDoux, & Phelps, 2007), consistent with animal models.

Aside from emotional learning, the amygdala has other roles that are less explicitly linked to decisions or actions, but could have an impact on the assessment of value. One such role is to modulate cognition in the presence of emotional events. Because of its extensive connectivity throughout the brain, the amygdala is ideally situated to detect emotional events in the environment quickly and enhance further processing to assure that these events receive priority. For example, through its interaction with the hippocampus, the amygdala enhances the storage or consolidation of memories with arousal to assure that emotional events persist in memory (McGaugh, 2000). In addition, the amygdala's reciprocal connection with sensory cortices results in the facilitation of attention for emotional stimuli (Anderson & Phelps, 2001) and enhanced sensory cortical responses (Vuilleumier, Richardson, Armony, Driver, & Dolan, 2004). By representing some aspects of affective value, the amygdala, through its wide connectivity, can insure that cognition is tuned to events with affective significance.

Finally, the amygdala's role extends to representing some aspects of social value. This is most evident in the detection of fear from facial expressions (Adolphs et al., 1999). Patients with lesions to the amygdala fail to rate faces with fear expressions as fearful, a deficit that seems primarily driven by their tendency to ignore the eyes, relative to normal control subjects (Adolphs et al., 2005). The amygdala is also involved in judging faces as more or less trustworthy (Adolphs, Tranel, & Damasio, 1998) and responds to some of the evaluative qualities of social group membership (Phelps et al., 2001). This social role for the amygdala includes some

aspects of detecting social intent. When viewing a movie in which geometric shapes move around in a way that suggests a social interaction, control subjects report a social interaction, whereas patients with lesions to the amygdala only report the movement of shapes (Heberlein & Adolphs, 2004). These broader roles for the amygdala in modulating cognitive processes and representing aspects of social value could affect decisions in a number of ways that have yet to be explored.

THE STRIATUM, THE AMYGDALA, AND VALUE In the preceding discussion, we highlighted a role for both the striatum and the amygdala in representing value, but how we define value varies. With the striatum, we discuss value as represented by reward signals in response to stimuli that would normally cause one to approach a situation, such as juice if one is thirsty, money, or social cooperation. With the amygdala, we refer to value representing an emotional significance that would cause one to avoid a situation, such as fear or untrustworthiness. This description suggests a clear dichotomy as to unique roles of the striatum and amygdala in the representation value. However, the data are not nearly as clear as the simple description suggests.

In fact, there is abundant evidence that the role of the striatum is not strictly limited to representing reward and appetitive learning and the amygdala is not solely involved in aversive conditioning. Rather, both structures play a role in mediating appetitive and aversive learning. For example, in the NAcc, dopamine responses are elevated in response to aversive outcomes, such as electric shocks, tail pinch, and social stress (Robinson, Becker, Young, Akil, & Castaneda, 1987; Kalivas & Duffy, 1995), and also in response to a CS or a context predicting potential aversive consequences (Murphy, Pezze, Feldon, & Heidbreder, 2000; A. Young, 2004). Dopamine in the NAcc is also important for aversive instrumental conditioning, such as active or passive avoidance and escape tasks (Schwartz & Carey, 1985; Wadenberg, Ericson, Magnusson, & Ahlenius, 1990; McCullough, Sokolowski, & Salamone, 1993). The dorsal striatum is also linked to aversive learning, with lesions to this region resulting in deficits in conditioned fear and active avoidance (Winocur & Mills, 1969; White & Salinas, 2003).

Consistent with research in other species, human fMRI studies also implicate the striatum in aversive classical and instrumental conditioning. Even though the striatum is not often the focus of neuroimaging studies on fear conditioning, most of these studies report activation of the striatum, in addition to the amygdala (Buchel et al., 1998; LaBar et al., 1998; Buchel, Dolan, Armony, & Friston, 1999; Phelps, Delgado, Nearing, & LeDoux, 2004). Striatal activation has also been observed in relation to pain (Ploghaus et al., 2000; Seymour et al., 2005) and monetary loss (Delgado, 2007;

Seymour, Daw, Dayan, Singer, & Dolan, 2007; Tom et al., 2007). In a recent review, it was found that across aversive learning paradigms, the striatum consistently represents prediction error signals, whereas the amygdala does not, suggesting a general role for the striatum in mediating temporal difference learning in both appetitive and aversive tasks (Delgado, Li, et al., 2008).

As outlined earlier, the amygdala is critical for classical fear conditioning, but it has also been suggested to play a role in classical conditioning paradigms involving rewards. It has been suggested that the basolateral nucleus of the amygdala (BLA) is important for maintaining and updating the representation of the affective value of an appetitive CS (Parkinson et al., 2001), which may rely on its interactions with the corticostriatum and dopaminergic circuitry (Rosenkranz & Grace, 2002; Rosenkranz, Moore, & Grace, 2003). Given this possibility the BLA appears to be involved in variations of standard appetitive conditioning paradigms, including when using a secondary reinforcer, when the value of the US has changed after conditioning, or in tasks that explore the interactions between Pavlovian and instrumental processes (Gallagher, Graham, & Holland, 1990). Similar effects have been observed when the BLA is disconnected from the NAcc, suggesting that amygdala-striatal interactions are important for processing learned motivational value (Setlow, Holland, & Gallagher, 2002). In addition, the CE may be critical for some expressions of appetitive conditioning, including enhanced attention (orienting) to the CS (Gallagher et al.), and controlling the general motivational influence of rewarding events (Corbit & Balleine, 2005). There is some evidence in humans supporting a role for the amygdala in appetitive conditioning. Patients with amygdala lesions are impaired in conditioned preference tasks (Johnsrude, Owen, White, Zhao, & Bohbot, 2000), and neuroimaging studies report amygdala activation during appetitive conditioning with food as a US (Gottfried, O'Doherty, & Dolan, 2003).

Although the complex interactions between the amygdala and striatum in affective learning and decisions needs to be further clarified, these studies indicate that the striatum and amygdala interact to represent learned value for both appetitive and aversive reinforcers, suggesting that there is not a clear division between the neural structures typically linked to value in decision making and those representing emotional value. While neuroeconomic researchers generally distinguish between emotion and value when investigating decision processes, affective scientists have a much broader view of value as a fundamental component of emotion. Future research integrating emotion and decision making will have to grapple with are the precise definition of value across disciplines, as well as the complex interactions of the striatum and amygdala in mediating value, learning, and actions.

Initial investigations of emotion's influence on economic decision making

In this section, we briefly review some published neuroeconomic research that has explicitly attempted to incorporate emotion variables. As mentioned earlier, emotion encompasses several independent and overlapping processes and functions that share a common goal in signaling relevance or importance to the organism (Frijda, 1986; Scherer, 2005). In spite of a growing interest in the role of emotion in decision making (e.g., Damasio, 1994; Cohen, 2005), relatively few studies have actually attempted to manipulate or measure specific emotion variables. We will highlight a few that have done so and outline what aspect of emotion each study incorporates. We have not included in this overview studies that use BOLD responses or lesions in specific brain regions as the primary assessment or manipulation of emotion. Although it is clear that certain brain regions have emotion functions, almost all these regions have roles in cognitive or sensory processes as well, so it is hard to infer emotion directly from BOLD or a lesion in the absence of any additional assessment of emotion (Phelps, 2008).

ASSESSING EMOTION AND LINKING IT TO CHOICE There are several means to assess emotion, including subjective report, physiological measurement, and actions (see Phelps, 2008, for a review). With the exception of action, which is a general response that is not unique to emotion, very few neuroeconomic studies have attempted to assess emotional responses and relate them to decisions. One exception is the classic study by Bechara, Damasio, Tranel, and Damasio (1997) in which they found that physiological arousal was correlated with decisions in an economic gambling task.

Using the Iowa Gambling Task (IGT) participants were required to pick a card from one of four decks over a series of trials. Each card represented a monetary reward or punishment, and the goal was to learn through trial and error which deck would yield a higher profit over time. The decks varied in their payoff schedules, with two of the decks yielding greater rewards, but also greater punishments resulting in less overall profit than the other two decks. Over trials, normal, healthy participants learned to increase their profits by selecting from the more advantageous decks more often than the less advantageous decks. Physiological arousal was assessed as participants contemplated selecting from the decks. Prior to selecting from the less advantageous decks, normal participants showed increased arousal. It was suggested that this arousal response cued the participant to move away from those decks and toward a more advantageous choice. In short, it was argued that physiological arousal mediated decision making in this task. Bechara and colleagues (1997) also conducted this study in patients with damage to the orbitofrontal cortex. These patients failed to

learn to select more from the advantageous decks over time and also failed to generate anticipatory arousal responses. These results inspired Antonio Damasio (1994) to propose the *somatic marker hypothesis*, which suggests that bodily states and emotional responses play a fundamental role in driving choice behavior.

Although several additional studies over the years have failed to find strong support for the somatic marker hypothesis (see Dunn, Dalgleish, & Lawrence, 2006, for a review), the Bechara and colleagues (1997) study represents one of the first attempts to assess an emotional response and relate it to decisions. In this way, it highlighted the importance of the considering emotion in decision-making research and inspired future investigations on this topic.

MANIPULATING EMOTION DIRECTLY AND OBSERVING THE IMPACT ON CHOICE There are several means to manipulate emotion in the laboratory (Phelps, 2008), but only a few of these techniques have been used in economic or neuroeconomic research. One of the first neuroeconomic studies to manipulate emotion and examine its impact on decisions utilized a pharmacological manipulation. Oxytocin is a drug that increases social affiliation and the social emotion of trust. Kosfeld, Heinrichs, Zak, Fischbacher, & Fehr (2005) administered either oxytocin or placebo to participants and then asked them to play the trust game. In this game, the investor has the opportunity to share a variable sum of money with a trustee. By sharing this money the overall amount is magnified. The trustee has the option to share back some of the profits or keep all the money for him- or herself. Thus sharing by the investor is risky and requires trust. The oxytocin group showed much higher rates of trust (and risk) by sharing more money, relative to the placebo. However, oxytocin did not increase risk in a nonsocial game, only in the social interaction. Although this initial study did not investigate the underlying neural systems mediating increased trust, a follow-up study found that responses in both the amygdala and dorsal striatum were linked to differential choices in the oxytocin group (Baumgartner, Heinrichs, Vonlanthen, Fischbacher, & Fehr, 2008).

In affective science, a more traditional means to manipulate emotion is to present stimuli that elicit an emotional response. Although there are no neuroeconomic studies we know of that have used this approach, there are a few behavioral economic studies. For instance, in a study aimed at investigating the influence of acute stress on financial decision making, stress was induced by asking participants to immerse their hand for a period of time in either cold (stress) or room-temperature (no stress) water (Porcelli & Delgado, 2009). It was hypothesized that the physiological and emotional consequences of stress would interfere with deliberative decision-making processes, leading one to depend on more intuitive or automatic processes. Participants were

asked to choose between two gambles that varied in terms of risk and value. Importantly, the choice between a risky and a conservative gamble was presented in a gain domain (the outcomes of both gambles are positive) and a loss domain (the outcomes of both gambles are negative). Participants' choices conformed to a pattern of behavior known as the reflection effect—that is, greater preference for risky options when decisions involve losses rather than gains (Kahneman & Tversky, 1979). This bias was exacerbated when participants were under stress. That is, participants were more conservative when choosing between gambles with positive outcomes (gain), while being riskier when choosing between gambles with negative outcomes (loss). This study suggests that participants perhaps fall back on automatized reactions to risk when in a stressful environment.

Another means to manipulate affect is to alter participants' moods. Mood can elicit action tendencies to approach or avoid (Scherer, 2005) that may impact economic choices. Lerner, Small, and Loewenstein (2004) induced sad and disgust moods and examined their impact on a classic economic problem—the endowment effect. When they came into the lab, half the participants were given a highlighter set. All the participants then watched one of three movies, chosen to elicit a sad, disgust, or neutral mood. Along with viewing the movie, participants were asked to write about how they would feel if they experienced the events depicted in the movie. After this procedure, participants were asked how much they would sell the highlighter set for (if endowed) or choose to pay for it (if not endowed). Those in the neutral mood condition showed the classic endowment effect—they would demand more to sell the product than they would pay for it. In contrast, the sad group showed the opposite. They were willing to sell the highlighter set for a lower price than they would pay for it. The disgust group showed no endowment effect at all. These results demonstrate not only that mood can have an effect on economic choices, but also that the effect is specific to different mood states.

MANIPULATING EMOTION THROUGH APPRAISAL AND OBSERVING ITS IMPACT ON CHOICE A fundamental component of emotion is appraisal (see Scherer, 2005, for a review). Appraisal is the process that occurs when an event is first encountered and its emotional meaning is determined. Although the evaluation or appraisal of the emotional significance of an event can occur quickly and automatically, appraisals and emotional reactions can also unfold as information about the circumstances is acquired. A classic example of the importance of appraisals in generating emotion is a study by Schacter and Singer (1962). They evoked physiological changes consistent with emotion by administering epinephrine. However, they only informed a subset of participants that the bodily changes are related to the drug. All the participants were then placed in a social

circumstance that might evoke happiness or anger. Only those participants who were unaware of the cause of their physiological state reported the subjective experience of euphoria or anger and behaved in a manner consistent with these emotions. This classic finding highlights the importance of appraisal in generating an emotional response.

In affective science, several types of manipulations or instruction have been shown to influence appraisal and subsequent emotional reactions (e.g., Ochsner & Gross, 2008). In economics, one such manipulation might be framing. By emphasizing loss or gain in how an identical economic choice is presented, participants will make a different decision in order to avoid loss (Kahneman & Tversky, 1979). It is suggested that this framing manipulation, by changing appraisal, alters the emotional significance of the outcome, thus biasing the decision (Gilovich, Griffin, & Kahneman, 2002). A study examining the neural basis of the framing effect found that BOLD responses in the amygdala were significantly altered by the framing manipulation (DeMartino, Kumaran, Seymour, & Dolan, 2006). This finding is consistent with a large body of research on emotion regulation suggesting that altering appraisal can influence amygdala activity and a range of emotional responses (see Ochsner & Gross, 2008, for a review). In addition, activity in the orbital and medial prefrontal cortices predicted the susceptibility to framing effects across individuals (DeMartino et al.).

A second study examined the impact of framing on economic auctions (Delgado, Schotter, et al., 2008). This study specifically investigated why people tend to pay too much, or overbid, in experimental auctions. Using fMRI, it was found when playing a two-person auction game versus a lottery game against a computer, the striatum showed an exaggerated response when the auction was lost, even though there was no monetary loss. Correlating the striatal response to winning or losing the auction with the bid chosen showed that only the loss response was related to the bid chosen and the tendency to overbid. This finding led to the hypothesis that perhaps it is the contemplation or fear of loss, in this case social loss, that is driving the tendency to overbid. To explore this hypothesis, a behavioral framing study was conducted in which some participants were given \$15 and were told they would lose it if they lost the auction, whereas other participants were told they would receive a bonus of \$15 if they won the auction. In these equivalent auctions, the loss frame increased overbidding and profit for a hypothetical auctioneer.

These framing studies (DeMartino et al., 2006; Delgado, Schotter, et al., 2008) produced results consistent with the suggestion that altering the appraisal of the economic choice can influence emotion and alter the decision. However, neither of these studies can confirm, with a direct assessment, that emotion was altered. A recent behavioral study adapted an emotion-regulation technique to examine the

impact of altering appraisal on both economic decisions and emotional reactions (Sokol-Hessner et al., 2009). In this study, participants were presented with risky gambles and had to choose between the gamble and a guaranteed outcome. On half of the trials, participants were instructed to view each choice as one in a portfolio of choices. For the other half, they were instructed to focus on each choice as if it were the only choice. Using the portfolio frame resulted in an overall decrease in loss aversion. The more loss-averse a participant was, the higher the physiological arousal response to monetary losses relative to gains at outcome. Furthermore, those participants who were more successful at decreasing loss aversion by adopting the portfolio frame also showed a greater decrease in their arousal response to losses. These findings indicate that a classic economic phenomenon, loss aversion, may be related to an emotional response, arousal, and that changing the framing or appraisal of a choice may impact both its emotional impact and loss aversion.

Conclusion

The purpose of emotion is to signal to the organism the events, situations, or information in the environment that may be relevant and potentially important for survival (Scherer, 2005). Therefore, it is not surprising that emotion should have a broad and critical role in decision making. However, research on the interaction of emotion and decision making is only beginning to emerge in neuroeconomics. Although it has long been acknowledged that emotion affects decisions (Kahneman, 2003), the traditional view that emotion is a unitary construct that has a single impact on decision processes fails to embrace the complexity of emotion and the broad and diverse impact it can have on decision processes across domains. As neuroeconomics begins to adopt the tools and theories of affective science and affective neuroscience, a more integrated view of decision making will emerge.

Introduction

CHRISTOF KOCH

THE NATURE OF the relationship between the objective, material world and the subjective world of conscious experience, of phenomenal content, lies at the heart of the ancient mind-body problem. Consciousness appears as mysterious to 21st century scholars as it was to the ancient Greeks who first systematically contemplated the nature of mind. Yet modern science is in a strong position to investigate and manipulate the physical basis of consciousness. Brain scientists seek an understanding of how and why the neural basis of one particular conscious sensation is the basis of that sensation rather than another, why so many behaviors occur outside the pale of consciousness, why sensations are structured the way they are, and how they acquire meaning. Finally, cognitive neuroscience is contributing to the problem of understanding the conscious sensation of willing an action.

The scholars represented in section X take the problem of consciousness, the first-person perspective, as given and assume that brain activity is both necessary and sufficient for biological creatures to experience something. A primary goal is to identify the specific nature of the activity of brain cells that gives rise to any one specific conscious percept, the neuronal correlates of consciousness (Crick & Koch, 1995; Metzinger, 2000; Chalmers, 2000). An auxiliary goal is to determine to what extent these correlates differ from activity that influences behavior without engaging consciousness.

Most everyone has a general idea of what it means to be conscious. According to the philosopher John Searle, “Consciousness consists of those states of sentience, or feeling, or awareness, which begin in the morning when we awake from a dreamless sleep and continue throughout the day until we fall into a coma or die or fall asleep again or otherwise become unconscious” (Searle, 1997). Practically speaking, consciousness is needed for nonroutine tasks that require retention of information over seconds. Although

provisional and vague, such a definition is good enough to get the process started. As the science of consciousness advances, such operational definitions will need to be refined and expressed in more fundamental neuronal terms. Until the problem is understood much better, though, a more formal definition is likely to be either misleading or overly restrictive, or both. If this statement seems evasive, try defining a gene (Keller, 2000).

The working hypothesis is that consciousness emerges from neuronal features of the brain. Emergence is used here without any new-age overtones but in the sense that the initiation and propagation of the action potential in axons, a highly nonlinear phenomenon, is the result of—and can be predicted from—the attributes of voltage-dependent ionic channels inserted into the neuronal membrane. Although consciousness is fully compatible with the laws of physics, it is not obvious how it follows from these laws. Something else might be needed.

Understanding the material basis of consciousness is unlikely to require any exotic new physics but rather a much deeper appreciation of how highly interconnected networks of a very large number of heterogeneous but highly structured neurons work. The abilities of rapidly forming and dissolving coalitions of corticothalamic neurons to learn from interactions with the environment and from their own internal activities are routinely underestimated. The individual neurons themselves are complex entities with unique morphologies and thousands of inputs and outputs. Humans have no real experience with such vast organization. Hence, even biologists struggle to appreciate the properties and power of the nervous system.

It would be contrary to evolutionary continuity to believe that consciousness is unique to humans. Most brain scientists assume that many species possess some, but not necessarily all, of the features of consciousness—that they see, hear, smell, and otherwise experience the world (Griffin, 2001). This assumption is particularly true for monkeys and apes, whose behavior, development, and brain structure are remarkably similar to those of humans. Of course, each species has its own unique sensorium, matched to its ecological niche, but that is not to deny that animals can have feeling, subjective states. To believe otherwise seems presumptuous and flies in the face of all experimental evidence. At this point in time, we have no clear idea whether animals from phyla other than Chordata have subjective states. But the nonstereotyped and adaptive behaviors of many mollusks and insects make it likely that they too share the gift of consciousness with us.

The focus of much of the empirical work in the field and in this section of the book is on visual consciousness. More than other aspects of sensation, visual awareness is amenable to empirical investigations for a variety of reasons. First, humans are visual creatures. This fact is reflected in the large

amount of brain tissue dedicated to vision and in the importance of seeing in daily life. Second, images are highly structured yet easy to control using computers. Third, phenomena such as binocular rivalry, continuous flash suppression, or motion-induced blindness can be used to manipulate the relationship between retinal input and visibility—that is, between objective sensory stimulus and subjective conscious percept. Last, the neuronal basis of many visual phenomena and illusions has been investigated throughout the animal kingdom. Perceptual neuroscience has advanced to such a point that reasonably sophisticated computational models have been constructed and have proven their worth in guiding experimental agendas and summarizing the data. It is not unlikely that all the different aspects of consciousness (smell, pain, vision, self-consciousness, the feeling of willing an action, and so on) employ one or perhaps a few common mechanisms. Figuring out the neuronal basis for one modality, therefore, will probably be the breakthrough event that will help us understand all of them.

Much has changed in consciousness studies in the five years since the previous edition of this book. So much so that an almost entirely new cast of philosophers and scientists discuss their findings in these pages, the vast majority of which have been published within the past few years. Better than anything else, this demonstrates the vitality of this research endeavor.

With the preceding background, let me briefly introduce the eight chapters. In chapter 77, Block summarizes and compares the three major theoretical approaches to consciousness that take science seriously: higher order theories, the global workspace account of consciousness, and biological theories—those that postulate that consciousness is some sort of biological state of the brain. Block, a philosopher, has the distinction of having himself directly contributed to the empirical debate, by drawing subtle but crucial distinctions between selective attention and consciousness and their underlying neuronal mechanisms (Block, 2007). In chapter 78, Schiff discusses the clinical literature pertaining to global impairments of consciousness following brain injury. The persistent vegetative state (PVS) or the minimal conscious state (MCS) are clinical conditions in which the patient is either permanently unconscious or hovering at the borderline between unconscious and conscious and in which midline structures in the brain stem and thalamus are affected. Given the large number of such patients—on the order of 100,000 in the United States alone—there is a great urgency to understand these pathologies. The exploratory work of Schiff and colleagues (2007) using thalamic deep-brain stimulation is particularly promising in this regard. Chapter 79 by Koch provides the conceptual framework and empirical data for a research program dedicated to discovering the neuronal basis of the content of conscious perception. It emphasizes what is not needed for consciousness

(e.g., neither sensory input nor motor output nor self-consciousness), the dissociation between attention and consciousness, and the interaction among coalitions of corticothalamic neurons that vie for dominance. Chapter 80 by Rees and chapter 81 by Macknik and Martinez-Conde focus on different aspects of vision. Rees describes the enormous contributions functional brain imaging has made to elucidate the cortical basis of visual awareness in both patients and neurologically normal people; in contrast, Macknik and Martinez-Conde concentrate on the anatomy and electrophysiology of the early stages of the visual thalamocortical system in monkeys and what they teach us about consciousness. One of the crucial conclusions is that attention and consciousness, so often conflated, are quite distinct processes. Koenigs and Adolphs' chapter 82 deals with data and theories that seek to explain the neuronal basis of the subjective states of joy, sorrow, anger, and fear. They rightfully emphasize that much emotional processing can occur outside the pale of consciousness. While most students of the mind have gotten used to unconscious visual processing, the idea of subliminal emotional processing is not (yet) as widely accepted. Lau's chapter 83 deals with the problem of the function of consciousness in the context of willed actions. What is not in doubt is the fact that most of us consciously experience a feeling of willing an action, such as raising our arm. What is more controversial is whether this feeling has any causal effect on the behavior. Is the sensation of volition simply an epiphenomenon? Lau challenges the community to come up with experiments that conclusively demonstrate that some function cannot be carried out unconsciously. It is not an easy challenge to meet. Last, the field of consciousness studies is greatly hampered by the lack of a widely accepted theory of consciousness. We need to know, on theoretical or conceptual grounds, why a particular system of interacting parts has subjective states. Is our immune system conscious? And if not, why not? What about a fetus, a newborn child, an aphasic patient, a monkey, or a honeybee? And can we replicate consciousness in silicon? These questions are addressed in chapter 84 by Tononi and Balduzzi. Proceeding from two simple phenomenological axiomatic observations, they construct an integrated theory of consciousness, including qualia space, that explains many

of the known anatomical, physiological, and psychological facts about consciousness. It is a very ambitious but enormously exciting development.

Collectively, the chapters in section X signal the emergence of a science of consciousness, an ability to investigate how phenomenal feelings emerge out of excitable brain matter in a rigorous, reliable, and reproducible manner. What are needed now are invasive experiments that begin to close the gap between correlation and causation. Molecular biology is delivering optogenetic techniques to deliberately, delicately, transiently, and reversibly dissect individual components of forebrain circuits in flies, mice, and, soon, monkeys (Adamantidis, Zhang, Aravanis, Deisseroth, & de Lecea, 2007). The applications of such technologies, in combination with continuous, long-term recordings from thousands of neurons and functional imaging techniques, will do much to advance this goal.

77 Comparing the Major Theories of Consciousness

NED BLOCK

ABSTRACT This article compares the three frameworks for theories of consciousness that are taken most seriously by neuroscientists: the view that consciousness is a biological state of the brain, the global workspace perspective, and an account in terms of higher order states. The comparison features the “explanatory gap” (Nagel, 1974; Levine, 1983), the fact that we have no idea why the neural basis of an experience is the neural basis of that experience rather than another experience or no experience at all. It is argued that the biological framework handles the explanatory gap better than do the global workspace or higher order views. The article does not discuss quantum theories or “panpsychist” accounts according to which consciousness is a feature of the smallest particles of inorganic matter (Chalmers, 1996; Rosenberg, 2004). Nor does it discuss the “representationist” proposals (Tye, 2000; Byrne, 2001a) that are popular among philosophers but not neuroscientists.

Three theories of consciousness

HIGHER ORDER The higher order approach says that an experience is phenomenally conscious only in virtue of *another* state that is about the experience (Armstrong, 1978; Lycan, 1996a; Byrne, 1997; Carruthers, 2000; Byrne, 2001b; Rosenthal, 2005a). This perspective comes in many varieties, depending on, among other things, whether the monitoring state is a thought or a perception. The version to be discussed here says that the higher order state is a thought (“higher order thought” is abbreviated as HOT) and that a conscious experience of red consists in a representation of red in the visual system accompanied by a thought in the same subject to the effect that the subject is having the experience of red.

GLOBAL WORKSPACE The global workspace account of consciousness was first suggested by Bernard Baars (1988) and has been developed in a more neural direction by Stanislas Dehaene, Jean-Pierre Changeux, and their colleagues (Dehaene, Changeux, Nacchache, Sackur, & Sergent, 2006). The account presupposes a neural network approach in which there is competition among neural coalitions involving both frontal and sensory areas (Koch, 2004), the winning coalitions being conscious. Sensory

stimulation causes activations in sensory areas in the back of the head that compete with each other to form dominant coalitions (indicated by dark elements in the outer rings in figure 77.1). Some of these dominant coalitions trigger central reverberations through long-range connections to frontal cortex, setting up activations that help to maintain both the central and peripheral activations. The idea that some brain areas control activations and reactivations in other areas is now ubiquitous in neuroscience (Damasio & Meyer, 2008), and a related idea is widely accepted: that one instance of reciprocal control is one in which workspace networks in frontal areas control activations in sensory and spatial areas (Curtis & D’Esposito, 2003). It is useful in thinking about the account to distinguish between suppliers and consumers of representations. Perceptual systems supply representations that are consumed by mechanisms of reporting, reasoning, evaluating, deciding, and remembering, which themselves produce representations that are further consumed by the same set of mechanisms. Once perceptual information is “globally broadcast” in frontal cortex this way, it is available to all cognitive mechanisms without further processing. Phenomenal consciousness is global broadcasting.

Although the global workspace account is motivated and described in part in neural terms, the substantive claims of the model abstract away from neuronal details. Nothing in the model requires the electrochemical nature of actual neural signals. The architectural aspects of the model can just as easily be realized in silicon-based computers as in protoplasm. In this respect, the global workspace theory of consciousness is a form of what philosophers call *functionalism* (Block, 1980), according to which consciousness is characterized by an abstract structure that does not include the messy details of neuroscience.

Another functionalist theory of consciousness is the integrated information theory (Tononi & Edelman, 1998), according to which the level of consciousness of a system at a time is a matter of how many possible states it has at that time and how tightly integrated its states are. This theory has a number of useful features—for example, retrodicting that there would be a loss of consciousness in a seizure in which the number of possible states drops precipitously

NED BLOCK Departments of Philosophy and Psychology; Center for Neural Science, New York University, New York, New York

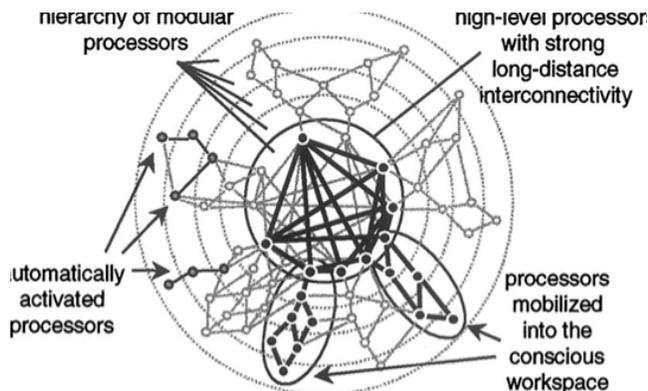

FIGURE 77.1 Schematic diagram of the global workspace. Sensory activations in the back of the brain are symbolized by dots and lines in the outside rings. Dominant sensory neural coalitions (dark lines and dots) compete with one another to trigger reverberatory activity in the global workspace (located in frontal areas) in the center of the diagram. The reverberatory activity in turn maintains the peripheral excitation until a new dominant coalition wins out.

(Tononi & Koch, 2008). Unfortunately, such predictions would equally follow from an integrated information theory of *intelligence* (in the sense of the capacity for thought, as in the Turing test of intelligence)—which also drops in a seizure. Consciousness and intelligence are on the face of it very different things. We all understand science fiction stories in which intelligent machines lack some or all forms of consciousness. And on the face of it, mice or even lower animals might have phenomenal consciousness without much intelligence. The separation of consciousness and cognition has been crucial to the success of the scientific study of consciousness. In a series of papers that established the modern study of consciousness, Crick and Koch (1990, 1998) noted in particular that the basic processes of visual consciousness could be found in nonprimate mammals and were likely to be independent of language and cognition. Although its failure to distinguish consciousness and intelligence is crippling for the current prospects of the integrated information theory as a stand-alone theory of consciousness, I will mention it at the end of the article in a different role: as an adjunct to a biological theory.

THE BIOLOGICAL THEORY The third of the major theories is the biological theory, the theory that consciousness is some sort of biological state of the brain. It derives from Democritus (Kirk, Raven, & Schofield, 1983) and Hobbes (1989), but was put in modern form in the 1950s by Place (1956), Smart (1959), and Feigl (1958). (See also Block, 1978; Crane, 2000; Lamme, 2003.) I will explain it using as an example the identification of the visual experience of (a kind of) motion in terms of a brain state that includes activations of a certain sort of area MT+ in the visual cortex. Although this explanation is useful as an example, we can expect that any theory of visual experience will be superseded.

Visual area MT+ reacts to motion in the world, different cells reacting to different directions. Damage to MT+ can cause loss of the capacity to experience this kind of motion; MT+ is activated by the motion aftereffect; transcranial magnetic stimulation of MT+ disrupts these afterimages and also can cause motion “phosphenes” (Zihl, von Cramon, & Mai, 1983; Britten, Shadlen, Newsome, & Movshon, 1992; Heeger, Boynton, Demb, Seideman, & Newsome, 1999; Kammer, 1999; Cowey & Walsh, 2000; Kourtzi & Kanwisher, 2000; Huk, Ress, & Heeger, 2001; Rees, Kreiman, & Koch, 2002; Théoret, Kobayashi, Ganis, Di Capua, & Pascual-Leone, 2002). However, it is important to distinguish between two kinds of MT+ activations, which I will call nonrepresentational activations and representational activations. Some activations in the visual system are very weak, do not “prime” other judgments (that is, do not facilitate judgments about related stimuli), and do not yield above-chance performance on forced-choice identification or detection (that is, they do not allow subjects to perform above chance on a choice of what the stimulus was or even whether there was a stimulus or not). On a very liberal use of the term “representation” in which *any* neural activation that correlates with an external property is a representation of it (Gallistel, 1998), one might nonetheless call such activations of MT+ representations, but it will be useful to be less liberal here, describing the weak activations just mentioned as nonrepresentational. (The term “representation” is very vague and can be made precise in different equally good ways.) However, if activations of MT+ are strong enough to be harnessed in subjects’ choices (at a minimum in priming), then we have genuine representations. (See Siegel, 2008, for a discussion of the representational contents of perceptual states.)

Further, there is reason to think that representations in MT+ that also generate feedback loops to lower areas are at least potentially conscious representational contents (Pascual-Leone & Walsh, 2001; Silvanto, Cowey, Lavie, & Walsh, 2005). (For a dissident anti-feedback-loop perspective, see Macknik & Martinez-Conde, 2007.) Of course, an activated MT+ even with feedback to lower visual areas is not all by itself sufficient for phenomenal consciousness. No one thinks that a section of visual cortex in a bottle would be conscious (Kanwisher, 2001).

What makes such a representational content phenomenally conscious? One suggestion is that active connections between cortical activations and the top of the brain stem constitute what Alkire, Haier, and Fallon (2000) call a “thalamic switch.” There are two important sources of evidence for this view. One is that the common feature of many if not all anesthetics appears to be that they disable these connections (Alkire & Miller, 2005). Another is that the transition from the vegetative state to the minimally conscious state (Laureys, 2005) involves these connections. However, there

is some evidence that the “thalamic switch” is an on switch rather than an off switch (Alkire & Miller, 2005) and that corticothalamic connections are disabled as a result of the large overall decrease in cortical metabolism (Velly et al., 2007; Alkire, 2008; Tononi & Koch, 2008)—which itself may be caused in part by the deactivation of other subcortical structures (Schneider & Kochs, 2007). Although this area of study is in flux, the important philosophical point is the three-way distinction between (1) a nonrepresentational activation of MT+, (2) an activation of MT+ that is a genuine visual representation of motion, and (3) an activation of MT+ that is a key part of a phenomenally conscious representation of motion.

The same distinctions can be seen in terms of the global workspace theory as the distinction among (1) a minimal sensory activation (the gray peripheral activations in figure 77.1), (2) a peripheral dominant coalition (the black peripheral activations in figure 77.1), and (3) a global activation involving both peripheral and central activation (the circled activations in figure 77.1 that connect to the central workspace). The higher order account is focused on the distinction between a visual representation and a conscious visual representation (2 versus 3), a visual representation that is accompanied by a higher order thought to the effect that the subject has it.

Here are some items of comparison between the three theories. According to the biological account, global broadcasting and higher order thought are what consciousness *does* rather than what consciousness *is*. That is, one function of consciousness on the biological view is to promote global broadcasting, and global broadcasting in some but not all cases can lead to higher order thought. Further, according to the biological view, both the global workspace and higher-order thought views leave out too many details of the actual working of the brain to be adequate theories of consciousness. Information in the brain is coded electrically, then transformed to a chemical code, then back to an electrical code, and it would be foolish to assume that this transformation from one form to another is irrelevant to the physical basis of consciousness.

From the point of view of the biological and global workspace views, the higher-order-thought view sees consciousness as more intellectual than it is, but from the point of view of higher-order-thought accounts, the biological and global workspace accounts underestimate the role of cognition in consciousness. The global workspace and higher-order-thought accounts are sometimes viewed as superior to the biological account in that the biological account allows for the possibility that a subject could have a phenomenally conscious state that the subject does not know about (Block, 2007a, 2007b). And this is connected to the charge that the biological account—as compared with the other accounts—neglects the connection between phenomenal

consciousness and the self (Church, 1995; Harman, 1995; Kitcher, 1995).

The higher order and global workspace accounts link consciousness to the ability to report it more tightly than does the biological view. On the higher-order-thought view, reporting is just expressing the higher order thought that makes the state conscious, so the underlying basis of the ability to report comes with consciousness itself. On the global workspace account, what makes a representational content conscious is that it is in the workspace, and that just is what underlies reporting. On the biological account, by comparison, the biological machinery of consciousness has no necessary relation to the biological machinery underlying reporting, and hence there is a real empirical difference among the views that each side seems to think favors its own view (Block, 2007b; Naccache & Dehaene, 2007; Prinz, 2007; Sergent & Rees, 2007).

To evaluate and further compare the theories, it will be useful to appeal to a prominent feature of consciousness, the explanatory gap.

The explanatory gap

Phenomenal consciousness is “what it is like” to have an experience (Nagel, 1974). Any discussion of the physical basis of phenomenal consciousness (henceforth just consciousness) has to acknowledge the “explanatory gap” (Nagel, 1974; Levine, 1983): nothing that we now know, indeed nothing that we have been able to hypothesize or even fantasize, gives us an understanding of why the neural basis of the experience of green that I now have when I look at my screen saver is the neural basis of *that* experience as opposed to *another* experience or no experience at all. Nagel puts the point in terms of the distinction between subjectivity and objectivity: the experience of green is a subjective state, but brain states are objective, and we do not understand how a subjective state could *be* an objective state or even how a subjective state could be *based in* an objective state. The problem of closing the explanatory gap (the “Hard Problem” as Chalmers, 1996, calls it) has four important aspects: (1) we do not see a hint of a solution; (2) we have no good argument that there is no solution that another kind of being could grasp or that we may be able to grasp at a later date (but see McGinn, 1991); so (3) the explanatory gap is not intrinsic to consciousness; and (4) most importantly for current purposes, recognizing the first three points requires no special theory of consciousness. All scientifically oriented accounts should agree that consciousness is in some sense based in the brain; once this fact is accepted, the problem arises of why the brain basis of this experience is the basis of this one rather than another one or none, and it becomes obvious that nothing now known gives a hint of an explanation.

The explanatory gap was first brought to the attention of scientists through the work of Nagel (1974) and Crick and Koch (Crick, 1994; Crick & Koch, 1998). Many would argue that the candid recognition of what we do not understand played an important role in fueling the incredible wave of research that still engulfs us.

How do the three theories account for the explanatory gap?

The HOT view says that consciousness of, say, red is a matter of three ingredients: a higher order thought, a representation with the content red, and an aboutness relation between the first and the second. According to the HOT perspective, each of these ingredients can exist individually without any consciousness. We have unconscious thoughts—for example, subliminal representations of red—and those unconscious thoughts are, unconsciously, about things. According to the HOT theory, if a subject has an unconscious representation of red, and then forms an unconscious thought about the representation of red, the representation of red automatically is conscious. Of course, in some trivial sense of “conscious” we might decide to *call* that representation of red conscious, meaning *only* that there is a higher-order thought about it; but if the HOT theory is about consciousness in the full-blooded sense in which for a state to be conscious is for there to be something it is like to be in that state, there is a fundamental mystery for the HOT view.

It may seem that this is just *the* explanatory gap in a new form, one appropriate to the HOT theory, but that assertion is a mistake. Consider the prime order thought (POT) view—which says that thoughts about thoughts about thoughts . . . are always conscious so long as the number of embeddings is prime. There is a puzzle of the *POT view’s own making* of why a prime number of embeddings creates consciousness, but that puzzle is not the *real* explanatory gap.

The real explanatory gap is the problem of why the neural basis of a conscious state with a specific conscious quality is the neural basis of that conscious quality rather than another or nothing at all. The real explanatory gap does not assume any specific theory except the common basis of all scientific approaches in the 21st century, that conscious qualities *have* a brain basis.

The problem for the HOT perspective is that it is part of the idea of it that putting together ingredients that are not in themselves conscious (thought, aboutness, and representation) automatically exhibits consciousness. The most neuroscience can do is explain thought, explain aboutness, and explain representation. But there is no reason to expect—and it is not part of any HOT perspective—that neuroscience will find some magic glow that occurs when those things combine.

The fact that the HOT theory cannot recognize the real explanatory gap makes it attractive to people who do not

agree that there is an explanatory gap in the first place—the HOT theory is a kind of “no consciousness” theory of consciousness. But for those who accept an explanatory gap (at least for our current state of neuroscientific knowledge), the fact that the HOT theory does not recognize one is a reason to reject the HOT theory. The HOT theory is geared to the cognitive and representational aspect of consciousness, but if those aspects are not the whole story, the HOT theory will never be adequate to consciousness.

This very short argument against the HOT approach also applies to the global workspace theory, albeit in a slightly different form. According to the global workspace account, the answer to the question of why the neural basis of my experience of red is the neural basis of a conscious experience is simply that it is globally broadcast. But why is a globally broadcast representation conscious? This is indeed a puzzle for the global workspace theory but it is not the explanatory gap because it presupposes the global workspace theory itself, whereas the explanatory gap (discussed previously) does not.

The most neuroscience can do for us according to the global workspace account is explain how a representation can be broadcast in the global workspace, but the task will still remain of explaining why global broadcasting, however realized, is conscious. In principle, global broadcasting could be realized in an electronic system rather than a biological system, and of course the same issue will arise. So that issue cannot be special to the biological realization of mind.

The biological account, by contrast, fits the explanatory gap—indeed, I phrased the explanatory gap in terms of the biological account, asking how we can possibly understand how consciousness could be a biological property. So the biological account is the only one of the three major theories to fully acknowledge the explanatory gap. From the point of view of the HOT and global workspace theories, their task concerning the explanatory gap is not to show how they can accommodate it, but rather to *explain away our impression that there is one*. One such attempt will be considered in the next section.

There is a fine line between acknowledging the explanatory gap and surrendering to dualism, as also discussed in the next section.

The explanatory gap and dualism

Dualism is the view that there is some aspect of the mind that is not physical (Chalmers, 1996). It comes in many varieties, but the issues to be discussed do not depend on any specific variety.

Let us start with a historical analogy (Nagel, 1974). A pre-Socratic philosopher would have no way of understanding how heat could be a kind of motion or of how light could be a kind of vibration. Why? Because the pre-Socratic

philosopher did not have the appropriate concepts of motion—namely, the concept of kinetic energy and its role—or of vibration—namely, the concepts involved in the wave theory of light—that would allow an understanding of how such different concepts could pick out the same phenomenon.

What is a concept? A concept is a mental representation usable in thought. We often have more than one concept of the same thing. The concept *light* and the concept *electromagnetic radiation of 400–700 nm* pick out the same phenomenon. What the pre-Socratic philosopher lacks is a concept of light and an appropriate concept of vibration (one that requires a whole theory). What is missing for the pre-Socratic is not just the absence of a theoretical definition but a lack of understanding of what things are *grouped together* from a scientific point of view. We now realize that ripples in a pond, sound, and light are all phenomena of the same kind: waves. And we now realize that burning, rusting, and metabolizing are all cases of oxidation (Churchland, 2002), but the pre-Socratics, given their framework in which the basic categories were fire, earth, air, and water, would have had no way to grasp these facts. One upshot is that if superscientists of the future were to tell us what consciousness is, we probably would not have the conceptual machinery to understand, just as the pre-Socratic would not have the conceptual machinery to understand that heat is a kind of motion or that light is a kind of vibration.

Armed with this idea, we can see how to steer between the explanatory gap and dualism. What we lack is an objective neuroscientific concept that would allow us to see how it could pick out the same phenomenon as our subjective concept of the experience of green. And we can expect that we do not even have the right subjective concept of the experience of green, since we are not sure what subjective phenomena truly should be grouped together. The resolution of the apparent conflict between the explanatory gap and physicalism is that subjectivity and objectivity can be seen as properties of *concepts* rather than properties of the states that the concepts are concepts of. This idea, that we can see arguments that apparently indicate ontological dualism—that is, a dualism of objects or substances or properties—as really an argument for *conceptual* dualism, stems from Nagel (1974) and Loar (1990/1997) and is sometimes called New Wave physicalism (see Horgan & Tienson, 2001).

Another way of seeing the point is to consider Jackson's (1982) famous thought experiment concerning Mary, a neuroscientist of the distant future who knows everything there is to know about the scientific basis of color experience, but has grown up in a black-and-white environment. When she sees red for the first time, she learns what it is like to see red, despite already knowing all the scientific facts about seeing red. Does this show that the fact of what it is like to see red is not a scientific fact? No, because we can think of what

Mary learns in terms of her acquiring a subjective *concept* of a state that *she already had an objective concept of*. Imagine someone who already knows that Lake Michigan is filled with H₂O, but learns something new: that Lake Michigan is filled with water. What this person learns is not a new fact but a new piece of knowledge, involving a new concept, of a fact the person already knew. Similarly, Mary acquires new knowledge, but that new knowledge does not go beyond the scientific facts that she already knew about, and so does not support any kind of dualism. (This line of thought is debated in Block, 2006; White, 2006.)

Importantly, this line of reasoning *does not do away with the explanatory gap* but rather reconceives it as a failure to understand how a subjective and an objective concept can pick out the same thing.

These points about different concepts of the same thing have sometimes been used to try to dissolve the explanatory gap (Papineau, 2002). The idea is that the false appearance of an explanatory gap arises from the gap between a subjective concept of a phenomenally conscious state and an objective concept of the same state. But note: I can think the thought that the color I am now experiencing as I look at an orange (invoking a subjective concept of orange) is identical to the color between red and yellow (invoking an objective concept of orange). But this use of the two kinds of concepts engenders no explanatory gap.

Thus far, the score is biological theory 1, HOT and global workspace 0. But the competition has not yet encountered the heartland of the HOT theory.

Consciousness-of

It is very often (but not always—Dretske, 1993) assumed that a conscious state is a state that one is conscious of being in (Lycan, 1996a). I am willing to agree in order to focus on other matters. The HOT theory has an attractive explanation of this claim, because consciousness-of can be cashed out as being the object of a HOT. However, there are two other accounts of why a conscious state is one that one is conscious of being in, and these accounts are preferable to the HOT account—according to the viewpoint of the biological theory and the global workspace theory. The deflationary account (Sosa, 2003) says that all there is to being conscious of one's experience is the triviality that in having an experience, one experiences it, just as one smiles one's smile and dances one's dance. Consciousness-of in this sense is to be firmly distinguished from attending to one's experience (Burge, 2006). One can have a conscious experience of red, and that experience can have whatever awareness comes with conscious experience, even in the absence of top-down attention to it (Koch & Tsuchiya, 2007). Another rival to the higher order account of why a conscious state is one that one is conscious of is the *same order* account in which

a conscious pain is reflexive in that it is about itself. That is, it has a content that turns back on itself, and that is what makes a pain a state one is conscious of. This view had its beginnings in Aristotle (Caston, 2002) and was later pursued by Brentano (1874/1973). (See Burge, 2006; Kriegel & Williford, 2006.) Either one of the deflationary or same order accounts can be adopted by advocates of the biological view and the global workspace view, so I see no real advantage for the HOT view here.

Further problems for the HOT theory

I argued that the HOT theory cannot recognize an explanatory gap, but my argument was oversimple because it neglected a crucial distinction between two types of HOT theories. The kind of HOT theory that cannot recognize an explanatory gap is the *ambitious* HOT theory of *phenomenal* consciousness that analyzes *phenomenal* consciousness in terms of higher order thought. But there is also a *modest* and therefore innocuous form of the HOT theory that just says that, in addition to phenomenal consciousness, there is *another kind of consciousness*, higher order consciousness. Phenomenal consciousness is one thing, and higher order consciousness is another. The modest form can recognize an explanatory gap for phenomenal consciousness. The modest account is suggested by Lycan's remark, "I cannot myself hear a natural sense of the phrase 'conscious state' other than as meaning 'state one is conscious of being in'" (Lycan, 1996b). As Lycan recognizes, what one can and cannot "hear" leaves the theoretical options open. The modest account is tantamount to a verbal claim—that there is a sense of the term "conscious" (distinct from "phenomenal consciousness") that has a higher order meaning—and does not dictate that there is no explanatory gap. The very short argument against the HOT theory (that it does not recognize an explanatory gap and so is false) is an argument only against the *ambitious* form of the HOT theory. In the rest of this section, I will explain some other problems with the ambitious HOT theory that also do not apply to the *modest* version.

The first thing to realize about the HOT theory in both the ambitious and modest forms is that it needs considerable qualification. Suppose I consciously infer that I am angry from my angry behavior, or—in a slightly different kind of case that need not involve conscious inference—I am aware of my anger in noticing my angry fantasies. In these cases we would not say the anger is thereby conscious. Further, Freudians sometimes suppose that a subject can unconsciously recognize his own desire to, for example, kill his father and marry his mother, along with the need to cloak that desire in a form that will not cause damage to the self. But we would not say that in virtue of such an unconscious HOT (one that cannot readily become conscious) about it, the desire is therefore conscious! These examples concerning

what we would say suggest that a HOT about a state is not something we regard as sufficient for the state to be conscious. Defenders of the HOT theory introduce *complications* in the HOT theory to try to avoid these counterexamples. Rosenthal (2005a) says that S is a conscious state if and only if S is accompanied by a thought to the effect that the subject is in S *that is arrived at without inference or observation of which the subject is conscious*. The italicized phrase avoids the problems posed by conscious observation of angry fantasies and conscious inference by stipulating that HOTs arrived at by conscious observation and inference are not sufficient for consciousness. (Another stipulation that I will not describe is supposed to handle the Freudian issue.) Suppose as a result of biofeedback training I come to have noninferential non-observational knowledge of states of my liver (Block, 1995). Since we would not count the state of the liver as conscious in virtue of the HOT about it, Rosenthal (2000b, p. 240) further stipulates that only mental states can be conscious. What if I have a HOT about my future or past mental state? Rosenthal (2000b, p. 241) further stipulates that if one has a thought about a state, that makes it conscious only when one thinks of it as present to oneself.

As Bertrand Russell noted in an often-quoted passage (1919, p. 71), "The method of 'postulating' what we want has many advantages; they are the same as the advantages of theft over honest toil." Honest toil is not required if the HOT view is understood as a modest account, since *stipulation is not a problem in a stipulated sense of a term*, but ad hoc stipulation is a problem if we take the HOT view as an ambitious account, especially as an empirical theory of consciousness.

A second class of issues concerns the "mismatch problem," the possibility of a mismatch in content between a sensory representation and the accompanying HOT. What phenomenally conscious quality does an experience have if a HOT to the effect that one has a dull throbbing pain in the toe is accompanied not by any representation of toe damage but instead a visual representation of red—or by no sensory representation at all? If the sensory representation determines the conscious quality all by itself, the contents of HOTs are irrelevant here, and if here, why not elsewhere? And if the HOT determines the conscious quality without the sensory representation, then the contents of sensory representations are irrelevant—so what is the difference between *thinking* you have a delightful experience and actually having one (Byrne, 1997; Neander, 1998; Balog, 2000; Rey, 2000; Levine, 2001)? Of course, new sophistication in one's HOTs, as when one learns to recognize different wines, can cause a corresponding differentiation in the sensory states that the HOTs are about, but HOTs are not always causally self-fulfilling (if only!), and in any case, causal self-fulfillment does not answer the *constitutive* question of what the difference is between thinking you have an experi-

ence of a certain sort and actually having one. Rosenthal (2000b; 2000a; 2005b, pp. 217–219) claims that a HOT is sufficient for a conscious state even without any sensory representation that the HOT is about. But suppose I have a sharp pain that causes a HOT to the effect that I have a sharp pain, through the normal processes by which pains often cause metacognitions about them. And suppose that by chance I also have a qualitatively different sharp pain (one pain is a bit sharper than the other) that produces no HOT at all. The content of the HOT—that I have a sharp pain—does not distinguish between the two pains even though by any ordinary standard it is about one of them but not the other. If the HOT theory follows common sense, saying that one pain is conscious but the other is not, it is hard to see how that (partly causal) way of cashing out aboutness could be compatible with the claim that a HOT to the effect that I am in pain could be a conscious pain on its own without any sensory representation.

A third class of issues concerns children. If you have seen and heard a circumcision, you may find it difficult to doubt that it hurts. Relevant evidence: newborns who are circumcised without anesthesia or analgesia are more stressed by later vaccination even 6 months later (Taddio, Goldbach, Ipp, Stevens, & Koren, 1995). My point is not that you should be totally convinced of phenomenal consciousness in early infancy, but rather that you should be convinced that there is a *better* case for phenomenal consciousness in infancy than there is for those instances of phenomenal conscious-

ness being accompanied by higher order thought.

One point against higher order thought in infancy is that frontal cortex, the likely neural home of thought about thought (Stone, Baron-Cohen, & Knight, 1998) is immature in infancy. Gazzaniga, Ivry, and Mangun (2002, pp. 642–643) discuss two sources of evidence that areas of the brain that specialize in sensory and motor function develop significantly earlier than areas responsible for thinking. One source of evidence derives from autopsy results on human brains from age 28 weeks after conception to 59 years of age. The result, diagrammed in figure 77.2, is that auditory synaptic density peaks at about 3 months (and probably likewise for synaptic density in other sensory areas), whereas the association areas of the frontal cortex peak at about 15 months. Similar results apply to PET imaging, which measures glucose metabolism in different parts of the brain.

As infants become more mature, our confidence in their phenomenal consciousness increases, as does our confidence in their capacity for higher order thought. However, it continues to be doubtful that phenomenally conscious states are always accompanied by higher order thoughts. Children even up to age 3–4 have difficulty thinking about their own states of mind. For example, Alison Gopnik and her colleagues (Gopnik & Graf, 1988) used a tube that was open at both ends and contained a window that could be open or closed. The child would be asked to either look in the window or reach into the side and identify a common object, for example, a spoon. Then with the apparatus taken away, the

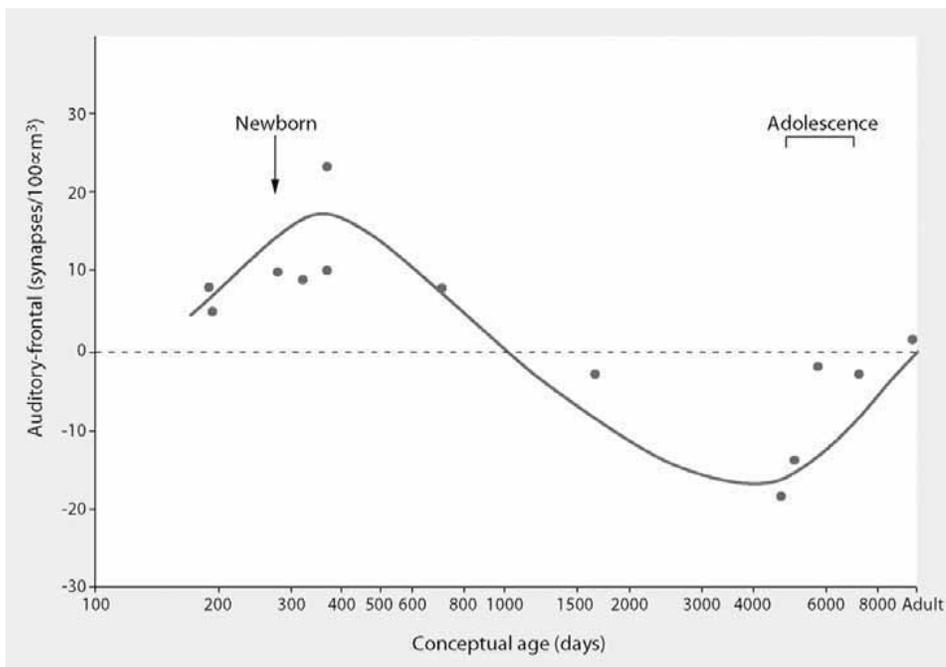

FIGURE 77.2 Relative synaptic density of auditory and frontal cortex. Conceptual age is age from conception. The peak at the left of roughly three months (postnatal) reflects a high number of auditory synapses relative to frontal synapses. (From Gazzaniga, Ivry, & Mangun, 2002.)

child was asked how he or she knew the spoon was in the tube. The children were nearly random in their answers, probably because, as Gopnik has pointed out in a series of papers (see Gopnik, 2007), they have difficulty attending to and thinking about their own representational states. Marjorie Taylor and her colleagues have compared “source amnesia” for representational states of mind with skills (Esbensen, Taylor, & Stoess, 1997). For example, some children were taught to count in Japanese, whereas other children were taught the Japanese word for “three.” Children were much less likely to be able to name the source of their representational state than the source of their counting skill. (For example, “You just taught me” in answer to the skill question versus “I’ve always known” in answer to the representational state question.) The source amnesia results apply most directly to conscious intentional states rather than conscious perceptual states, but to the extent that perceptual states are representational, they may apply to them as well. Older autistic children who clearly have phenomenally conscious states also have problems attending to and thinking about representational states of mind (Baron-Cohen, 1995; Charman & Baron-Cohen, 1995). Will a defender of the ambitious HOT theory tell us that these autistic children lack phenomenal states? Or that contrary to the evidence they do have HOT states?

I emphasize that it is difficult for young children and autists to think about representational states of mind—but not impossible. Indeed, children as young as 13 months can exhibit some ability to track others’ beliefs (Onishi & Baillargeon, 2005; Surian, Caldi, & Sperber, 2007). In the case of false belief, as in many other examples of cognition, a cognitive achievement is preceded by a highly modular and contextualized analog of it, one that partly explains the development of the cognitive achievement. My point is not that metacognition in all its forms is impossible in young children and autists but that, at all ages, our justification for attributing conscious states exceeds our justification for attributing metacognitive states.

Although the empirical case against the higher-order-thought point of view is far from overwhelming, it is strong enough to make the question salient of what the advantages of the *ambitious* higher-order-thought theory of consciousness actually are (as contrasted with the advantages of the modest version, which none of these points apply to).

But how do we know whether a version of the HOT theory is ambitious or modest? One way to tell is to ask whether, on that theory, a phenomenally conscious state—considered independently of any HOT about it—is something that is bad or good in itself. For example, Carruthers (1989, 1992) famously claimed that because pains in dogs, cats, sheep, cattle, pigs, and chickens are not available to be thought about, they are not felt and hence not anything to be concerned about; that is, they are states with no moral

significance. (Carruthers later, in 1999, took a different view on the grounds that frustration of animal desires is of moral significance even though the pains themselves are not.)

I turn now to related issues about the self that may seem to go against the biological view.

The self

The biological view may seem at a disadvantage with respect to the self. Since Hume (1740/2003) described the self as “that connected succession of perceptions,” many (Dennett, 1984; Parfit, 1984) have thought about persons in terms of integrated relations among mental states. The global workspace view seems well equipped to locate consciousness as self-related given that broadcasting in the global workspace is itself a kind of integration. And the HOT view at least requires the integration of one state being about another. By contrast, it looks as if, on many views of the biological basis of a conscious state (Block, 1995), it could exist without integration, and this point has resulted in accusations of scanting the self (Church, 1995; Harman, 1995; Kitcher, 1995). One response would be to favor a biological neural basis of consciousness that itself involves integration (Tononi & Edelman, 1998; Tononi & Koch, 2008). But it is worth pointing out that phenomenal consciousness has less to do with the self than critics often suppose.

What is the relation between phenomenal consciousness and the self? We could raise the issue by thinking about pain asymbolia, a syndrome in which patients have pain experiences without the usual negative affect (Aydede, 2005): they do not seem to mind the pain. In this syndrome, patients sometimes describe the pains as painful for someone else, and perhaps they are right given pain’s unusual lack of connection to the subject’s emotions, planning, and valuation. Here is a question about such a dissociation syndrome: If such a subject thinks about the painfulness of such a pain (as opposed to its merely sensory aspect), is the painfulness thereby phenomenally conscious? It would seem not, suggesting that the kind of integration supplied by HOTs is not actually sufficient for consciousness.

Here is another conundrum involving the relation between phenomenal consciousness and the self. In many experiments, activation in the fusiform face area at the bottom of the temporal lobe has been shown to correlate with the experience of a face. Now, injury to the parietal lobe often causes a syndrome called visuospatial extinction. If the patient sees a single object, the patient can identify it, but if there are objects on both the right and the left, the patient claims not to see one—most commonly the one on the left. However two fMRI studies (Rees et al., 2000; Rees, Wojciulik, et al., 2002) have shown that in patient GK, when GK claims not to see a face on the left, his fusiform face area lights up almost as much as when he reports seeing the

face. One possibility is that the original identification of the fusiform face area as the neural basis of face experience was mistaken. But another possibility is that the subject genuinely has face experience that he does not know about and cannot know about. Wait—is that really a possibility? Does it even make sense to suppose that a subject could have an experience that he does not and cannot know about? What would make it *his* experience?

The question about GK can be answered by thinking about the subject's visual field. We can answer the question of what the visual field is by thinking about how it is measured. If you look straight ahead, hold a rod out to the side, and slowly move it forward, you will be able to see it at roughly 100° from the forward angle. If you do the same coming down from the top, you will see it at roughly 60°, and if you do it from the bottom, you will see it at roughly 75°. More accurately, it is measured with points of light or gratings. Thus the visual field is an oval, elongated to the right and left, and slightly larger on the bottom. The Humphrey Field Analyzer HFA-II-I can measure your visual field in as little as 2 minutes. The United Kingdom has a minimum visual field requirement for driving (60° to the side, 20° above and below); U.S. states vary widely in their requirements (Peli & Peli, 2002). I mention these details to avoid skepticism about whether the visual field is real.

The visual field can help us think about GK. If GK does genuinely experience the face on the left that he cannot report, then it is in his visual field on the left side, and as such has relations to other items in his visual field, some of which he will be able to report. The fact that it is his visual field shows that it is *his* experience. I caution the reader that this discussion concerns the issue of whether it *makes sense* to describe GK as having an experience that he cannot know about and does not constitute any evidence for his actually having an experience that he cannot know about (but see Block, 2007a).

A second point about the relation between phenomenal consciousness and the self is that self-related mental activities seem inhibited during intense conscious perception. Malach and his colleagues (Goldberg, Harel, & Malach, 2006) showed subjects pictures and audio clips with two different types of instructions. In one version, subjects were asked to indicate their emotional reactions as positive, negative, or neutral. In another version (in which the stimuli were presented much faster), subjects were asked to categorize the stimuli, for example, as animals or not. Not surprisingly, subjects rated their self-awareness as high in the introspective task and low in the categorization task. And this testimony was supported by fMRI results that showed that the introspective task activated an “intrinsic system” that is linked to judgments about oneself, whereas the categorization task inhibited the intrinsic system, activating instead an extrinsic system that is also activated when subjects viewed

clips from Clint Eastwood's *The Good, the Bad, and the Ugly*. Of course this result does not show that intense perceptual experiences are not part of a connected series of mental states constituting a self, but it does suggest that theories that bring any *sense of self* into phenomenal experience are wrong-headed. Malach's result disconfirms the claim that a conscious visual experience consists in a perceptual state causing a thought to the effect that *I myself* have a visual experience (Rosenthal, 2005a).

Machine consciousness

The global workspace account lends itself particularly well to the idea of machine consciousness. There is nothing intrinsically biological about a global workspace. And the HOT view also is friendly to machine consciousness. If a machine can think, and if it can have representational contents, and if it can think about those contents, it can have conscious states, according to the HOT view. Of course, we do not know how to make a machine that can think, but whatever difficulties are involved in making a machine think, they are not difficulties about consciousness per se. (However, see Searle, 1992, for a contrary view.) By comparison, the biological theory says that only machines that have the right biology can have consciousness, and in that sense the biological account is less friendly to machine consciousness. Information is coded in neurons by electrical activations that travel from one part of a neuron to another, but in the most common type of transfer of information between neurons, that electrical coding is transformed into a chemical coding (by means of neurotransmitters) which transfers the information to another neuron where the coding of information is again electrical. On the biological view, it may well be that this transfer of coding of information from electrical to chemical and back to electrical is necessary to consciousness. Certainly it would be foolish to discount this possibility without evidence.

As should be apparent, the competitors to the biological account are profoundly nonbiological, having more of their inspiration in the computer model of the mind of the 1960s and 1970s than in the age of the neuroscience of consciousness of the 21st century. (For an example, see McDermott, 2001.) As Dennett (2001, 234) confesses, “The recent history of neuroscience can be seen as a series of triumphs for the lovers of detail. Yes, the specific geometry of the connectivity matters; yes, the location of specific neuromodulators and their effects matter; yes, the architecture matters; yes, the fine temporal rhythms of the spiking patterns matter, and so on. Many of the fond hopes of opportunistic minimalists [a version of computationalism: NB] have been dashed: they had hoped they could leave out various things, and they have learned that no, if you leave out *x*, or *y*, or *z*, you can't explain how the mind works.” Although Dennett resists the

obvious conclusion, it is hard to avoid the impression that the biology of the brain is what matters to consciousness—at least the kind we have—and that observation favors the biological account.

ACKNOWLEDGMENTS I am grateful to Susan Carey, Peter Carruthers, Christof Koch, David Rosenthal, and Stephen White for comments on an earlier version.

78 Recovery of Consciousness after Brain Injury: An Integrative Research Paradigm for the Cognitive Neuroscience of Consciousness

NICHOLAS D. SCHIFF

ABSTRACT This chapter reviews the evolving understanding of recovery of consciousness following severe brain injuries. Important questions guiding current research are considered including the need to develop new diagnostic tools based on neuroimaging methods that can guide longitudinal assessments of brain function. Novel assessments of cognitive function in the absence of behavior and slowly evolving plastic changes in brain structure that may arise after injury are reviewed. Emphasis is placed on the importance of developing more precise and testable models at the “circuit level” that are predictive of patterns of recovery and response to treatments. It is argued that recovery of consciousness in the human brain is likely to depend on interactions between dynamic circuit-level mechanisms that support reestablishment of goal-directed behaviors and cellular repair mechanisms. Further suggestions for the development of a cognitive neuroscience of the recovery of consciousness based on quantitative assessment of evolving changes in behavior and brain function are outlined.

Despite major advances in neuroscience, recovery of consciousness after brain injuries remains poorly understood. At the origin of this challenge is the surprisingly wide range of underlying brain function that may be present when confronted by a patient at the bedside with very limited or even no overt signs of behavioral responsiveness. Across the range of behavioral features consistent with clinical diagnoses ranging from vegetative state (no evidence of self or environmental awareness), minimally conscious state (at least some evidence of awareness), and up to but not including patients in locked-in state (full consciousness with no motor control), there are many patients whose level of consciousness we cannot at present confidently assess. This

chapter reviews several recent studies that have expanded our understanding of this problem and the fascinating conceptual challenges it presents for a cognitive neuroscience of consciousness. As will be discussed in greater detail, some patients with clinical examination features consistent with vegetative state, or demonstrating only the lowest level of nonreflexive motor responses indicating minimally conscious state (MCS), can be shown through the use of neuroimaging techniques to be able to follow commands and possibly have higher cognitive capacities. Other patients who show no functional recovery beyond MCS for five, ten, or twenty years may have substantial spontaneous (or induced) recoveries of spoken language and cognitive functions. Such patients have remained amnesic for the decades of intervening time while charting new and stable patterns of recovery. Other patients may recover memory and cognition but remain unable to control intact motor pathways, so that they cannot communicate their awareness to the people in their environment.

Among the central concerns of current research aimed at understanding the recovery of consciousness after brain injury are the following questions: Can functional neuroimaging techniques reliably, and operationally, identify levels of awareness, memory, and other higher brain functions in patients who do not show behavioral evidence of these cognitive capacities? What role do changes in brain structure and brain dynamics play in the recovery process? How do such changes, if present, evolve over time and develop? Can the natural recovery process be impeded by abnormal functional activity or be facilitated by interventions? As further developed in this chapter, several recent observations reveal hints of common “circuit-level” mechanisms linked to the impairment and recovery of human consciousness. Specific observations of the process of recovery of consciousness after

NICHOLAS D. SCHIFF Laboratory for Cognitive Neuromodulation, Department of Neurology and Neuroscience, Weill Medical College, Cornell University, New York, New York

brain injuries also point to a related set of biological mechanisms associated with changes in brain structure and intrinsic cellular function.

Disorders of consciousness: An overview

Figure 78.1 diagrams the varying relationships between impaired cognitive function and motor function in human disorders of consciousness. From the bottom left of figure 78.1, the conditions of coma and vegetative state (VS) are both considered unconscious brain states as judged behaviorally by complete unresponsiveness to environmental stimuli and lack of self-initiated behavior despite integrity of the motor pathways that could enable such action. Importantly, these clinical conditions are not diagnosed solely on behavioral criteria, and the natural history of the type of brain injury producing the condition is generally more important to the diagnostic process (see Posner, Saper, Schiff, & Plum, 2007; Schiff, 2007). Whereas comatose patients show no variations in state, and typically their eyes remain closed and they show no response to the most vigorous stimulation, VS patients recover a crude sleep-wake cycling reflected in irregular periods of eye opening and eye closure. This cyclical variation in VS does not correlate with identifiable electroencephalographic (EEG) features of either sleep or normal wakefulness; permanent vegetative state is typically associated with low-frequency, monotonous EEG signals, whereas MCS patients generally show preservation

of many key features of the normal structure of the sleep-wake EEG (Kobylarz & Schiff, 2005).

To the right of VS on figure 78.1 is a gray zone indicating a transitional group of patients with atypical clinical features who nonetheless show no response to external stimulation or evidence of intentional behaviors (see Schiff, 2004; Schiff, Ribary, et al., 2002). Once unequivocal but inconsistent evidence of awareness of self or the environment can be demonstrated at the bedside, patients enter into the minimally conscious state (MCS). MCS patients may show a wide range of clinical features (Giacino & Whyte, 2005) with the upper boundary determining a patient's emergence from MCS based on the recovery of reliable verbal or gestural communication. At present, there is no predictive time frame for emergence from MCS following severe brain injuries with rare examples of full recovery of fluent spoken language after more than ten years (see the section "Association between functional recovery and white matter structural changes"). Studies of functional outcome five years after injury demonstrate a lack of correlation of time in MCS and ultimate level of recovery (Lammi, Smith, Tate, & Taylor, 2005).

As seen in figure 78.1, it is possible that a patient with no controllable motor output channel may be fully conscious yet display a behavioral profile consistent with deep coma: eyes closed and unresponsive to any external stimuli as judged by a bedside examination. The locked-in state (LIS) at the far right bottom of the figure defines this condition and is not a disorder of consciousness. LIS patients

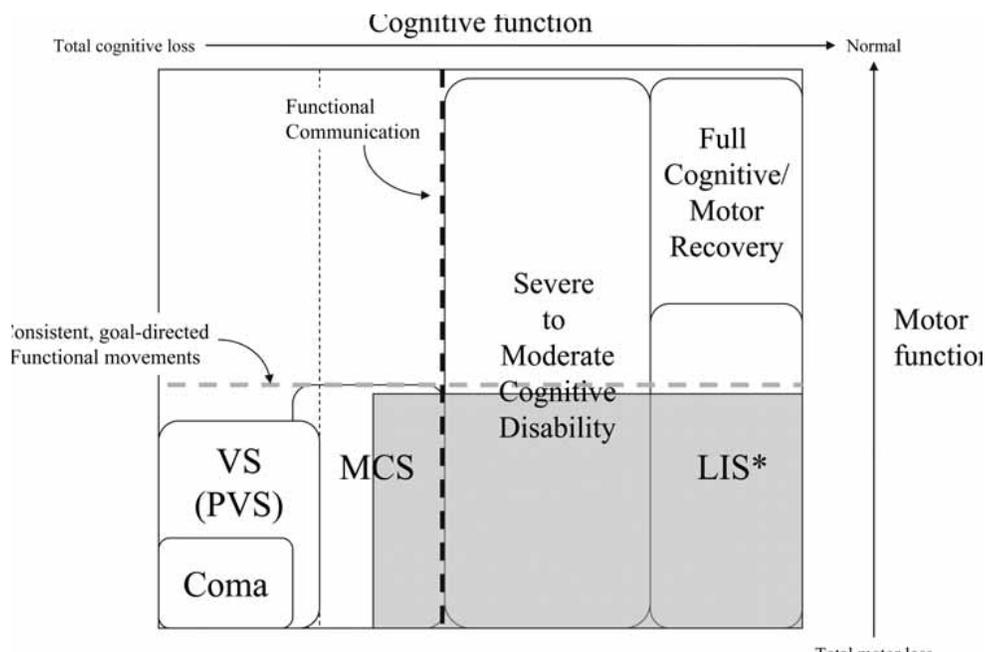

FIGURE 78.1 Correspondence of cognitive and motor impairment across human disorders of consciousness. VS, vegetative state; MCS, minimally conscious state; LIS, locked-in state, which is not a disorder of consciousness.

retain total preservation of cognitive function but may have no or little motor function. Those that have no motor function whatsoever are represented below the horizontal interrupted gray line in figure 78.1. Many LIS patients, however, can signal using eye movements and sometimes lateral head movements, and this group of LIS patients is represented above this line (Laureys et al., 2005). Brain injuries producing LIS typically involve the ventral pontine regions. Because of initial swelling causing transient dysfunction of nearby brain stem neurons that maintain arousal level (located in the dorsal pons and midbrain), LIS patients typically experience an initial comatose phase at onset of injury.

While a natural history of a neurological disorder that selectively disrupts the motor pathways or slowly erodes motor function may lead to the appropriate prospective expectation that the subject is conscious, the complexity of many brain injuries can make this determination highly uncertain. The large gray box covering the upper range of MCS and extending to the extreme left of the diagram identifies the most problematic set of patients where motor function is so severely impaired as to prohibit consistent goal-directed movements that allow for communication. Patients who retain significant cognitive capacity or remain within the normal range of cognitive function may not be recognizably different from MCS patients if motor impairment places them within this region of the figure. The uncertainty present in the assessment of such patients is perhaps the most difficult area for accurate measurement of brain state and cognitive capacity and indicates where evolving use tools of cognitive and clinical neuroscience will have their greatest impact. The variations of brain function and behavior seen between patients in vegetative state and minimally conscious state are treated elsewhere (see Schiff, 2004, 2005, 2006).

Between MCS and LIS, patients may retain varying levels of cognitive processing capabilities, awareness, memory, and other higher brain functions. If motor function is sufficiently impaired such that patients cannot reliably signal through controlled goal-directed movements (dashed horizontal line), it is not possible even using quantitative behavioral assessments to judge their cognitive capacity or communicate with them. Thus disentangling a patient's potential for cognitive function from limitations due to dysfunction of internal motor control systems and sensorimotor integration mechanisms presents the main challenge to understanding the nature of patients' interior states and developing strategies to help them. This diagnostic challenge is now being addressed by development of hierarchical neuroimaging protocols to systematically assess the integrity of sensory processing systems and assess the capacity to follow commands or establish a communication channel in the absence

of overt behavior (Owen et al., 2006; Coleman et al., 2007; Kübler & Kotchoubey, 2007).

Detecting awareness in the absence of behavioral responsiveness

Using a novel functional magnetic resonance imaging (fMRI) assessment paradigm, Owen and colleagues provided the first evidence that neuroimaging can be used in the absence of a visible behavioral response to obtain unambiguous evidence of the conscious responses indicated by command following (Owen et al., 2006). Typically, simple command following is assessed at a patient's bedside by observation of small movements such as finger, thumb, or eye movements in response to an examiner's direction. Reliable command following without the concomitant ability to use such small movements to establish a communication system is seen in many MCS patients (Giacino & Whyte, 2005). In a study of a patient who had remained in a diagnosed VS for 5 months following a severe traumatic brain injury, fMRI measurements provided evidence that the patient was able to activate very specific brain regions in response to complex commands when asked to carry out imaginary actions. As shown in figure 78.2, when asked to imagine playing tennis, the patient exhibited elevated brain activity in the supplementary motor areas matching the activity profile of normal subjects; similarly, when asked to imagine walking through the rooms of her house, the patient activated the parahippocampal gyrus, posterior parietal cortex, and lateral premotor cortex, regions activated in the normal control subjects carrying out this task (see figure 78.2 legend). At the time of the fMRI study, bedside examination of the patient showed evidence of only brief visual fixation, a possible transitional sign for evolution into MCS (Giacino et al., 2002) but a finding also consistent with permanent vegetative state in some patients (Jennett, 2002). Another examination 11 months later revealed visual tracking to a mirror, another transitional sign consistent with MCS, but no evidence of object manipulation or behavioral manifestations of command following or other external motor responses.

These imaging findings demonstrate a preservation of cognitive function that the clinical bedside examination in this particular patient failed to reveal and indicate a functional level at least consistent with MCS. Nonetheless, the demonstration of command following alone cannot clarify this patient's potential level of conscious awareness and cognitive capacity and leaves open the possibility that higher levels of function could be present. The findings, however, do demonstrate that the fMRI technique can be operationally exchangeable with behavioral evidence of command following as judged clinically at the bedside and in principle could provide a method for diagnosis of a nonbehavioral

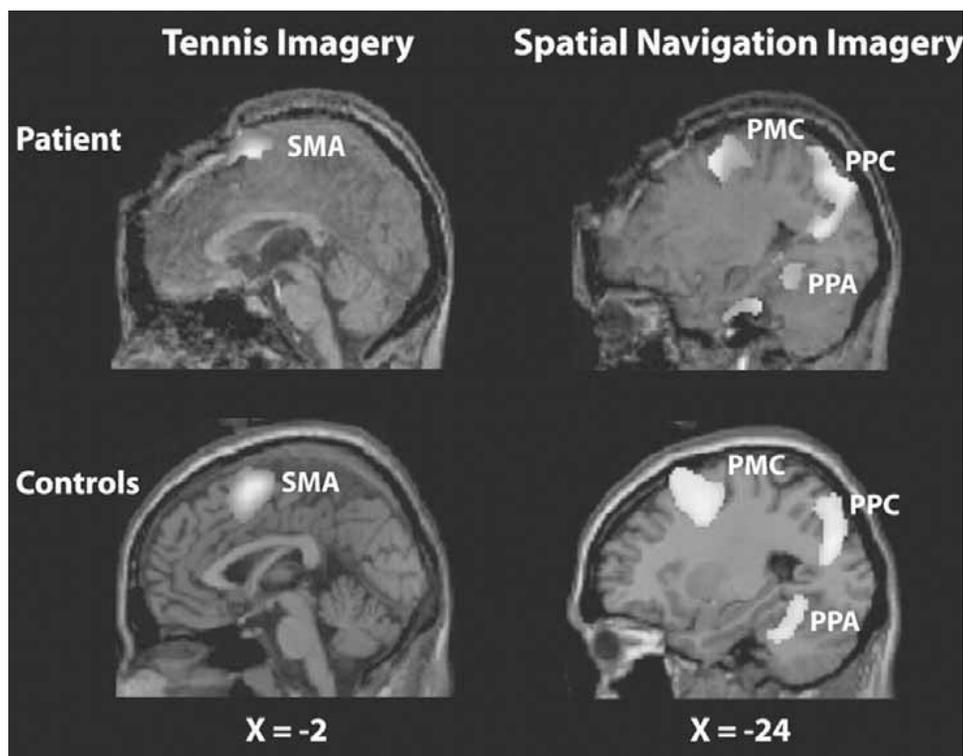

FIGURE 78.2 Command following in vegetative state (Owen et al., 2006). A 23-year-old woman with clinical exam consistent with VS, five months after severe traumatic brain injury with only brief periods of visual fixation, was asked to imagine playing tennis or

minimally conscious state (Fins & Schiff, 2006). Owen and Coleman (2008) have argued that “a ‘non-behavioural fully conscious state’ is equally plausible” for this patient, perhaps inferring the capacity for communication and higher cognition as implicit in the complex imaginal aspects of the commands followed. As noted previously, however, MCS patients who show consistent visible motor responses to complex commands and yet are unable to sustain interactive communication are not uncommon (Giacino & Whyte, 2005; Schiff et al., 2005).

More importantly, fMRI findings (or those of any other neuroimaging/measurement technique) should be not considered in isolation of the pathophysiological mechanisms underlying a patient’s brain injury. In the case of the patient studied by Owen and colleagues (2006), at least two factors raise doubts about the claim that the patient is likely to be “fully conscious.” The severe diffuse axonal injury suffered by the patient and the evident impact of the patient’s head injury on frontal systems (seen in the collapsed regions of skull across the patient’s frontal lobe visible in both panels of figure 78.2) likely index a significant underlying functional impairment of the frontal executive motor control systems. The cortico-striatopallidal-thalamocortical loop frontal systems are selectively vulnerable at the “circuit” level in the setting of many types of multifocal brain injury (see the

walking throughout her own house. The regionally selective brain activation patterns obtained from functional magnetic resonance imaging measurements for each condition were identical to those of normal controls. (Reproduced with permission.) (See color plate 91.)

following discussion), and metabolic depression of activity in these networks specifically grades with severity of behavioral impairment following diffuse axonal injury (Kato et al., 2007). Importantly, Owen and colleagues demonstrated the integrity of the motor pathways in their patient using transcranial magnetic stimulation methods, ruling out a contribution of interruption of the outflow from the motor cortex to the skeletal muscles accounting for their lack of initiated movements (Owen et al.). Thus a more parsimonious inference is that although this patient could follow commands, they likely remained unable to communicate and carry out goal-directed intentional behaviors because of generalized cognitive impairment.

The findings of the Owen and colleagues (2006) study extend earlier observations of widely preserved language responsive networks in some MCS patients (Schiff et al., 2005) by unambiguously demonstrating higher levels of cognitive function (command following) in a patient with only limited behavioral evidence of nonreflexive movements (limited to brief fixation that gradually improved to show isolated visual tracking). Importantly, such evidence of higher-level cerebral integrative activity indicates a potential substrate for further recovery. As noted earlier, time to recovery from MCS is variable, and some patients can make substantial improvement recovering spontaneous

fluent speech and reliable communication after a year or more of remaining at the MCS level of observable behaviors.

Association between functional recovery and white matter structural changes

Perhaps the most extreme case of late recovery is that of Terry Wallis, a man who at age 40 recovered full expressive and receptive language after remaining in MCS for 19 years following a severe traumatic brain injury suffered in a motor vehicle accident (Schiff & Fins, 2003). Structural magnetic resonance imaging studies of Wallis's brain revealed extensive cerebral and subcortical atrophy particularly affecting the brain stem and frontal lobes. Diffusion tensor magnetic resonance imaging (DTI), a technique that quantifies proton diffusion (in this case primarily water) and is used to measure the restriction of the direction of water flow (fractional anisotropy) as a proxy for axonal fiber integrity, revealed marked reduction in fractional anisotropy consistent with severe diffuse axonal injury. The severity of loss of axonal fibers can be appreciated qualitatively in figure 78.3 and quantitatively in figure 78.4 by comparing the volumes of the medial corpus callosum in 20 normal subjects to the measured values from Wallis's brain.

In a longitudinal DTI study of Wallis's brain, Voss and colleagues (2006) identified that in contrast to the overall severe reduction of brain connectivity demonstrated by reduced fractional anisotropy in most brain regions, DTI measurements also revealed large regions of increased fractional anisotropy in posterior brain white matter not seen in the normal subjects (figures 78.3 and 78.4) that had a prominent left-right directionality (colored red in the figure). These regions of posterior white matter anisotropy showed less strong directionality when measured in a second DTI study 18 months later, whereas similar significant increases in fractional anisotropy and left-right directionality were identified within the midline cerebellar white matter. At the time of the second study Wallis showed significant clinical improvements in motor control (limited use of lower extremities and left upper extremity, and improvement in dysarthria) over the intervening time period between the two studies correlating with the changes observed in the cerebellum (figures 78.3 and 78.4). These findings suggest the possibility that structural changes within Wallis's white matter may have played a role in his functional recovery of limb, trunk, and articulatory movements. A prospective study of severely brain-injured patients followed from early injury until approximately one year after injury found similar changes in recovery of initially reduced fractional anisotropy

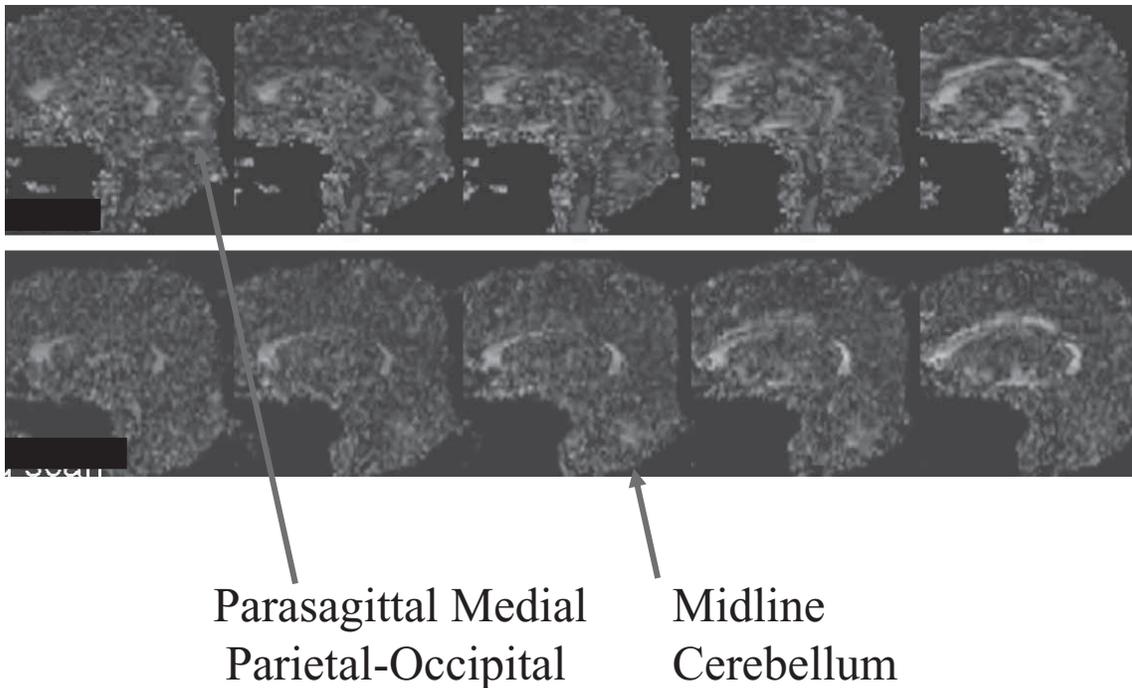

FIGURE 78.3 Diffusion tensor imaging studies of patient with late recovery (19 years) from MCS (Voss et al., 2006). Fractional anisotropy maps showing fiber tracks: red, fibers with left-right directionality; blue, fibers with up-down directionality; green, fibers with anterior-posterior directionality. Top images show volume loss of the corpus callosum throughout the medial component and regions

in parieto-occipital white matter with prominent left-right directionality. Bottom row images show fractional anisotropy maps obtained 18 months later that demonstrate reduction of left-right direction in parieto-occipital regions with increased anisotropy noted in the midline cerebellum. (See color plate 92.)

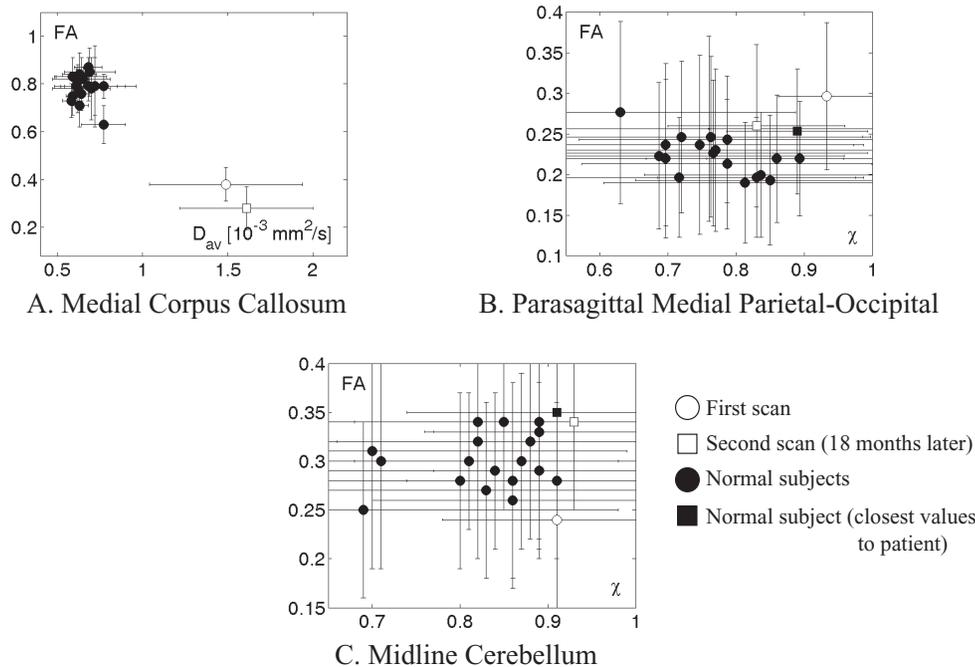

FIGURE 78.4 Quantitative comparison of midline cerebellum fractional anisotropy (FA) versus apparent diffusion (D_{av}) and left-right directionality (χ) for regions of interest following late recovery from MCS. Open-circle values were obtained from patient's first scan; open-square values were obtained from second scan; filled-circle values are from 20 normal subjects; filled squares indicate values of individual normal subject closest to patient value. (A) Medial

corpus callosum shows marked loss of fractional anisotropy in patient measured on both scans. (B) Parasagittal medial parietal-occipital region shows strong left-right directionality and increased fractional anisotropy in patient's first scan (see Voss et al., 2006, for details). (C) Midline cerebellum shows marked increase in fractional anisotropy over two studies. (Plots from Voss et al., 2006, with permission.)

in the internal capsule and centrum ovale, which later showed normal or supernormal levels of fractional anisotropy parallel to the axis of axonal fibers in the patients who recovered neurological function (Sidaros et al., 2008).

These findings can be compared with experimental studies that demonstrate late remodeling of cortical white matter connections following ischemic (stroke) injuries in monkeys. Following strokes, existing neurons are found to form extensive axonal arborizations to establish novel connections in intact brain regions (Dancause et al., 2005). Taken together, these observations suggest that the normal recovery process includes a component of structural remodeling that may stall and potentially be restarted under the appropriate conditions. Whether this process may have restarted in Wallis at close to the time of his reemergence of spoken language is not known. However, approximately 18 months prior to speaking he had been placed on paroxetine (a serotonin reuptake inhibitor), and his behavioral responsiveness for several years after emergence from MCS remained delicately dependent on the level of this medicine (unpublished observations). Recent studies suggest that chronic exposure to serotonin reuptake inhibitors may promote some aspects of neuronal plasticity (Wang, David, Monckton, Battaglia, & Hen, 2008).

Circuit mechanisms underlying forebrain dysfunction follow severe brain injury

The preceding observations that patients with no apparent, or only very limited, evidence of awareness may retain or regain large-scale integrative brain activity raises the critical question of what mechanisms might underlie their failure to exhibit goal-directed behavior despite, in some cases, the integrity of motor pathways. An important clue is given by recent studies of the anatomic pathology associated with severe brain injuries producing chronic disorders of consciousness. Autopsy studies of both traumatic and nontraumatic severe brain injuries demonstrate a common finding in permanent vegetative state of widespread death of thalamic neurons in patients with either multifocal cerebral neuronal death from anoxia or diffuse axonal injury producing multiple disconnections of fiber pathways (Adams, Graham, & Jennett, 2000). The severe bilateral thalamic damage seen in both types of injury is not invariably associated with diffuse cortical damage. This finding can be understood in the context of the dense innervation of the thalamus by the cortex so that multifocal loss of cortical neurons is reflected by a greater impact on thalamic neurons that undergo neuronal death following sufficient deafferentation.

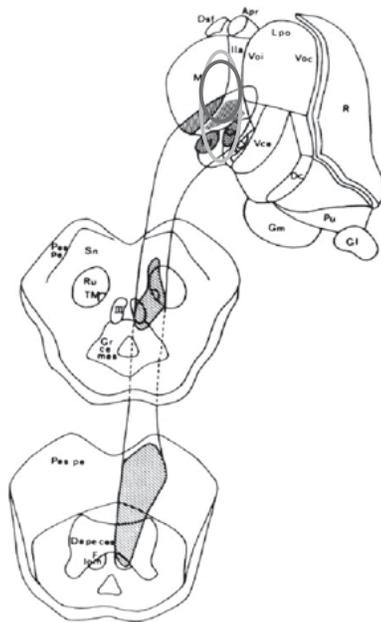

Importantly, specific components of the thalamus are more sensitive reporters of global, multifocal injuries. The nuclei that comprise the central thalamus (the intralaminar nuclei and related paralaminar nuclei) show the most marked cell loss with traumatic injuries and the degree of neuronal loss observed in these nuclei grades with outcome (Maxwell, MacKinnon, Smith, McIntosh, & Graham, 2006). Loss of neurons within the anterior intralaminar nuclei (central lateral nucleus, central medial, paracentralis) is identified in patients who recovered to a level of moderate disability with progressive involvement of more ventral and lateral nuclei of the central thalamus (posterior intralaminar group) seen in patients with severe disability and permanent vegetative state. Figure 78.5 diagrams the pattern of structural injury to the central thalamus and midbrain seen in patients with bilateral focal strokes that produce immediate coma and enduring vegetative state or minimally conscious state (Castaigne et al., 1981; Schiff & Plum, 2000). The neuronal populations overlap those neurons that undergo progressive deafferentation with increasingly severe multifocal brain injuries (Maxwell et al.) as shown in figure 78.5B, whereas the first loss of neurons associated with moderate disability

following brain injury occurs in the more anterior intralaminar regions.

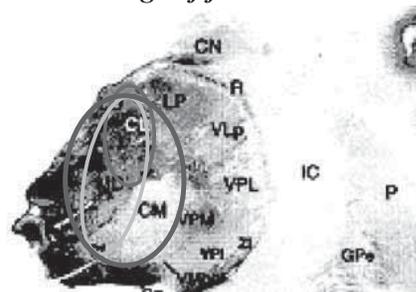

The observation that neurons within the central thalamus are more vulnerable to multifocal injuries can be first understood simply in terms of their geometry of connections: they have wide point-to-point connectivity across the four lobes of the cerebral hemisphere and are positioned to integrate neuronal cell death across these large territories (van der Werf, Witter, & Groenewegen, 2002; Scannell, Burns, Hilgetag, O'Neil, & Young, 1999). The marked impact of isolated injuries to these neuronal populations noted previously indicates that neurons in the central thalamus also have a specific causal role in producing impaired integrative forebrain function when damaged directly (Castaigne et al., 1981; Schiff & Plum, 2000). This contribution to forebrain dysfunction following either focal injury or deafferentation as a consequence of diffuse brain injuries is most likely linked to their established contribution to normal mechanisms of arousal regulation (Schiff, 2008).

Neurons within the central thalamus have anatomical and physiological specializations that make them uniquely positioned to control arousal levels and the dynamic

A. Anatomical localization of focal subcortical injuries producing acute coma, persistent vegetative state and minimally conscious state

B. Regional neuronal cell loss in central thalamus across range of functional outcomes

- Vegetative

FIGURE 78.5 Contributions of the central thalamus to disorders of consciousness. (A) Focal injury patterns in the central thalamus associated with coma, vegetative state, and minimally conscious state. (B) Regional neuronal cell loss in central thalamus across the range of function outcomes. Moderately disabled (red): neuronal loss in median dorsalis, rostral central medial, central lateral and

paracentral nuclei. Severely disabled (green): includes moderately disabled regions plus neuronal loss from median dorsalis, caudal central medial, parafascicular nucleus. Permanent vegetative state (blue): all of above and centromedian nucleus. (Figure elements adapted from Castaigne et al., 1981, and Munkle, Waldvogel, & Faull, 2000.) (See color plate 93.)

patterns of activation across large-scale cerebral networks (Groenewegen & Berendse, 1994; Llinas, Leznik, & Urbano, 2002; Jones, 2001; van der Werf et al., 2002; Purpura & Schiff, 1997; Schiff & Purpura, 2002; Schiff, 2008). The central thalamus is interposed between brain stem/basal forebrain “arousal systems” that control overall levels of depolarization of cortical and thalamic neurons and frontal “executive systems” that organize premotor shifts of attention and adjust the level of alertness and cognitive effort (Kinomura, Larsson, Gulyás, & Roland, 1996; Paus et al., 1997; van der Werf et al., 2002; reviewed in Schiff, 2008). In addition, individual neurons within these cellular aggregates are targets of a variety of dedicated brain stem sensory relays that have evolved to quickly capture attention and redirect behavior. The neurons within the central thalamus are recruited in response to increasing cognitive demands, stress, fatigue, and other perturbations that reduce behavioral performance (Kinomura et al., 1996; Paus et al., 1997; Nagai et al., 2004; Schiff, Hudson, & Purpura, 2002). From a functional point of view, central thalamic neurons may act as gain controls for distributed networks across the cortex, thalamus, and basal ganglia through a common mechanism of shifting the overall level of balanced excitatory and inhibitory synaptic barrage associated with an “UP state” like phenomena during wakefulness (Rudolph, Pelletier, Paré, & Destexhe, 2005; Shu, Hasenstaub, & McCormick, 2003; Schiff, 2008). Adjustments of firing rates within the central thalamus by mesial frontal control systems could thus depolarize neurons across the cerebral cortex and striatum and selectively gate their activation.

As illustrated in figure 78.6, an important aspect of vulnerability of the forebrain to dysfunction produced by deafferentation of the central thalamus is the key role of neurons from the intralaminar nuclei (both central lateral nucleus and parafascicularis nucleus) that project to the medium spiny neuron (MSN) of the striatum (Lacey, Bolam, & Magill, 2007). The MSNs have a “high-threshold”

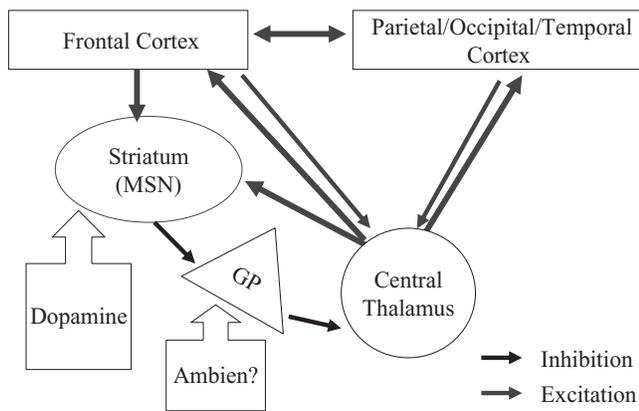

FIGURE 78.6 Connections of the central thalamus underlying their role in forebrain arousal regulation. See text.

UP state making it difficult to bring these neurons to their firing threshold; they require both sufficient levels of dopamine neuromodulation and a high level of spontaneous synaptic activity arising from excitatory corticostriatal and thalamostriatal inputs (Grillner et al., 2005). The output from the MSNs, in turn, opposes a tonic inhibitory activity of the globus pallidus interna on the thalamus. Loss of input from the central thalamus can potentially shut down the MSNs both through withdrawal of direct excitatory striatal projections (Lacey, Bolam, & Magill, 2007) and through downregulation of the frontocortical regions that provide the main corticostriatal input (Schiff & Posner, 2007). The circuit model shown in figure 78.6 provides an explanation for well-known observations that some patients with either mesial frontal or thalamic/midbrain injuries may respond to dopaminergic and similar agents that facilitate output of the MSNs and mesial frontal systems (Whyte et al., 2005). In addition, this simplified circuit description predicts that direct activation of the central thalamus would reverse downregulation across the corticostriatalpallidal-thalamocortical system produced by severe brain injury. It also offers an explanation of a surprising, paradoxical phenomenon recently described that zolpidem (the sedative agent known as Ambien that is a nonbenzodiazepine hypnotic that potentiates GABA-A receptors expressed in large quantity in the globus pallidus interna) can improve alertness and behavioral responsiveness in some severely brain-injured patients (Breufel-Courbon et al., 2007; Schiff & Posner, 2007).

Figure 78.7 shows unpublished positron emission tomography (PET) studies of resting brain metabolism from a patient who remained in MCS for two years prior to speaking after receiving a single dose of zolpidem. Over a five-year period with repeated dosing the patient gradually improved to emergence from MCS and reliable communication on or off the medication. During the patient’s off-drug periods, however, he was cognitively slowed and unable to complete oral feeding. As seen in figure 78.7, in the off-medication state a marked downregulation of metabolic activity is apparent across the corticostriatalpallidal-thalamocortical system of the anterior forebrain, which reverses with application of zolpidem. These findings reproduce identical shifts in forebrain metabolism measured by PET in another published study of zolpidem-induced recovery of function in a severely brain-injured patient (Breufel-Courbon et al., 2007). As noted in figure 78.6, because zolpidem binds selectively to the alpha-1 subunit of the GABA-A receptor that is highly expressed in the globus pallidus interna (GPI), it may act to suppress disinhibited GPI neurons facilitating thalamocortical and thalamostriatal afferents outflow to restore sufficient background synaptic activity to drive the MSNs and reestablish the long-loop network activation seen in the ON state (Schiff & Posner, 2007).

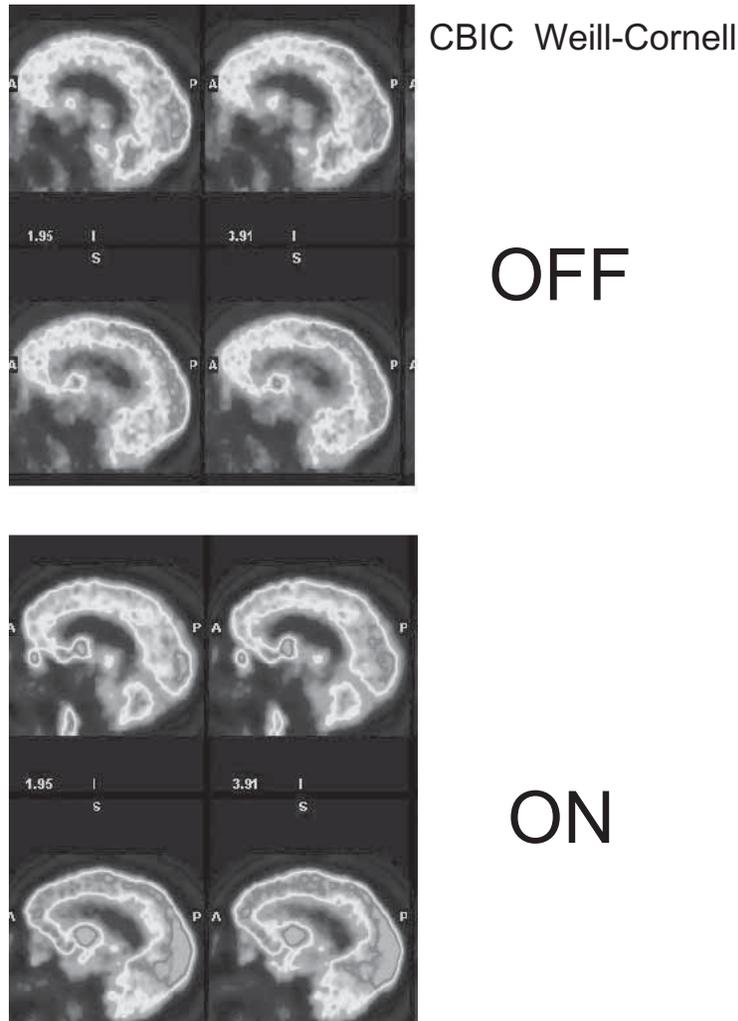

FIGURE 78.7 Changes in cerebral metabolism associated with zolpidem administration in severe brain injury. Two sets of parasagittal images of fluorodeoxyglucose positron emission tomography studies obtained in an awake, severely brain-injured patient are shown obtained one day apart. The OFF images show the resting metabolic profile in an awake state and demonstrate qualitative downregulation of metabolism in the anterior forebrain (frontal,

prefrontal cortex), basal ganglia, and thalamus. The ON images show the resting metabolic profile in an awake state 45 minutes after administration of the drug zolpidem. A marked qualitative increase in metabolism is observed in the anterior forebrain, basal ganglia, and thalamus. In addition, overall metabolic activity across cerebral structures is increased. (See color plate 94.)

Modulating behavioral responsiveness in the severely injured brain using central thalamic deep-brain stimulation

In the context of the model diagrammed in figure 78.6, the observations of indirect control of central thalamic output by facilitating MSNs firing through dopaminergic modulation or withdrawal of GPi inhibition predict that directly controlling excitatory output from the central thalamus would produce more consistent and sustained effects. Direct activation of central thalamic neurons through deep-brain electrical stimulation (DBS) has been proposed as an experimental therapeutic strategy (Schiff, Plum, & Rezai, 2000, 2002; Schiff & Purpura, 2002). A single-subject study of

central thalamic DBS tested the underlying hypothesis that electrical stimulation could restore arousal regulation and promote greater behavioral responsiveness in a 38-year-old man who had remained in MCS for six years (Schiff et al., 2007). Although the patient was unable to communicate reliably, earlier neuroimaging studies showed preservation of a large-scale cerebral language network (Schiff et al., 2005), suggesting that a substrate for further recovery might exist. Central thalamic DBS was proposed to, in part, substitute for the loss of top-down monitoring and regulation of arousal level by mesial frontal cortical regions and ascending brain stem arousal system inputs damaged by injury and functionally impaired through the same general circuit-level disturbance as diagrammed in figure 78.6 (multifocal cerebral

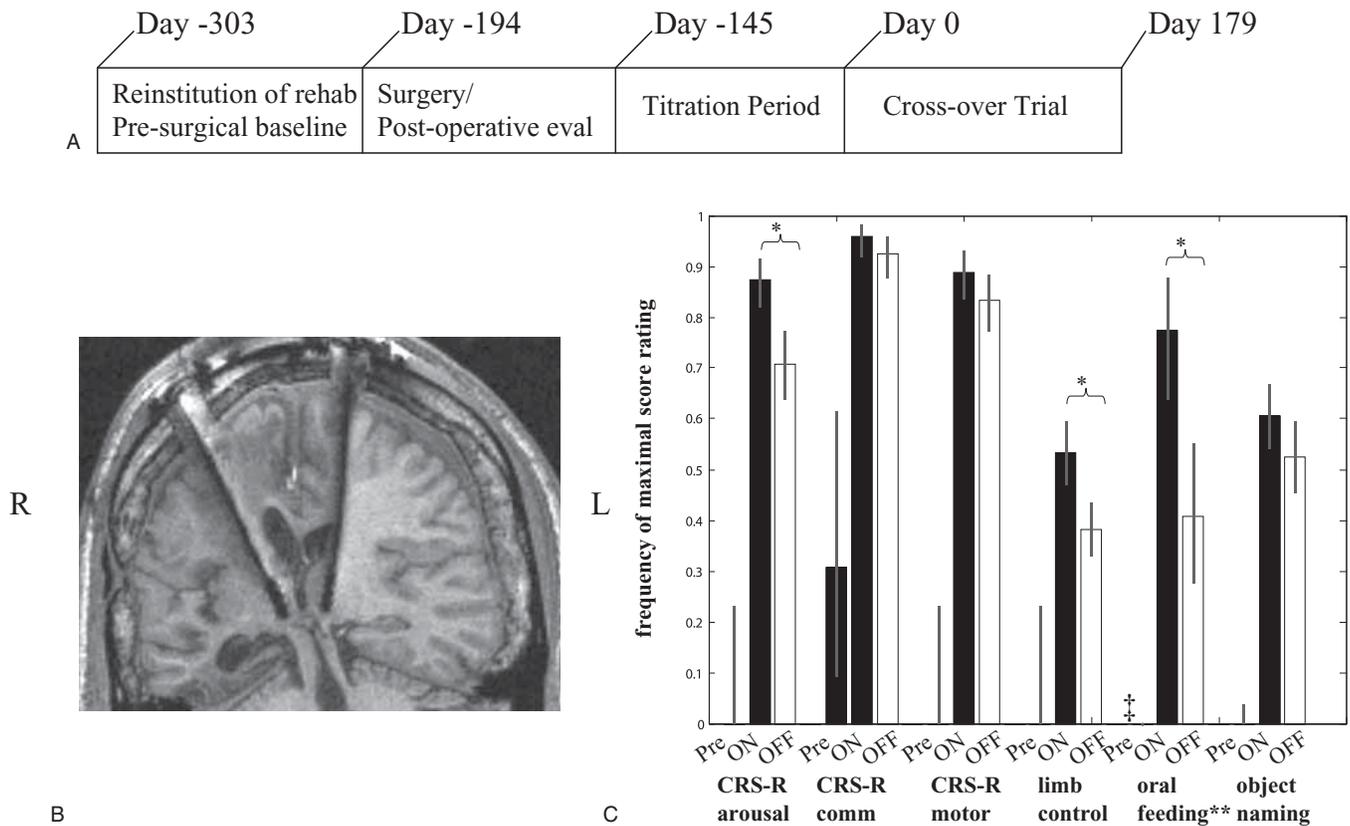

FIGURE 78.8 Central thalamic electrical stimulation in the minimally conscious state. (A) Time line of a single-subject study of deep-brain stimulation (DBS). (B) Placement of electrodes in the central thalamus. (C) Results of 180-day crossover study of DBS.

Statistically significant improvements during the crossover study in attentive behavior, oral feeding, and limb control are marked with asterisks (see text and Schiff et al., 2007, for further details).

deafferentation and dampening of forebrain arousal regulation within the mesial frontal and central thalamic network connections).

Figure 78.8 displays the overall design of the study and main results (Schiff et al., 2007). The patient was monitored over an 11-month period that included six months of behavioral baseline evaluations (four months prior to surgery, two months following surgery prior to titration testing of stimulation parameters) that indicated no change in level of behavioral responsiveness as compared to testing done prior to discharge to chronic care facility more than two years before the start of the trial. Electrodes were placed bilaterally in the central thalamus targeting the intralaminar nuclei with the central lateral nucleus in midposition of the electrode contacts (see figure 78.8). A five-month period of titration testing demonstrated immediate and accumulating effects of DBS that included the emergence of consistent and intelligible spoken language, recovery of limb control, and the capacity for oral feeding (the patient was fed by a gastrostomy tube for five years prior to this phase of the study). Following titration testing, a single stimulation parameter set was chosen for testing in a blinded six-month, 30-day alternating ON-versus-OFF study. The results of the crossover

study are shown in the graph in figure 78.8C. The crossover study demonstrated a robust overall effect on behavioral responsiveness measured by a formal quantitative assessment tool (see figure 78.8 legend) and significant stimulation-dependent modulation of oral feeding and limb control. Notably, all functional testing showed marked improvement against the six-month prestimulation baselines, but several measures hit a ceiling of improvement whether DBS was on or off during this later phase of the trial.

The observed carryover effects of improvements from the ON to the OFF state may be a result of strengthening activated synapses or other mechanisms underlying neuronal plasticity. These findings can be compared to evidence of accumulating effects of central thalamic electrical stimulation as shown in a rodent model. Herrera and colleagues studied rats undergoing continuous unilateral electrical stimulation of the central lateral nucleus (Shirvalkar, Seth, Schiff, & Herrera, 2006). The stimulated rats exhibited enhancements of observed improvements in an untrained goal-directed seeking behavior that requires object recognition memory over three days of testing (figure 78.9). The study also found increases in exploratory motor behaviors and grooming activity (Shirvalkar et al.). Separate experiments

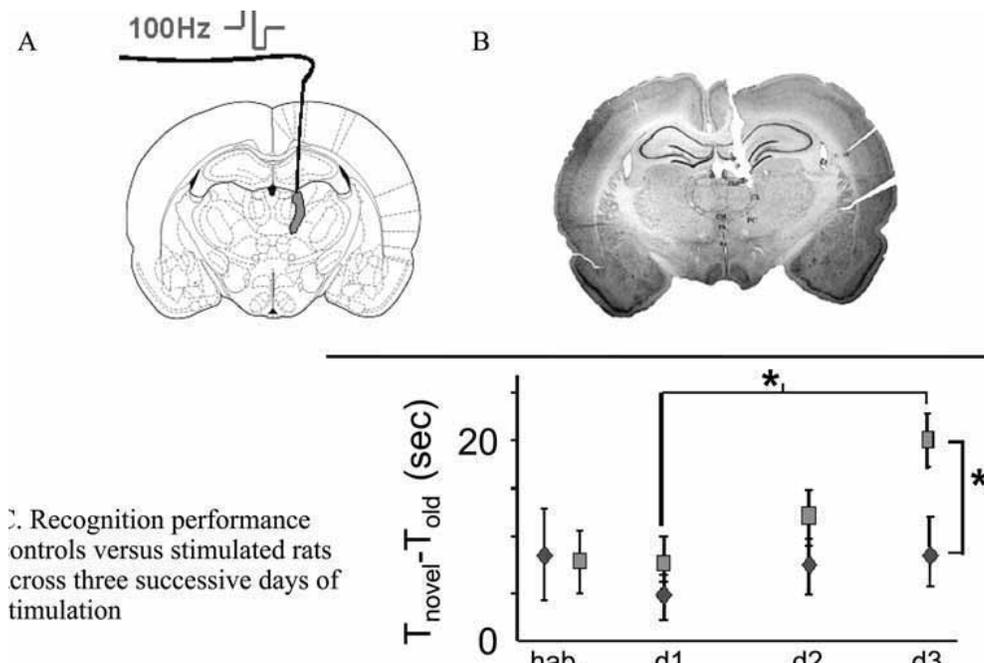

FIGURE 78.9 Facilitation of recognition memory with continuous electrical stimulation of the rat central thalamus (Shirvalkar, Seth, Schiff, & Herrera, 2006). (A) Electrode placement in the central thalamus. (B) Representative gross histological section. (C) Com-

parison of sham-stimulated controls and stimulated rat cohorts on object recognition task across three successive days of stimulation. Stimulated rats show increased performance and accumulation of effects. (See color plate 95.)

evaluated cerebral gene expression following exposure to the same electrical stimulation parameters. Central thalamic DBS produced upregulation of memory-related immediate early genes in the anterior cingulate cortex, motor cortex, and hippocampus indicating a link between DBS and cellular mechanisms of memory formation (figure 78.10). The pattern of memory-related immediate early gene activation observed shows a variation across cortical layers consistent with the known innervation pattern of the central lateral intralaminar afferents and laminar activation profile with electrical stimulation (figure 78.10; Llinas et al., 2002). Of note, similar changes in neocortical gene expression are observed after periods of sleep following induction of long-term potentiation (Ribeiro et al., 2002). These findings suggest that changes in cellular gene expression may be part of the mechanism for the observed carryover effects in the human trial and that effects on the sleep-wake periods may also have a role.

Conclusions and future directions

The evolving understanding of the recovery of consciousness in the severely injured brain described in this chapter indicates the need for developing new tools to guide longitudinal assessments of brain function. In addition, systematic efforts to evaluate time trials of pharmacologic agents and novel therapeutics should become part of the general approach to the problem. The goal of such work should be to formulate more precise and testable models at the circuit

level that are predictive of patterns of recovery and response to treatment. An important aspect of recovery is the evidence that plastic changes can arise very late after injury and likely depend on interactions between circuit mechanisms that reestablish goal-directed behavior initiating changes in the efficacy, or simply engagement of, cellular repair mechanisms. The findings reviewed indicate that impaired fore-brain dynamics may in some patients be dramatically altered by pharmacologic agents or central thalamic electrical stimulation. That carryover effects are seen with brain stimulation suggests that this induced recovery process may share common mechanisms with the slow changes observed in the Wallis case; however, the biological mechanisms remain unclear.

A unifying speculation is that changes in the overall level of activity within the circuit diagrammed in figure 78.6 occur in the setting of spontaneous or induced recovery of goal-directed behavior and communication that are the hallmarks of observed recovery of consciousness—although this process clearly can also evolve without correlative observable behavior! The main variable controlling the recovery of consciousness may be gradual improvements in the integrity of basic arousal regulation processes within the corticothalamic (corticostriatopallidal-thalamocortical) system. If this recovery process can be supervised, we will be able to understand in much greater detail how brain mechanisms link integrative dynamics of circuit-level functions such as attention, working memory, and motor preparation to the

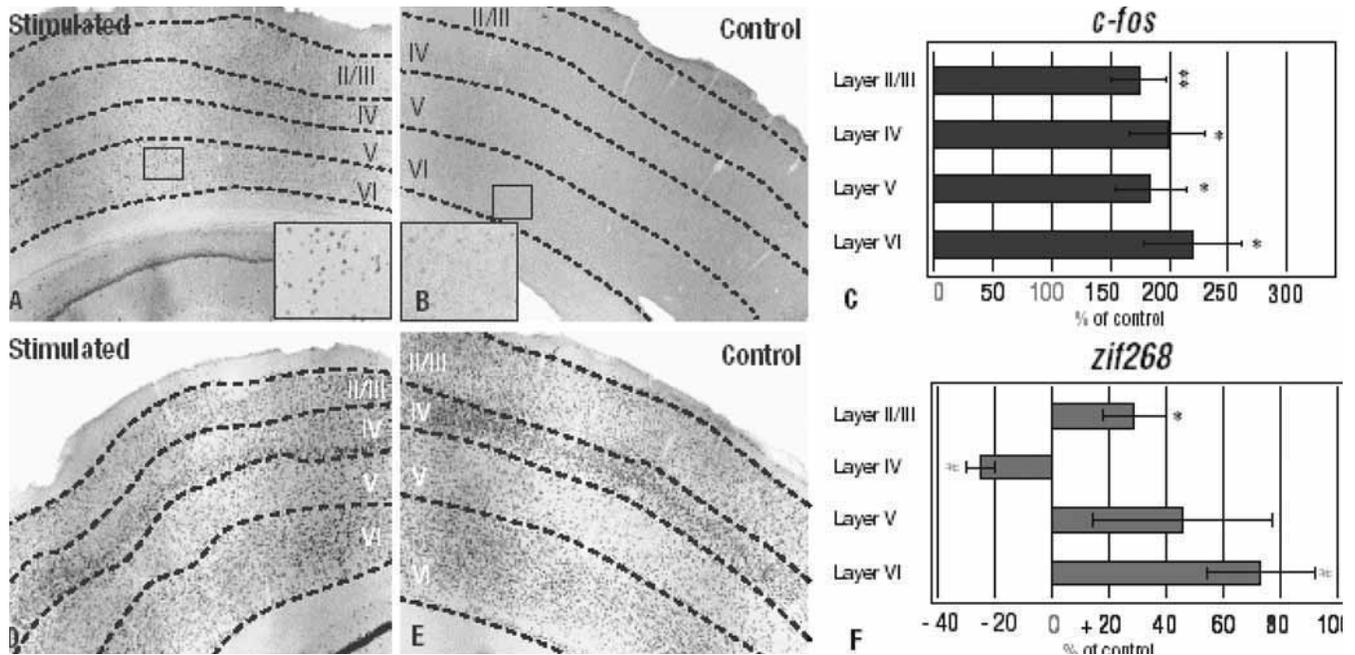

FIGURE 78.10 Gene expression changes in the motor cortex following central thalamic electrical stimulation. Gene expression changes associated with 30 minutes of electrical stimulation of the central thalamus in two immediate early genes, *c-fos* and *zif268*, are shown (Shirvvalkar et al., 2006). A broad increase of *c-fos* across cortical lamina is seen, consistent with increased synaptic activity.

A laminar specific pattern of changes in *zif268*, a memory-related gene, may link to accumulation effects seen in figure 78.9 and possibly to carryover effects observed in human-subject DBS study shown in figure 78.8 (see text and Shirvvalkar et al., 2006, for further details). (See color plate 96.)

cellular learning and memory mechanisms that support continuing functional improvements. Viewed from this perspective, controlling the interplay of observed behavioral and measured brain recovery may be the overarching goal of a cognitive neuroscience of the recovery of consciousness.

79 The Neurobiology of Consciousness

CHRISTOF KOCH

ABSTRACT Over the past two decades, the mystery of consciousness and its material basis has begun to be investigated by the sciences. The neurobiological approach to consciousness aims to identify its correlates at the neuronal level. Electrophysiological, psychophysical, and functional imaging studies in humans and nonhuman animals have allowed brain scientists to narrow their focus to the neural substrates of consciousness and conscious perception in the circuits of the forebrain, in particular the thalamocortical system and its satellites. These findings, complemented by the development of a robust theoretical predictive framework, should eventually lead to a rational understanding of the phenomenon of consciousness.

Consciousness is one of the most enigmatic features of the universe. People not only act but feel: they see, hear, smell, recall, plan for the future. These activities are associated with subjective, ineffable, immaterial feelings that are tied in some manner to the material brain. The exact nature of this relationship—the classical mind-body problem—remains elusive and the subject of heated debate (see Block, chapter 77, this volume). These firsthand, subjective experiences pose a daunting challenge to the scientific method that has, in many other areas, proven so immensely fruitful. The brute fact of consciousness comes as a total surprise; it does not appear to follow from any phenomena in traditional physics or biology.

People willingly concede that when it comes to nuclear physics or molecular biology, specialist knowledge is essential; but many assume that there are few relevant facts about consciousness, and therefore everybody is entitled to his or her own theory. Nothing could be further from the truth. There is an immense amount of relevant psychological, clinical, and neuroscientific data and observations that need to be accounted for.

Consciousness is a state-dependent property of certain complex, biological, adaptive, and highly interconnected systems. The best example of consciousness is found in a healthy and attentive human brain. In deep sleep, consciousness ceases. Small lesions in the midbrain, brain stem, and thalamus can lead to a complete loss of consciousness—

probably through inactivation of the cerebral cortex (Sukhotinsky et al., 2007)—while destruction of circumscribed parts of the cerebral cortex can eliminate very specific aspects of consciousness, such as the ability to be aware of motion or to recognize faces, without a concomitant loss of vision in general. Brain scientists are focusing on experimental approaches that shed light on the neural basis of consciousness rather than on eristic philosophical arguments with no clear resolution. This chapter reviews these experimental approaches.

What phenomena does consciousness encompass?

Consciousness has been dissected on conceptual grounds (access versus phenomenal consciousness; see Block, 2005, and chapter 77, this volume), ontological grounds (Hard versus Easy problem; Chalmers, 1996), and psychological grounds (explicit versus implicit processes; Tulving, 1993).

One common philosophical definition is “*Consciousness is what it is like to be something*,” such as the experience of what it feels like to smell a rose or to be in love. This what-it-feels-like-from-within definition expresses the principal irreducible characteristic of the phenomenal aspect of consciousness: *to experience something*.

What it feels like to have a particular experience is called the *qualia* of that experience: the quale of red is what is common to such disparate conscious states as seeing a red sunset, the red flag of China, arterial blood, or a ruby gemstone. All four subjective states share “redness.” There are countless qualia (the plural of quale): the ways things look, sound, and smell, the way it feels to have a pain, the way it feels to have thoughts and desires, and so on. To have an experience means to have qualia, and the quale of an experience is what specifies it and makes it different from other experiences.

Science must explain the *exact relationship between the immaterial, conscious mind and its physical basis in the electrochemical interactions in the body*. This challenge can be decomposed into several subproblems.

Why is there any experience at all? Why does a brain state feel like anything? Many scholars have argued that the exact nature of this relationship will remain a central puzzle of

CHRISTOF KOCH Division of Biology, California Institute of Technology, Pasadena, California

human existence, without an adequate reductionistic, scientific explanation. However, similar sentiments have been expressed in the past for the problem of seeking to understand life or to determine what material the stars are made of. Thus it is best to put this question aside for the moment and not be taken in by defeatist arguments.

Why is the relationship among different experiences the way it is? For instance, red, yellow, green, cyan, blue, and magenta are all colors that can be mapped onto the topology of a circle. Why? Furthermore, as a group, these color percepts share certain communalities that make them different from other percepts, such as seeing motion or smelling a rose. Why?

Why are feelings private? As expressed by poets and novelists, we cannot communicate an experience to somebody else except by way of example.

How do feelings acquire meaning? Subjective states are not abstract states but have an immense amount of associated explicit and implicit feelings. Think of the unmistakable smell of dogs coming in from the rain or the crunchy texture of potato chips. How do these arise?

Why are only some behaviors associated with conscious states? Much brain activity and many associated behaviors occur without any conscious sensation. Why? And where is the difference between the two at the neuronal level?

The neurobiology of free will

A further aspect of the mind-body problem is the question of free will and will power. Answering this question goes to the heart of the way people think of themselves. Of great relevance are the classical findings by Libet and colleagues (1983) of brain events that precede the conscious initiation of a voluntary action. This simple result has been replicated and extended but, because of its counterintuitive implication that conscious will has no causal role, continues to be vigorously debated (Haggard & Eimer, 1999; Soon, Brass, Heinze, & Haynes, 2008; Brass & Haggard, 2008; see Lau, chapter 83, this volume).

Psychological work in both normals and patients reveals dissociations between the conscious perception of a willed action and its actual execution: subjects believe that they perform actions that they did not do while, under different circumstances, subjects feel that they are not responsible for actions that are, demonstrably, their own (Wegner, 2002).

Whether volition is illusory or is free in some libertarian sense does not answer the question of how subjective states relate to brain states. The perception of free will, which psychologists call the *feeling of agency* or *authorship* (e.g., “I

decided to lift my finger”), is a subjective state with an associated quale no different in kind from the quale of a toothache or seeing marine blue. It must also have some neuronal correlate. Direct electrical brain stimulation during neurosurgery, as well as fMRI experiments, implicates medial premotor and anterior cingulate cortices in generating the subjective feeling of triggering an action (see Lau, chapter 83, this volume).

Consciousness in other species

Data about conscious states come not only from people who can talk about their subjective experiences but also from nonlinguistic competent individuals—newborn babies (Lagercrantz & Changeux, 2009) or patients with complete paralysis of nearly all voluntary muscles (locked-in syndrome)—and, most importantly, from animals other than humans. There are at least three reasons to assume that many species, in particular those with complex behaviors such as mammals, share at least some aspects of consciousness with humans:

Similar neuronal architectures Except for size, there are no large-scale, dramatic differences between the cerebral cortex and thalamus of mice, monkeys, humans, and whales. It is difficult to distinguish a cubic millimeter of neocortex among different mammals, except by expert neuroanatomists.

Similar behavior Almost all human behaviors have precursors in the animal literature. Take the case of pain. The behaviors seen in humans when they experience pain and distress—facial contortions, moaning, yelping or other forms of vocalization, motor activity such as writhing, avoidance behaviors at the prospect of a repetition of the painful stimulus—can be observed in all mammals and in many other species. Likewise for the physiological signals that attend pain—activation of the sympathetic autonomous nervous system resulting in change in blood pressure, dilated pupils, sweating, increased heart rate, release of stress hormones, and so on. The discovery of cortical pain responses in premature babies shows the fallacy of relying on language as the sole criterion for consciousness (Slater et al., 2006).

Evolutionary continuity The first true mammals appeared at the end of the Triassic period, about 220 million years ago, with primates proliferating following the Cretaceous-Tertiary extinction event, about 60 million years ago, while humans and macaque monkeys did not diverge until 30 million years ago (Allman, 1999). *Homo sapiens* is part of an evolutionary continuum with its implied structural and behavioral continuity, rather than an independently developed organism.

While certain aspects of consciousness, in particular those relating to the recursive notion of self and to abstract, culturally transmitted knowledge, are not widespread in nonhuman animals, there is little reason to doubt that nonhuman mammals share conscious feelings—sentience—with humans. To believe that people are special, are singled out by the gift of consciousness above all other species, is a remnant of humanity’s atavistic, deeply held belief that *Homo sapiens* occupies a privileged place in the universe, a belief with no empirical basis.

The extent to which nonmammalian vertebrates, such as tuna, cichlid, and other fish; crows, ravens, magpies, parrots, and other birds; or even invertebrates such as the octopus or bees, with complex, nonstereotyped behaviors including delayed matching, nonmatching to sample, and other forms of learning (Giurfa, Zhang, Jenett, Menzel, & Srinivasan, 2001) are conscious is difficult to answer at this point in time (Edelman, Baars, & Seth, 2005). Without a sounder understanding of the neuronal architecture necessary to support consciousness, it is unclear where in the animal kingdom to draw the Rubicon that separates species with at least some conscious percepts from those that never experience anything and that are nothing but pure automata (Griffin, 2001).

Arousal and states of consciousness

There are two common, but quite distinct, usages of the term consciousness, one revolving around *arousal* and *states of consciousness* (see Schiff, chapter 78, this volume) and another one around *the content of consciousness* and *conscious states*. To be conscious of anything, the brain must be in a relatively high state of arousal (sometimes also referred to as *vigilance*). This statement is as true of wakefulness as it is of REM sleep that is vividly, consciously experienced—though usually not remembered—in dreams. The level of brain arousal, measured by electrical or metabolic brain activity, fluctuates in a circadian manner, and is influenced by lack of sleep, drugs and alcohol, physical exertion, and so on in a predictable manner. High arousal states are always associated with some conscious state—a percept, thought, or memory—that has a specific *content*. We see a face, hear music, remember an incident, plan an experiment, or fantasize about sex. Indeed, it is not clear whether one can be awake without being conscious of something. Referring to such conscious states is conceptually quite distinct from referring to states of consciousness that fluctuate with different levels of arousal.

Different levels or states of consciousness are associated with different kinds of conscious experiences. The awake state in a normal functioning individual is quite different from the dreaming state (for instance, the latter has little or

no self-reflection) or from the state of deep sleep. In all three cases, the basic physiology of the brain is changed, affecting the space of possible conscious experiences. Physiology is also different in *altered states of consciousness*, for instance, after taking psychedelic drugs when events often have a stronger emotional connotation than in normal life. Yet another state of consciousness can occur during certain meditative practices, when interoceptive perception and insight may be enhanced compared to the normal waking state.

In some obvious but difficult to rigorously define manner, the *richness of conscious experience* increases as an individual transitions from deep sleep to drowsiness to full wakefulness. This richness of possible conscious experience could be quantified using notions from complexity theory that incorporate both the dimensionality and the granularity of conscious experience (e.g., Tononi, 2004; see chapter 84, this volume). For example, inactivating all of visual cortex in an otherwise normal individual would significantly reduce the dimensionality of conscious experience, since no color, shape, motion, texture, or depth could be perceived or imagined. A singular exception to this progression is REM sleep where most motor activity is shut down in the *atonia* that is characteristic of this phase of sleep, and the person is difficult to wake up. Yet this low level of behavioral arousal goes, paradoxically, hand in hand with high metabolic and electrical brain activity and conscious, vivid states.

Clinicians speak of impaired states of consciousness as in “the comatose state,” “the persistent vegetative state” (PVS), and the “minimal conscious state” (MCS). Here, state refers to different levels of consciousness, from a total absence in the case of coma, PVS, or general anesthesia, to a fluctuating and limited form of conscious sensation in MCS, in sleepwalking, or during a complex partial epileptic seizure (Schiff, 2004, and chapter 78, this volume)

The repertoire of distinct conscious states or experiences that are accessible to a patient in MCS is presumably minimal (possibly including pain, discomfort, and sporadic sensory percepts; but see Owen et al., 2006), immeasurably smaller than the possible conscious states that can be experienced by a healthy brain. Given the absence of any accepted theory for the minimal neuronal criteria necessary for consciousness, the distinction between a PVS patient—who shows regular sleep-wave transitions and who may be able to move eyes or limbs or smile in a reflexive manner, as in the widely publicized 2005 case of Terri Schiavo in Florida—and an MCS patient who can communicate (on occasion) in a meaningful manner (for instance, by differential eye movements) and who shows some signs of consciousness is often difficult to make in a clinical setting. Functional brain imaging of patients with global disturbances of consciousness (including akinetic mutism) reveal that dysfunction in a widespread cortical network including medial and lateral

prefrontal cortex and parietal associative areas is associated with a global loss of consciousness (Laureys, 2005).

In contrast to diffuse cortical damage, relatively discrete bilateral injuries to midline (paramedian) subcortical structures can also cause a complete loss of consciousness. These structures are therefore part of the *enabling* factors that control the level of brain arousal and that are needed for any form of consciousness to occur. For an example, consider the heterogeneous collection of more than two dozen (on each side) of nuclei in the upper brain stem (pons, mid-brain, and posterior hypothalamus), collectively referred to as the *reticular activating system*. These nuclei—three-dimensional collections of neurons with their own cytoarchitecture and neurochemical identity—release distinct neuromodulators such as acetylcholine, noradrenaline/nor-epinephrine, serotonin, histamine, and orexin/hypocretin. Their axons project widely throughout the brain. These neuromodulators control the excitability of thalamus and forebrain and mediate the alternation between wakefulness and sleep, as well as the general level of both behavioral and brain arousal. Acute lesions in the reticular activating system can result in loss of consciousness and coma. Another enabling factor for consciousness is the *intralaminar nuclei of the thalamus* (ILN). These receive input from many brain stem nuclei and from frontal cortex and project strongly to the basal ganglia and, in a more distributed manner, into layer I of much of neocortex. Comparatively small (1 cm³ or less) bilateral lesions in the ILN can completely eliminate awareness (Bogen, 1995). Thus, the ILN are necessary for somebody to be conscious at all but do not appear to be responsible for mediating specific conscious percepts. It is likely that the specific content of any one conscious sensation is mediated by neurons in cortex and their associated satellite structures, including the amygdala, thalamus, claustrum, and basal ganglia.

The neuronal correlates of consciousness

One key objective of the inchoate science of consciousness is to search for the neuronal correlates—and ultimately the causes—of consciousness. As defined by Crick and Koch (2003), the neuronal correlates of consciousness (NCC) are the *minimal neuronal mechanisms jointly sufficient for any one specific conscious percept* (figure 79.1).

This definition of the NCC stresses the word “minimal,” because the question of interest is which subcomponents of the brain are actually needed. For instance, it is likely that neural activity in the cerebellum does not underlie any conscious perception and thus is not part of the NCC. That is, trains of spikes in Purkinje cells (or their absence) will not induce a sensory percept, although they may ultimately affect some behaviors.

This definition does not focus on the necessary conditions for consciousness, because of the great redundancy and parallelism found in neurobiological networks. While activity in some population of neurons may underpin a percept in one case, a different population might mediate a related percept if the former population is lost or inactivated.

Every phenomenal, subjective state will have associated NCC: one for seeing a red patch, another one for seeing Grandmother, yet a third one for feeling that a particular behavior was freely caused (feeling of agency). Perturbing or inactivating the NCC for any one specific conscious experience will affect the percept or cause it to disappear. If the NCC could be induced artificially—for instance, by cortical microstimulation in a prosthetic device or during neurosurgery—the subject will experience the associated percept. What characterizes the NCC? What are the communalities between the NCC for seeing and for hearing? Will the NCC involve all pyramidal neurons in cortex at any given point in time? Or only a varying subset of long-range projection

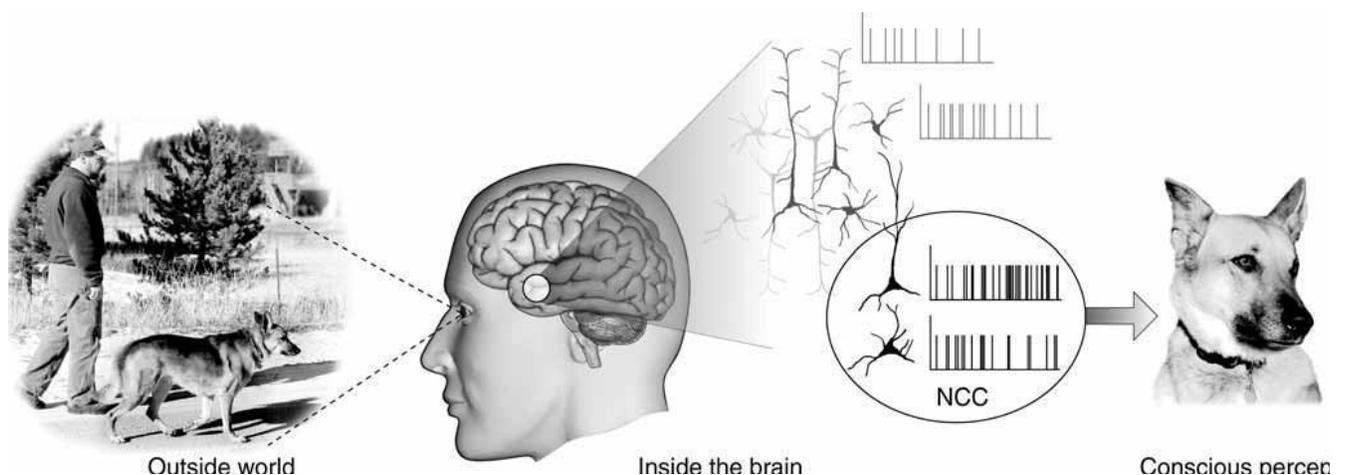

FIGURE 79.1 The neuronal correlates of consciousness (NCC) make up the minimal set of neural events and structures—here synchronized action potentials in neocortical pyramidal neurons—sufficient for a specific conscious percept or memory. (From Koch, 2004.)

cells in frontal lobes that project to the sensory cortices in the back? Only layer 5 cortical cells? Neurons that fire in a rhythmic manner? Neurons that fire in a synchronous manner? These are some of the proposals that have been advanced over the years (Chalmers, 2000).

The extent to which the NCC depends on emotions, moods, and homeostatic signals is controversial. This topic is taken up in detail by Koenigs and Adolphs, chapter 82, this volume).

Quantum mechanics and consciousness

It is implicitly assumed by neurobiologists that the relevant variables giving rise to consciousness are to be found at the neuronal level, among the synaptic releases or the action potentials in one or more population of cells, rather than at the molecular level. A few scholars have proposed that macroscopic quantum behaviors underlie consciousness. Of particular interest here is *entanglement*, the observation that the quantum states of multiple objects, such as two coupled electrons, may be highly correlated even though they are spatially separated, violating our intuition about locality (entanglement is also the key feature of quantum mechanics hoped to be exploited in quantum computers). The role of quantum mechanics for the photons received by the eye and for the molecules of life is not controversial. But there is no evidence that any components of the nervous system—a 37° Celsius wet and warm tissue strongly coupled to its environment—display quantum entanglement. And even if quantum entanglement were to occur inside individual cells, molecular diffusion and action potential generation and propagation, the principal mechanism for getting information into and out of neurons, would destroy superposition. At the cellular level, the interaction of neurons is governed by classical physics (Koch & Hepp, 2006).

Interaction with the world is not required for consciousness

We are usually conscious of what goes on around us, and occasionally of what goes on within our body. So it is only natural to think that consciousness may be tightly linked to the ongoing interaction we maintain with the world and the body (O'Regan & Noe, 2001). However, there are many examples to the contrary. We are conscious of our thoughts, which do not seem to correspond to anything out there; we can also imagine things that are not out there. When we do so, cortical sensory areas can be activated from the inside, though there are some differences from normal visual perception. Also, stimulus-independent consciousness is associated with its own patterns of activation within cortex and thalamus (Mason, Norton, Van Horn, Wegner, & Grafton, 2007). During dreams, we are virtually disconnected from

the environment (Hobson, Pace-Schott, & Stickgold, 2000)—hardly anything of what happens around us enters consciousness, and our muscles are paralyzed (except for eye muscles and diaphragm). Nevertheless, we are vividly conscious: all that seems to matter is that the thalamocortical system continues to function more or less as in wakefulness, as shown by neuronal recording, EEG, and neuroimaging studies performed during rapid eye movement (REM) sleep, when dreams are most intense (Maquet et al., 1996).

Neurological evidence indicates that neither sensory inputs nor motor outputs are needed to generate consciousness. For instance, retinally blind people can both imagine and dream visually if they become blind after 6–7 years of age or so (Hollins, 1985; Buchel, Price, Frackowiak, & Friston, 1998). Patients with the locked-in syndrome can be almost completely paralyzed, and yet they are just as conscious as healthy subjects (Laureys, 2005) and can compose eloquent accounts of their condition (Bauby, 1997). A transient form of paralysis is one of the characteristic features of narcolepsy. Severe cataleptic attacks can last for minutes and leave the patient collapsed on the floor, utterly unable to move or to signal, but fully aware of her surroundings (Siegel, 2000). Or consider the Californian drug addicts known as the *frozen addicts* who acquired some of the symptoms of severe, late-stage Parkinson's disease, fully conscious, yet unable to move or speak (Langston & Palfreman, 1995). All six had previously taken synthetic heroin tainted with MPTP, which selectively and permanently destroyed dopamine-producing neurons in their basal ganglia.

Consciousness here and now depends on what certain parts of the brain are doing, without requiring any obligatory interaction with the environment or the body. Whether the *development* of consciousness requires such interactions in early childhood, though, is a different matter.

Consciousness does not require self-consciousness, introspection, or language

Consciousness is usually evaluated by verbal reports. Questions about consciousness (“Did you see anything on the screen?”) are answered by “looking inside” retrospectively and reporting what one has just experienced. So it is perhaps natural to suggest that consciousness may arise through the ability to reflect on our own perceptions: our brain would form a scene of what it sees, but we would become conscious of it—experience it subjectively—only when we, as a subject of experience, watch that scene from the inside. This suggestion is often framed in a neurobiological context by assuming that patterns of activity corresponding to “unconscious” or “subconscious” percepts form in posterior regions of the cerebral cortex involved in the categorization/association of sensory stimuli. These percepts then become conscious when mainly

anterior prefrontal and cingulate regions involved in self-representations and introspection interact with posterior cortex, perhaps by reading signals through forward connections and selectively amplifying them through back connections.

There is no doubt that the brain categorizes its own patterns of activity in the sense that neurons respond mainly to the activity of other neurons, so the brain is constantly “looking at itself.” However, this process is not necessarily understood in terms of a “subject” (the front) looking at an “object” represented in sensory cortices (the back). Leaving aside the mystery of why reflecting on something should make it conscious, this scenario is made less plausible by a common observation: when we become absorbed in some engaging task—for example, watching an engrossing movie, playing a fast-paced video game, or driving a motorcycle at high speed through traffic—we are vividly conscious without reflection or introspection. Often, we become so immersed in this rapid flow of experience—for example, during a difficult climb up a rock wall—that we may lose the sense of self, the inner voice. Perhaps the habit of thinking about consciousness has distracted the scholars who write upon such matters to devalue the unreflective nature of much of experience.

A neuroimaging study by Malach and collaborators (Hasson, Nir, Levy, Fuhrmann, & Malach, 2004) suggests that activation of prefrontal regions is not necessary for the emergence of perceptual consciousness but may be needed to reflect upon it and report it to others (however, see Bar et al., 2006 for evidence of very rapid and visual object-specific activation of orbitofrontal cortex). Indeed, it appears that self-related activity is actually shut off during highly demanding sensory tasks. Lesion studies also support the notion that perceptual consciousness may not require prefrontal cortex and, by inference, the functions it performs: A man who, at the age of 21, had fallen on an iron spike that completely penetrated through both of his frontal lobes, nevertheless went on to live a stable life—marrying and raising two children—in an appropriate professional and social setting. Although displaying many of the typical frontal lobe behavioral disturbances, he never complained of loss of sensory perception, nor did he show visual or other deficits (Mataró, Jurado, García-Sánchez, Barraquer, & Costa-Jussa, 2001). Another case is that of a 27-year-old woman with massive bilateral prefrontal damage of unclear etiology (Markowitsch & Kessler, 2000). While manifesting grossly deficient scores in frontal-lobe-sensitive tests, she has no abnormal perceptual abilities (that is not to say that such patients do not suffer from subtle visual deficits; Barcelo, Suwazono, & Knight, 2000).

Finally, being conscious does not require language. Humans continually affirm consciousness through speech, describing and discussing their sensory and other experiences. So it is natural to think that speech and consciousness

are somehow inextricably linked. They are not. Infants and animals cannot speak, but they are conscious and can report their experiences in other ways. And, of course, there are numerous patients who lost the ability to understand or use words and yet remained conscious.

Consciousness and attention are independent processes

Few would dispute that the relationship between consciousness and selective, visual attention is an intimate one. When subjects pay attention to an object, they become conscious of its various attributes; when the focus of attention shifts away, the object fades from consciousness. Indeed, more than a century of research efforts have quantified the ample benefits accrued to attended and consciously perceived events (Pashler, 1998; Braun, Koch, & Davis, 2001). This intimate connection has prompted many to posit that the two processes are inextricably interwoven, if not identical (Posner, 1994; Merikle & Joordens, 1997; Chun & Wolfe, 2000; O’Regan & Noe, 2001). Others, however, going back to the 19th century, have argued that attention and consciousness are distinct phenomena, with distinct functions and neuronal mechanisms (Iwasaki, 1993; Hardcastle, 1997; Lamme, 2003; Baars, 2005; Dehaene, Changeux, Naccache, Sackur, & Sergent, 2006; Koch & Tsuchiya, 2007). Recent psychophysical and neurophysiological evidence argues in favor of a dissociation between selective attention and consciousness, suggesting that events or objects can be attended to without being consciously perceived. Conversely, an event or object can be consciously perceived in the near absence of top-down attentional processing.

ATTENTION WITHOUT CONSCIOUSNESS Consider that subjects can attend to a location for many seconds and yet fail to see one or more attributes of an object at that location. In lateral masking (visual crowding), the orientation of a peripherally presented grating is hidden from conscious sight but remains sufficiently potent to induce an orientation-dependent aftereffect (He, Cavanagh, & Intriligator, 1996). Montaser-Kouhsari and Rajimehr (2004) showed that an aftereffect induced by an invisible illusory contour required focal attention, even though the object at the center of attention was invisible. Naccache, Blandin, and Dehaene (2002) elicited priming for invisible words (suppressed by forward and backward masking) but only if the subject was attending to the invisible prime; without attention, the same word failed to elicit priming. In another experiment, male/female nudes attracted attention when they were rendered completely invisible by continuous flash suppression (Jiang, Costello, Fang, Huang, & He, 2006). When subjects had to discriminate the location of the masked nude from the location of a masked shuffled nude, they were at chance; without the intraocular masking, the images are clearly

visible. Functional MRI evidence confirms attentional modulation of invisible images in primary visual cortex (Bahrami, Lavie, & Rees, 2007). In conclusion, attentional selection by itself is not sufficient for consciousness to occur.

CONSCIOUSNESS IN THE ABSENCE OF ATTENTION When one focuses intensely on one event, the world is not reduced to a tunnel, with everything outside the focus of attention gone: we are always aware of some aspects of the world surrounding us, such as its gist. Indeed, gist is immune from inattentional blindness (Mack & Rock, 1998). In the 30 ms necessary to apprehend the gist of a scene, top-down attention cannot play much of a role (because gist is a property associated with the entire image, any process that locally enhances features is going to be of limited use; Fei-Fei, Iver, Koch, & Perona, 2007).

Take the perception of a single object (say a bar) in an otherwise empty display, a nonecological but common arrangement in many animal and human experiments. Here, what function would top-down, selective attention need to perform without any competing objects nearby? Indeed, the most popular neuronal model of attention, biased competition (Desimone & Duncan, 1995), predicts that in the absence of competition no or little attentional enhancement occurs, yet we are perfectly aware of the object and its background.

In a dual-task paradigm, the subject's attention is drawn to a demanding central task, while at the same time a secondary stimulus is flashed somewhere in the periphery. Using the identical retinal layout, the subject performs either the central task, or the peripheral task, or both simultaneously (Sperling & Doshier, 1986; Braun & Sagi, 1990; Braun & Julesz, 1998). With focal attention engaged at the center, the subject can still distinguish a natural scene containing an animal (or a vehicle) from one that does not include an animal (or a vehicle), while being unable to discriminate a red-green bisected disk from a green-red one (Li et al., 2002). Likewise, subjects can tell male from female faces or even distinguish a famous from a nonfamous face (Reddy, Wilken, & Koch, 2004; Reddy, Reddy, & Koch, 2006), but are frustrated by computationally much simpler tasks (e.g., discriminating a rotated letter *L* from a rotated *T*). Thus, although we cannot be sure that observers do not deploy some limited amount of top-down attention in dual-task experiments that require training and concentration (that is, high arousal), it remains true that subjects can perform certain discriminations but not others in the near absence of top-down attention. And they are not guessing. They can be quite confident of their choices and “see,” albeit often indistinctly, what they can discriminate.

The existence of such dissociations—attention without consciousness and consciousness without attention—should

not be surprising when considering their different functions. Attention is the set of mechanisms whereby the brain selects a subset of the incoming sensory information for higher-level processing, while the nonattended portion of the input is analyzed at a lower bandwidth, that is, with fewer processing resources. In primates, about one million fibers leave each eye and carry on the order of one megabyte per second of raw information. One way to deal with this deluge of data is to select a small fraction and process this reduced input in real time while nonattended stimuli suffer from benign neglect. By contrast, consciousness appears to be involved in providing a kind of “executive summary” of the current situation that is useful for decision making, planning, and learning (Koch, 2004; Baars, 2005).

The neuronal basis of perceptual illusions

The possibility of precisely manipulating visual percepts in time and space has made vision a preferred modality for seeking the NCC. Psychologists have perfected a number of techniques—masking, binocular rivalry, continuous flash suppression, motion-induced blindness, change blindness, inattentional blindness—in which the seemingly simple and unambiguous relationship between a physical stimulus in the world and its associated percept in the privacy of the subject's mind is disrupted (Kim & Blake, 2005; see also Rees, chapter 80 in this volume, and Macknik & Martinez-Conde, chapter 81). A stimulus can be perceptually suppressed for minutes at a time: the image is projected into one of the observer's eyes, but it is invisible, not seen. In this manner the neural mechanisms that respond to the subjective percept rather than the physical stimulus can be isolated, permitting the footprints of visual consciousness to be tracked in the brain.

A popular illusion is binocular rivalry (Blake & Logothetis, 2002). Here, a small image (e.g., a horizontal grating) is presented to the left eye and another image (e.g., a vertical grating) is shown to the corresponding location in the right eye. In spite of the constant visual stimulus, observers consciously see the horizontal grating alternate every few seconds with the vertical one. The brain does not allow for the simultaneous perception of both images.

Macaque monkeys can be trained to report whether they see one or the other image. The distribution of switching times and the way in which changing the contrast of one image affects the reports leave little doubt that monkeys and humans experience the same basic phenomenon. In a series of elegant experiments, Logothetis and colleagues (Leopold & Logothetis, 1996; Logothetis, 1998) recorded from a variety of visual cortical areas in the awake macaque monkey while the animal performed a binocular rivalry task. In primary visual cortex (V1), only a small fraction of cells weakly modulate their response as a function of the percept of the monkey. The majority of cells responded to one or the

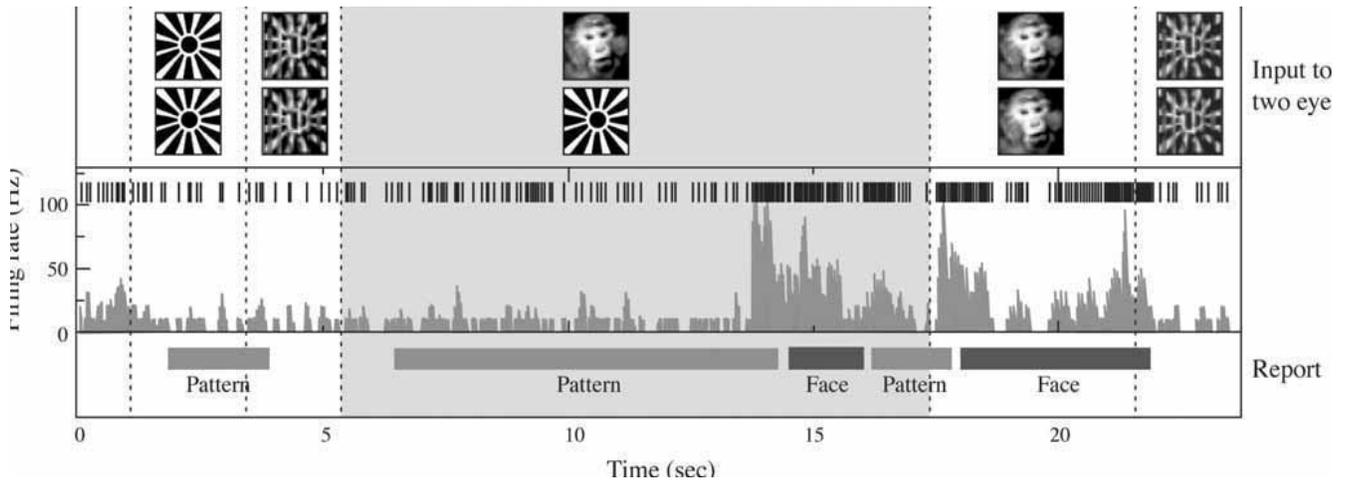

FIGURE 79.2 A fraction of a minute in the life of a typical IT cell while a monkey experiences binocular rivalry. The upper row indicates the visual input, with dotted vertical boundaries marking stimulus transitions. The second row shows the individual spikes, the third row the smoothed firing rate, and the bottom row the monkey's behavior. The animal was taught to press a lever when it saw either one or the other image, but not both. The cell

responded only weakly to either the sunburst design or to its optical superposition with the image of a monkey's face. During binocular rivalry (gray zone), the monkey's perception vacillated back and forth between seeing the face and seeing the bursting sun. Perception of the face was consistently accompanied (and preceded) by a strong increase in firing rate. (From N. Logothetis, private communication, as modified by Koch, 2004.)

other retinal stimulus with little regard to what the animal perceived at the time. In contrast, in a high-level cortical area such as the inferior temporal (IT) cortex along the ventral pathway, almost all neurons responded only to the perceptual dominant stimulus, that is, to the stimulus that was being reported. For example, when a face and a more abstract design were presented, one of these to each eye, a "face" cell fired only when the animal indicated by its performance that it saw the face and not the design presented to the other eye (figure 79.2). This result implies that the NCC involve activity in neurons in inferior temporal cortex.

Clearly this does not imply that the NCC are local to IT. Given known anatomical connections, it is likely that specific reciprocal interactions between IT cells and neurons in parts of the prefrontal cortex are necessary for the NCC. This possibility is compatible with the widely accepted notion that the NCC involve positive feedback to ensure that neural activity is persistent and strong enough to exceed some threshold and to be distributed to multiple cognitive systems, including working memory, planning, and language.

In a related perceptual phenomenon, *flash suppression*, the percept associated with an image projected into one eye is transiently suppressed by flashing another image into the other eye (while the original image remains; Wolfe, 1984). Its methodological advantage over binocular rivalry is that the timing of the perceptual transition is determined by an external trigger rather than by an internal event. The majority of responsive cells in inferior temporal cortex and in the superior temporal sulcus follow the monkey's behavior—and therefore its percept (Sheinberg & Logothetis, 1997). That is, when the animal perceives a cell's preferred stimulus, the

neuron fires; when the stimulus is present on the retina but is perceptually suppressed, the cell falls silent, even though legions of V1 neurons fire vigorously to the same stimulus. Single-neuron recordings in the medial temporal lobe of epileptic patients during flash suppression likewise demonstrate abolition of their responses when their preferred stimulus is present on the retina but not seen (Kreiman, Fried, & Koch, 2002).

A related question is the extent to which a specialized network of neurons in any one cortical region mediates the NCC for all columnar properties associated with that region. This has been directly tested by recording from individual neurons in the middle temporal cortex (MT) of monkeys viewing perceptual rivalrous motion stimuli (Maier, Logothetis, & Leopold, 2007). Contrary to expectations, small changes in the stimulus configuration lead to large changes in the firing activity of cells that carry perceptual rather than purely sensory signals. Depending on which one of four stimulus configurations the physiologists used, between 70% and 90% of all MT cells can carry NCC-related signals. This result implies either that specialized cells expressing the NCC are located beyond area MT or that such specialized cells do not exist in large numbers and that almost any neuron can participate in mediating perceptual consciousness.

A number of fMRI experiments have exploited binocular rivalry and related illusions to identify the hemodynamic activity underlying visual consciousness in humans. They demonstrate quite conclusively that BOLD activity in the upper stages of the ventral pathway (e.g., the fusiform face area and the parahippocampal place area) follow the percept

and not simply the retinal stimulus (Rees & Frith, 2007; Rees, chapter 80, this volume).

There is a lively debate about the extent to which neurons in primary visual cortex are directly responsible for expressing the subject's conscious percept. That is, is V1 part of the NCC (Crick & Koch, 1995)? It is clear that retinal neurons are not part of the NCC for visual experiences. While retinal neurons often correlate with visual experience, the spiking activity of retinal ganglion cells does not accord with visual experience (for example, there are no photoreceptors at the blind spot; yet no hole in the field of view is apparent; in dreams, vivid imagery occurs despite closed eyes; and so on).

A number of compelling observations link perception with fMRI BOLD activity in human V1 and even LGN (Tong, Nakayama, Vaughan, & Kanwisher, 1998; Lee, Blake, & Heeger, 2005). These data appear to be at odds with single-neuron recordings from the monkey (but see Maier et al., 2008). It is known that modulatory, feedback signals—for example those mediating selective attention—can be much more easily detected by means of fMRI than by single-unit recordings (Wilke, Logothetis, & Leopold, 2006; Logothetis, 2008). Indeed, unless attentional effects are carefully controlled for, their neural correlates cannot be untangled from those of consciousness (Huk, Rees, & Heeger, 2001; Tse, Martinez-Conde, Schlegel, & Macknik, 2005). This aim has now been achieved in an elegant study of Lee, Blake, and Heeger (2007). Using a dual-task paradigm they find that hemodynamic BOLD activity in human V1 reflects attentional processes but does not directly correlate with the conscious percept of the subject. Haynes and Rees (2005) exploited multivariate decoding techniques to read out perceptually suppressed information (the orientation of a masked stimulus) from V1 BOLD activity, even though the stimulus orientation was so efficiently masked that subjects performed at chance levels when guessing the orientation. This finding supports the hypothesis that information present in V1 is accessible neither to behavior nor to consciousness, as hypothesized by Crick and Koch (1995).

In a powerful combination of binocular rivalry and flash suppression, a stationary image in one eye can be suppressed for minutes on end by continuously flashing different images into the other eye (*continuous flash suppression*; Tsuchiya & Koch, 2005; Tsuchiya, Koch, Gilroy, & Blake, 2006). This paradigm lends itself naturally to further investigate the relationship between neural activity—whether assayed at the single-neuron or at the brain-voxel level—and conscious perception (Jiang & He, 2006).

Other questions related to perceptual consciousness

The attributes of even simple percepts seem to vary along a continuum. For instance, a patch of color has a brightness

and a hue that are variable, just as a simple tone has an associated loudness and pitch. However, is it possible that each particular, consciously experienced, percept is all-or-none? Might a pure tone of a particular pitch and loudness be experienced as an atom of perception, either heard or not, rather than gradually emerging from the noisy background? The perception of the world around us would then be a superposition of many elementary, binary percepts (Sergent & Dehaene, 2004).

Is perception continuous, like a river, or does it consist of a series of discontinuous batches, rather like the discrete frames in a movie (Purves, Paydarfar, & Andrews, 1996; VanRullen & Koch, 2003)? In *cinematographic vision* (Sacks, 2004), a rare form of visual migraine, the subject sees the movement of objects as fractured in time, as a succession of different configurations and positions, without any movement in between. The hypothesis that visual perception is quantized in discrete batches of variable duration, most often related to EEG rhythms in various frequency ranges (from theta to beta), is an old one. This idea is being revisited in light of the discrepancies of timing of perceptual events within and across different sensory modalities. For instance, even though a change in the color of an object occurs simultaneously with a change in its direction of motion, it may not be perceived that way (Zeki, 1998; Bartels & Zeki, 2006; Stetson, Cui, Montague, & Eagleman, 2006).

Forward versus feedback projections

Many actions in response to sensory inputs are rapid, transient, stereotyped, and unconscious (Milner & Goodale, 1995). They can be thought of as cortical reflexes and are sometimes called *zombie behaviors* (Koch & Crick, 2001). A slower, all-purpose conscious mode deals with broader, less stereotyped, and more complex aspects of the sensory input (or a reflection of these, as in imagery) and takes time to decide on appropriate responses. A consciousness mode is needed because otherwise a vast number of different zombie modes would be required to react to unusual events. The conscious system may interfere somewhat with the concurrent zombie systems (Beilock, Carr, MacMahon, & Starkes, 2002): focusing consciousness onto the smooth execution of a complex, multi-component, and highly trained sensorimotor task—dribbling a soccer ball, to give one example—can interfere with its smooth execution, something well known to athletes and their trainers. Having both a zombie mode that responds in a well-rehearsed and stereotyped manner and a slower system that allows time for planning more complex behavior is a great evolutionary discovery. This latter aspect, planning, may be one of the principal functions of consciousness.

It seems possible that visual zombie modes in the cortex mainly use the dorsal stream in the parietal region (Milner

& Goodale, 1995). However, parietal activity can affect consciousness by producing attentional effects on the ventral stream, at least under some circumstances. The basis of this inference is clinical case studies and fMRI experiments in normal subjects (Corbetta & Shulman, 2002). The conscious mode for vision depends largely on the ventral “what” stream (but see Bar et al., 2006).

Seemingly complex visual processing (such as detecting animals in natural, cluttered images) can be accomplished by cortex within 130–150 ms (Thorpe, Fize, & Marlot, 1996; VanRullen & Koch, 2003), too fast for consciousness to occur. It is plausible that such behaviors are mediated by a purely feedforward moving wave of spiking activity that passes from the retina through V1, into V4, IT, and prefrontal cortex, until it affects motor neurons in the spinal cord that control the finger press (as in a typical laboratory experiment). The hypothesis that the basic processing of information is feedforward is supported most directly by the short times required for a selective response to appear in IT cells (Perrett, Hietanen, Oram, & Benson, 1992). Indeed, Hung and colleagues (2005) were able to decode from the spiking activity 100 ms after image onset from a couple of hundred neurons in monkey IT the identity of a single image flashed onto the retina of the fixating animal. Coupled with a suitable motor output, such a feedforward network implements a zombie behavior—rapidly and efficiently subserving a binary categorization task in the absence of any conscious experience.

Conscious perception is believed to require more sustained, reverberatory neural activity, most likely by way of cortico-cortical feedback from other neocortical regions (see Macknik & Martinez-Conde, chapter 81, this volume). These feedback loops would explain why in backward masking a second stimulus, flashed 80–100 ms after onset of a first image, can still interfere (mask) with the percept of the first image. The reverberatory activity builds up over time until it exceeds a critical threshold. At this point, the sustained neural activity rapidly propagates to parietal, prefrontal, and anterior cingulate cortical regions, thalamus, claustrum (Crick & Koch, 2005), and related structures that support short-term memory, multimodality integration, planning, speech, and other processes intimately related to consciousness. Competition prevents more than one or a very small number of percepts to be simultaneously and actively represented. This is the hypothesis at the heart of the *global workspace* model of consciousness (Baars, 1988; Dehaene, Sergent, & Changeux, 2003). Sending visual information to more frontal structures would allow the associated visual events to be decoded and placed into context (for instance, by accessing various memory banks) and to have this interpretation feed back to the stimulus representation in visual cortex (Jazayeri & Movshon, 2007).

Conclusion

Ever since the Greeks first considered the mind-body problem more than two millennia ago, it has been the domain of armchair speculations and esoteric debates with no apparent resolution. Yet many aspects of this ancient set of questions now fall squarely within the domain of science.

It is known that consciousness does not require sensory input or motor output. Based on clinical and brain-imaging evidence, consciousness does not require self-consciousness, reflection, introspection, or language, although all these capabilities deeply enrich consciousness. Psychophysical and imaging evidence demonstrates that consciousness and selective attention can be dissociated. It appears that the neuronal correlates of consciousness require extensive but selective activity in the thalamocortical system, supported by enabling systems in the central thalamus, midbrain, and brain stem.

To further progress, it is imperative to record from a large number of neurons simultaneously at many locations throughout the thalamocortical system and related satellites (in particular the claustrum; Crick & Koch, 2005) in behaving subjects. This effort also demands a battery of behaviors (akin to but different from the well-known Turing test for intelligence; Koch & Tononi, 2008) that the subject—a newborn infant, immobilized patient, or nonhuman animal—has to pass before considering him, her, or it to possess some measure of consciousness. This is not an insurmountable step for mammals such as the monkey or the mouse that share many behaviors and brain structures with humans. For example, one particular mouse model of contingency awareness (C. Han et al., 2003) is based on the differential requirement for awareness of trace versus delay associative eyeblink conditioning in humans (Clark & Squire, 1998).

The growing ability of neuroscientists to manipulate in a reversible, transient, deliberate, and delicate manner identified populations of neurons using methods from molecular biology (Aravanis, Wang, Zhang, Meltzer, & Mogri, 2007; X. Han & Boyden, 2007; Zhang, Wang, Adamantidis, de Lecea, & Deisseroth, 2007) opens the possibility of moving from correlation—observing that a particular conscious state is associated with some neural or hemodynamic activity—to causation. Exploiting these increasingly powerful tools depends on the simultaneous development of appropriate behavioral assays and model organisms amenable to large-scale genomic analysis and manipulation, particularly in mice (Lein et al., 2007).

Finally, as mentioned previously, it is not known to what extent animals whose nervous systems have an architecture considerably different from the mammalian neocortex are conscious. Furthermore, whether artificial systems, such as

computers, robots, or the World Wide Web as a whole, which behave with considerable intelligence, are or can become conscious remains speculative (Koch & Tononi, 2008). What is needed is a theory of consciousness that explains in quantitative terms what type of systems, with what architecture, can possess conscious states.

Information theory may be such a theoretical approach that establishes at the fundamental level what consciousness is, how it can be measured, and what requisites a physical system must satisfy in order to generate it (Chalmers, 1996; Tononi & Edelman, 1998).

The most promising candidate for such a theoretical framework is the *integrated information theory* of consciousness discussed in more detail by Tononi and Balduzzi (chapter 84, this volume).

It is the combination of fine-grained neuronal analysis in animals, with ever more sensitive psychophysical and brain-imaging techniques in patients and healthy individuals, and the development of a robust theoretical framework that lend hope that we can ultimately understand one of the central mysteries of life.

80 Visual Awareness

GERAINT REES

ABSTRACT Human vision gives rise to subjective experience of the external world. Vision depends on signals and processing within the central nervous system, yet it is apparent that not all activity associated with vision reaches awareness. For example, the state of a single photoreceptor in the retina cannot be directly reported, even though that receptor processes sensory information that contributes to perception. Processing of visual signals can therefore occur in the absence of awareness, and a central question in the neurobiology of consciousness is which neural signals and psychological processes in the brain are correlated with visual awareness and which remain unconscious. Qualitatively and quantitatively dissociating brain activity associated with conscious and unconscious vision will reveal the neural correlates of visual awareness. This chapter will review the current state of progress in understanding the neural signals underlying human visual awareness, with a particular focus on work carried out in the last five years.

Measuring visual awareness

Visual awareness is the subjective experience of the external world mediated by the visual system. In this chapter, I will treat *awareness* and *consciousness* as interchangeable descriptions of the same subjective phenomena in humans. Visual awareness is individuated by its subjective content, which typically represents the presence, qualities (e.g., color, motion), and identity of objects in the environment. Here we will be concerned with the neural correlates of such phenomenal content, setting aside a consideration of those neural factors that contribute to the waking state and thus enable normal visual awareness (see Schiff, chapter 78, this volume, for further discussion of the neural basis of the waking state). In establishing a relationship between the contents of awareness and neural activity or psychological process, we rely on the ability of humans to report their experience, either verbally or through other means. Understanding the nature of such subjective reports is therefore important to appreciating inferential limitations in determining neural correlates of visual awareness.

RELIANCE ON SUBJECTIVE REPORTS The most common measure of visual awareness relies on observers directly reporting their experience. Such subjective reports directly

capture the introspective and phenomenal, subjective, nature of consciousness. They thus have face validity. Critically, however, they depend not only on the sensitivity of an observer's brain to a visual stimulus but also on his or her decision criterion (an internal state) for reporting it. This fact renders such purely subjective measures potentially unreliable as a measure of whether a visual stimulus has reached awareness or not. For example, if observers are uncertain about their visual experience, they may adopt a conservative decision criterion and report uncertain or unclear perception of a stimulus as failure to perceive. In such circumstances erroneous inferences can potentially be made about brain activity. For example, on a trial where an observer erroneously reports unclear perception as absent perception, brain activity on that trial may be incorrectly characterized as unconscious or unaware.

OBJECTIVE APPROACHES AND THEIR VARIANTS Methods that factor out the effects of confidence and decision criterion on measures of awareness exist and are increasingly used in the study of the neural correlates of visual awareness. Compared to subjective report, objective methods such as those provided by signal detection theory furnish estimates of whether a signal is (consciously) discriminable independently of the criterion of the observer, removing the inferential problem we have described. However, such signal detection methods also have a number of disadvantages. In particular, the relatively large number of trials required to accurately determine sensitivity (d') raises the possibility that if decision criterion varies over time, even a demonstration of absent sensitivity over a number of individual trials may not be sufficient to claim that awareness was absent on every single trial.

More recently, alternative objective methods for judging the contents of visual consciousness have been put forward, such as postdecision wagering. In this method, observers make a visual discrimination and then subsequently make a cash wager about the outcome of that discrimination (Persaud, McLeod, & Cowey, 2007). In a range of tasks, observers can fail to maximize cash earnings despite making correct discriminations. This failure is taken to indicate that observers were objectively unaware of the outcome of their discrimination; otherwise, they could have wagered to maximize their earnings. However, good performance on both discrimination and wagering is taken as direct evidence of

GERAINT REES Institute of Cognitive Neuroscience and Wellcome Trust Centre for Neuroimaging, University College London, London, United Kingdom

awareness of the stimuli. Such novel objective measures are intriguing, but have been criticized on conceptual grounds for failing to provide a “direct” measure of visual awareness, as wagering is taken to represent a “second-order” or “metacognitive” decision, depending on second-order information *about* the content of visual awareness, rather than that content *per se* (Seth, 2008). Other approaches continue to be explored, including hybrid methodologies that combine subjective report with assessment of confidence and that appear to be relatively free of response bias (Evans & Azzopardi, 2007).

THE CHARACTER OF VISUAL AWARENESS Signal detection theory and some theoretical approaches to consciousness suggest that mental representations, including those associated with visual awareness, are graded rather than discrete. On such an account, conscious visual percepts exist on a continuum of clarity. However, other theoretical proposals (discussed later; also see Tononi & Balduzzi, chapter 84, this volume) predict qualitative differences between unconscious and conscious processing, suggesting a discrete representation. The degree to which visual representations are graded or discrete has therefore been under increasing scrutiny. When observers are asked to rate the visibility of targets rendered difficult to see by presentation during the “attentional blink,” surprisingly they use a continuous scale in an all-or-none fashion (Sergent & Dehaene, 2004). Either targets are rated as easy to identify and as clearly visible as targets presented outside the attentional blink, or they are not detected at all. This result suggests a discrete “all-or-none” phenomenological classification of stimuli as either fully visible or invisible. However, it has been argued that observers may be confused by the large number of categories and lack of clarity of definitions for categories intermediate between “visible” and “invisible” (Overgaard, Rote, Mouridsen, & Ramsøy, 2006). Indeed, when a smaller four-point scale is employed in a masked visual discrimination task, observers use the full range of the four-point scale to categorize visibility, and the probability of correct report varies systematically with the score on the visibility scale. Further work will therefore be needed to reconcile these accounts.

Whatever the method used for determining awareness, the necessity of an effective behavioral measure of whether an observer is aware or unaware of a visual stimulus is a prerequisite for valid inference about the neural correlates of consciousness. Without such a measure, experiments that measure neural activity associated with visual stimulation cannot make secure inferences about neural correlates of conscious or unconscious processing. This is a particular problem for experiments using animal models of human consciousness; though ingenious behavioral measures have been described (Cowey & Stoerig, 1997), they often require lengthy training. Indeed, it has been proposed that identify-

ing hallmarks of visual awareness in nonhuman animals might need to rely on strategies other than behavioral report, such as searching for evolutionary homologies in anatomical substrate and measurement of neural correlates of conscious states (Edelman, Baars, & Seth, 2005).

Relating visual awareness to brain activity

The ability to characterize visual awareness behaviorally opens up the possibility of relating such reports to brain activity. Determining the neural correlates of the contents of visual awareness requires dissociation of such activity from activity associated with merely unconscious aspects of perception or action (see also Lau, chapter 83, this volume). The most empirically tractable way of controlling for these unwanted effects is to keep them constant, and it has been proposed (Frith, Perry, & Lumer, 1999) that it is useful to distinguish three kinds of neural activity:

1. Neural activity associated with the contents of visual awareness
2. Neural activity associated with changes in a visual stimulus, in the absence of changes in visual awareness
3. Neural activity associated with visually guided behavior, in the absence of changes in visual awareness

Such an approach can be used to elucidate a taxonomy classifying the types of experimental paradigms relevant to these three different types of neural activity, while remembering that whether they can be distinguished is ultimately an empirical question. Table 80.1 illustrates some examples of neuroimaging and behavioral experiments in the domain of visual awareness that fit such a taxonomy.

Having established how reports of visual experience can be assessed, and appropriate experimental designs used to dissociate the neural correlates of conscious and unconscious vision, we can proceed to consider the neural substrates of each in turn.

Characterizing the unconscious homunculus

Several decades of behavioral research have led to significant understanding of the potential theoretical and empirical difficulties associated with studying unconscious processing (Kouider & Dehaene, 2007). Although the debate over the existence of unconscious perception continues (Hannula, Simons, & Cohen, 2005), most authors accept the occurrence of implicit visual perception, where unconscious visual processing can alter behavior. A significant body of brain-imaging studies now shows that many regions of human visual cortex can be activated by visual stimuli that do not reach awareness (see figure 80.1).

Activity can be identified in the absence of visual awareness at the earliest retinotopic cortical stages of visual pro-

TABLE 80.1

Examples of experimental paradigms for studying the neural correlates of visual awareness

In each category two examples are given of experimental paradigms that have been used to identify neural correlates of visual awareness, visual stimulation, or visually guided behavior.

Examples of Paradigms		
Subjective experience changes, visual stimulation and/or behavior remain constant	Neural correlates of binocular rivalry (e.g., Haynes, Deichmann, & Rees, 2005).	Neural correlates of change awareness (Beck, Rees, Frith, & Lavie, 2001)
Visual stimulation changes, subjective experience remains constant	Adaptation under conditions of visual crowding (e.g., He, Cavanagh, & Intriligator, 1996)	Neural correlates of visual masking (e.g., see Macknik & Martinez-Conde, chapter 81, this volume)
Behavior changes, subjective experience remains constant	Neural correlates of correct discrimination without awareness (e.g., Sahraie et al., 1997)	Unconscious priming of cognitive control (e.g., Lau & Passingham, 2007)

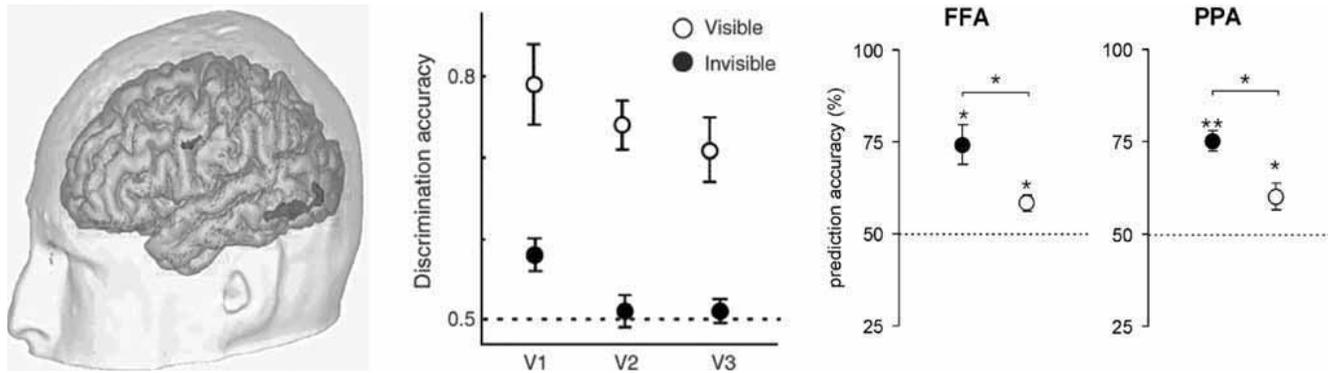

FIGURE 80.1 Activation of sensory cortices by invisible stimuli. *Left panel:* Masked and invisible words nevertheless evoke activation (shown in orange, superimposed on an anatomical image of the brain) of the fusiform gyrus. See Dehaene et al. (2001) for further details. *Middle panel:* Activity measured using BOLD contrast functional MRI in human V1–V3 can be used to discriminate the orientation (right or left tilted) of a grating stimulus. Open symbols representing mean decoding accuracy for a group of subjects (error bars, one SE) for visible stimuli; closed symbols for similarly oriented stimuli rendered invisible by masking. The orientation of these invisible stimuli can still be discriminated at a rate significantly better than chance in human V1. See Haynes and Rees

(2005a) for further details. *Right panel:* Performance of support-vector-machine (SVM) classifiers for pairwise classification of face and house presentations from fusiform face area (FFA) and parahippocampal place area (PPA). Average prediction accuracies across participants for visible faces versus houses are denoted by filled circles (\pm SEM) and for invisible faces versus houses by empty circles. The dotted lines denote chance level (50%). * $p < 0.05$; ** $p < 0.005$; n.s. = non significant ($p > 0.1$). Above-chance performance for invisible stimuli indicates that information is still present in higher visual areas sufficient to discriminate stimulus category. See Sterzer, Haynes, and Rees (2008) for further details. (See color plate 97.)

cessing. For example, when a simple achromatic disc is flashed briefly, activity is elicited in the corresponding retinotopic location of primary visual cortex (V1) even when the target is rendered completely invisible by a surrounding mask (Haynes, Driver, & Rees, 2005). This activation of visual cortex by stimuli that cannot be accurately reported continues to higher stages of processing. For example, activation of functionally specialized areas is consistently observed for masked words, faces, and objects that observers do not report seeing. Masked and unreported words can activate the “temporal word form area” (Dehaene et al., 2001), and activation associated with words that are not perceived can extend to left-hemisphere language regions (Diaz & McCarthy, 2007). Dichoptically masked object and face stimuli can nevertheless activate functionally specialized

areas of ventral visual cortex (Moutoussis & Zeki, 2002), and category selectivity can also be identified in responses of these areas to stimuli rendered invisible through interocular suppression (Sterzer, Haynes, & Rees, 2008). Such observations are not restricted to different types of visual masking, as unconscious activation of the ventral visual pathway during the “attentional blink” can reflect object category (Marois, Yi, & Chun, 2004) and semantic analysis of visually presented words (Luck, Vogel, & Shapiro, 1996). Similarly, visual motion rendered invisible through “crowding” can still activate V5/MT (Moutoussis & Zeki, 2006). Unconscious activation also extends to cortical areas considered part of the dorsal stream of visual processing; images of tools rendered invisible by continuous flash suppression nevertheless activate the human dorsal stream (Fang & He, 2005).

Such neuroimaging evidence converges with electrophysiological studies showing that electrical potentials associated with higher levels of visual processing can be elicited by invisible stimuli. For example, the N400 potential—thought to reflect semantic processing—can be modulated by unconsciously perceived masked prime words (e.g., Luck et al., 1996; though see Kouider & Dehaene, 2007, for a thorough review of evidence for and against unconscious semantic priming), and such effects persist even when prime visibility is carefully controlled to ensure that masked primes are indeed invisible (Kiefer & Brendel, 2006). Convergence between fMRI and electrophysiological measures is not confined to words; both blood oxygenation level dependent (BOLD) signals and event-related potentials in the ventral visual pathway are modulated by subliminally presented face stimuli, indicating unconscious face processing (Henson, Mouchlianitis, Matthews, & Kouider, 2008; Kouider, Dehaene, Jobert, & Le Bihan, 2007).

Many of these neuroimaging studies rely on subjective behavioral measures of awareness (see previous discussion) and have been criticized for not eliminating the possibility of low-confidence conscious perception confounding trials where masked stimuli were not reported (Hannula et al., 2005). Nevertheless they show striking convergence with the rather small number of experiments that assess awareness that employ “objective” behavioral measures or rating scales (discussed earlier). For example, even when participants’ visibility ratings do not deviate from the lowest value on a scale, occipitotemporal event-related potentials can be evoked by an invisible word (Sergent, Baillet, & Dehaene, 2005). Taken together, they suggest that under conditions that render stimuli subjectively or objectively invisible, a substantial degree of processing continues in visual cortex, including higher stages of visual processing.

Subcortical pathways can also show activation in response to subjectively invisible and unreported emotional visual stimuli. For example, the amygdala responds selectively to fearful faces under conditions of masking and binocular suppression, even when observers are unable to report their presence (e.g., Morris, Ohman, & Dolan, 1999; Williams, Morris, McGlone, Abbott, & Mattingley, 2004). Notably, however, these results were obtained using “subjective” measures of behavioral report, and as individuals show large interindividual differences in sensitivity to emotional faces (Pessoa, Japee, & Ungerleider, 2005) there are likely to be large differences between objective and subjective thresholds for awareness of emotional stimuli, a fact which similarly places constraints on the strength of the conclusions that can be drawn about unconscious processing in subcortical pathways (see Pessoa, 2005, for a thorough discussion of these issues).

Many of the studies described here use masking or interocular suppression approaches to render stimuli invisible.

Neuronal populations signals elicited by such masked or suppressed stimuli are generally substantially lower than for the equivalent unmasked stimuli that reach awareness. Such observations have led to theoretical claims (Zeki, 2008) that conscious perception of a given visual attribute resides in the extrastriate area specialized for that attribute (e.g., area MT/V5 for motion or area V4 for color). While this topic will be discussed further in this chapter and theoretical approaches discussed elsewhere (see Tononi & Balduzzi, chapter 84, this volume), it is sufficient to note at this point that several studies using paradigms other than masking show that invisible stimuli can nevertheless elicit population neuronal activity or event-related potentials equivalent in amplitude to visible stimuli. The degree to which signals associated with invisible stimuli are attenuated therefore appears to depend on the experimental paradigm rather than visibility per se, though this question merits further investigation.

Probing unconscious vision with multivariate pattern analyses

Neurons in early visual cortex are sensitive to a number of visual features, such as orientation and direction of motion. It is well established that orientation-selective aftereffects can result from exposure to grating stimuli that are too fine to be consciously perceived (He & MacLeod, 2001), suggesting that orientation-selective but unconscious activation of visual cortex is possible. Direct physiological measurement of such unconscious feature-selective processing in human V1 has proven elusive because of the relatively low spatial resolution (several millimeters) of functional neuroimaging methods compared to the size of orientation columns in visual cortex (hundreds of microns). However, it has recently become possible to use fMRI even at conventional resolutions (typically, voxels measuring $3 \times 3 \times 3$ mm) to obtain a direct measure of orientation-selective processing in V1 (Haynes & Rees, 2005a; Kamitani & Tong, 2005). Many individual voxels in V1 show subtle but reproducible biases in their activity when differently oriented stimuli are presented to the experimental subject. This result may reflect biased sampling by the (relatively) low-spatial-resolution voxels of the underlying columnar organization of orientation-specific neuronal populations, resulting from an uneven distribution of different orientation specificities across the cortical surface (for more detailed explanations, see Kamitani & Tong, 2005, or Haynes & Rees, 2005a). Importantly, this information can be efficiently accumulated across the whole of V1 using multivariate pattern recognition analyses (for reviews see Haynes & Rees, 2006; Norman, Polyn, Detre, & Haxby, 2006). Such multivoxel pattern analysis can successfully predict which one of two oriented stimuli a participant is viewing, even when masking renders that stimulus invisible (Haynes & Rees, 2005a). This finding indicates the presence

of feature-selective processing in early visual cortex, even for invisible stimuli. At higher levels of the visual system, multivariate pattern analyses reveal unconscious representation of category-selective information about face and house stimuli rendered invisible by continuous flash suppression (Sterzer et al., in press). Such analyses thus open up the possibility of probing different levels of neuronal representation associated with conscious or unconscious processing.

Awareness making a difference

Visual stimuli can therefore elicit considerable processing outside awareness, and this can influence subsequent behavior. Why might this statement be true? Crick and Koch (2000) have argued that the brain may consist of a series of specialized unconscious “zombie” systems that can control behavior on the basis of visual signals but in the absence of awareness. Such “zombie systems” raise the question of why the brain does not simply consist of a series of such specialized systems. Crick and Koch (2000) argue that such an arrangement would be inefficient in circumstances where many such systems are required, such as for complex organisms capable of generating multiple behaviors such as humans. In such situations the processing of unconscious systems might be better used to produce a single more complex representation that is available to make a choice among different but possible plans for action.

To understand such a claim we need to establish whether differences exist in the pattern and character of neural activity associated with stimuli that reach awareness compared to those that do not. Studies that have examined this question typically contrast situations where physically identical visual stimulation either gives rise to awareness or does not (Frith et al., 1999). Visual awareness is associated with changes not only in the level and timing of neural activity, but also in the cortical areas that show changes in activity.

LEVEL OF NEURAL ACTIVITY A common but not invariable finding is that awareness of a particular visual feature or object in the environment is associated with enhancement of neuronal signals in functionally specialized regions of visual cortex whose neuronal specificities represent that stimulus attribute or object category. At the anatomically earliest stages of visual processing, signals in V1 scale linearly with the magnitude of change in retinal illumination, as do subjects’ subjective ratings of the perceived brightness of the stimuli (Haynes, Lotto, & Rees, 2004). Such a close correspondence between fMRI signals and phenomenal perception is consistent with a role for these areas in representing conscious contents. More direct evidence has been provided by studies of sensory stimulation at perceptual threshold. For simple grating stimuli, a stimulus that is successfully detected by a subject evokes significantly greater

activity in V1 compared to identical stimuli that do not reach awareness (Rees & Heeger, 2003). Importantly, the change in overall level of visual cortical activity associated with conscious (versus unconscious) visual stimulation is not identified in all paradigms (discussed earlier). Visual awareness does not therefore invariably depend on a modulation of activity in functionally specialized regions of visual cortex. A certain level of neuronal activity may be necessary but not sufficient for awareness.

TIMING OF NEURAL ACTIVITY Conscious detection of threshold-level stimuli is associated with very early differential electrical signals at posterior electrodes (Pins & Ffytche, 2003), suggesting that changes in conscious contents can be associated with activity that is both temporally and anatomically early in processing. However, it is important to note that it is not necessarily the case that conscious and unconscious processing can always be distinguished early in time. In some experimental situations, conscious and unconscious processing can only be dissociated at a much later stage, after several hundred milliseconds (Sergent et al., 2005; Vogel, Luck, & Shapiro, 1998). Neither need it be the case that such late divergence does not reflect V1 involvement, as such temporally delayed correlates of conscious perception can be identified in monkey V1 (Super, Spekreijse, & Lamme, 2001), supporting theoretical suggestions that conscious perception correlates not with the “feedforward” sweep of information processing following stimulation processing but rather with later feedback or recurrent signals, perhaps to V1 (Lamme & Roelfsema, 2000).

INVOLVEMENT OF EARLY VISUAL CORTIX In V1, retinotopic activity can reflect conscious perception of illusory features. When a moving grating is divided by a large gap, observers report seeing a moving “phantom” in the gap, and there is enhanced activity in the locations in early retinotopic visual cortex corresponding to the illusory percept (Meng, Remus, & Tong, 2005). Moreover, when phantom-inducing gratings are paired with competing stimuli that induce binocular rivalry, spontaneous fluctuations in conscious perception of the phantom occur together with changes in early visual activity. Similarly, V1 activation can be found on the path of apparent motion (Muckli, Kohler, Kriegeskorte, & Singer, 2005) and is associated with strengthened feedback connections to that retinotopic location from cortical area V5/MT (Sterzer, Haynes, & Rees, 2006). Finally, when two objects subtending identical angles in the visual field are made to appear of different sizes using three-dimensional context, the spatial extent of activation in the V1 retinotopic map reflects the perceived rather than actual angular size of the objects (Murray, Boyaci, & Kersten, 2006). These data thus show that either the level or spatial extent of V1 activation can correspond to the perceived phenomenal properties of the visual world independently of visual stimulation. This

finding extends to cross-modal influences on visual perception. Irrelevant auditory stimulation can lead to illusory perception of a single flash as two flashes, and primary visual cortex shows enhanced activity compared to physically identical stimulation that is perceived correctly (Watkins, Shams, Tanaka, Haynes, & Rees, 2006). Moreover, these alterations in the contents of visual consciousness are associated with very early modulation of MEG responses over posterior occipital sensors (Shams, Iwaki, Chawla, & Bhattacharya, 2005). Responses in human V1 can therefore be altered by sound, and can reflect subjective perception rather than the physically present visual stimulus. Although neuronal population activity in V1 can show a close relationship with the contents of visual awareness, the earlier discussion of data showing that neuronal populations in V1 can also be activated in the absence of awareness indicates that V1 activity alone cannot be sufficient for awareness. Either the precise character of V1 activity or involvement of other brain areas must be required.

INVOLVEMENT OF HIGHER VISUAL CORTICES V1 is not the only area in the human visual pathway whose activity can reflect the contents of consciousness. Visually presented objects can be made difficult to identify by degrading them, and in such circumstances occipitotemporal activity shows a close correlation with recognition performance (Grill-Spector, Kushnir, Hendler, & Malach, 2000). Similarly, conscious detection of changes in a visually presented object is associated with enhanced activity in ventral visual cortex (Beck et al., 2001). There are many other examples of similarly close correspondence between the level of activity in the ventral visual pathway and conscious perception. For example, patients with schizophrenia who experience visual hallucinations show activity in modality-specific cortex during hallucinatory episodes (Silbersweig et al., 1995). Similarly, patients with damage to the visual system who experience hallucinations with specific phenomenal content show activity in functionally specialized areas of visual cortex corresponding to the contents of their hallucinations (Ffytche et al., 1998). In healthy volunteers, visual imagery activates category-specific areas of visual cortex (O'Craven & Kanwisher, 2000) and category-selective neurons in the human medial temporal lobe (Kreiman, Koch, & Fried, 2000). Contingent aftereffects based on color or motion lead to activation of either V4 (Barnes et al., 1999; Sakai et al., 1995) or V5/MT (He, Cohen, & Hu, 1998; Tootell et al., 1995), respectively, and the time course of such activation reflects phenomenal experience. Perception of illusory or implied motion in a static visual stimulus is associated with activation of V5/MT (e.g., Zeki, Watson, & Frackowiak, 1993), whereas perception of illusory contours activates extrastriate cortex (Hirsch et al., 1995). Differential

activity in word-processing areas is present when subjects are consciously aware of the meaning of visually presented words and absent when they are not (Rees, Russell, Frith, & Driver, 1999).

Some of the most popular paradigms for studying the neural correlates of visual awareness are bistable phenomena such as binocular rivalry. When dissimilar images are presented to the two eyes, they compete for perceptual dominance so that each image is visible in turn for a few seconds while the other is suppressed (see figure 80.2). This binocular rivalry is associated with relative suppression of local, eye-based representations that can also be modulated by high-level influences such as perceptual grouping (see Tong, Meng, & Blake, 2006, for a review). Because perceptual transitions between each monocular view occur spontaneously without any change in the physical stimulus, neural correlates of consciousness may be distinguished from neural correlates attributable to stimulus characteristics. All stages of visual processing show such activity changes associated with rivalrous fluctuations. For example, even at the earliest subcortical stages of visual processing, signals recorded from the human lateral geniculate nucleus (LGN) exhibit fluctuations in activity during binocular rivalry (Haynes, Deichmann, et al., 2005; Wunderlich, Schneider, & Kastner, 2005). Primary visual cortex shows a similar pattern of changes in activity correlated with changes in the contents of consciousness (S. Lee & Blake, 2002; S. Lee, Blake, & Heeger, 2005; Polonsky, Blake, Braun, & Heeger, 2000; Tong & Engel, 2001). In general (though see Tong & Engel, 2001) such fluctuations in activity are about half as large as those evoked by nonrivalrous stimulus alternation. This difference indicates that the suppressed image during rivalry undergoes a considerable degree of unconscious processing. Finally, further along the ventral visual pathway, responses in fusiform face area (FFA) during rivalry are larger than those in V1, and equal in magnitude to responses evoked by nonrivalrous stimuli (Tong, Nakayama, Vaughan, & Kanwisher, 1998). This finding suggests that neural competition during rivalry has been resolved by these later stages of visual processing, and activity in FFA thus reflects the contents of consciousness rather than the retinal stimulus. However, such an account is inconsistent with the finding that binocularly suppressed faces can nevertheless still activate the FFA (Moutoussis & Zeki, 2002) and with the recent demonstration of category-selective signals in these areas for binocularly suppressed face or house stimuli (Sterzer et al., in press).

SPATIAL PATTERNS OF ACTIVITY IN VENTRAL VISUAL CORTIX As with unconscious processing, pattern-based decoding approaches have recently been applied to fMRI signals from human ventral visual cortex. These techniques have the

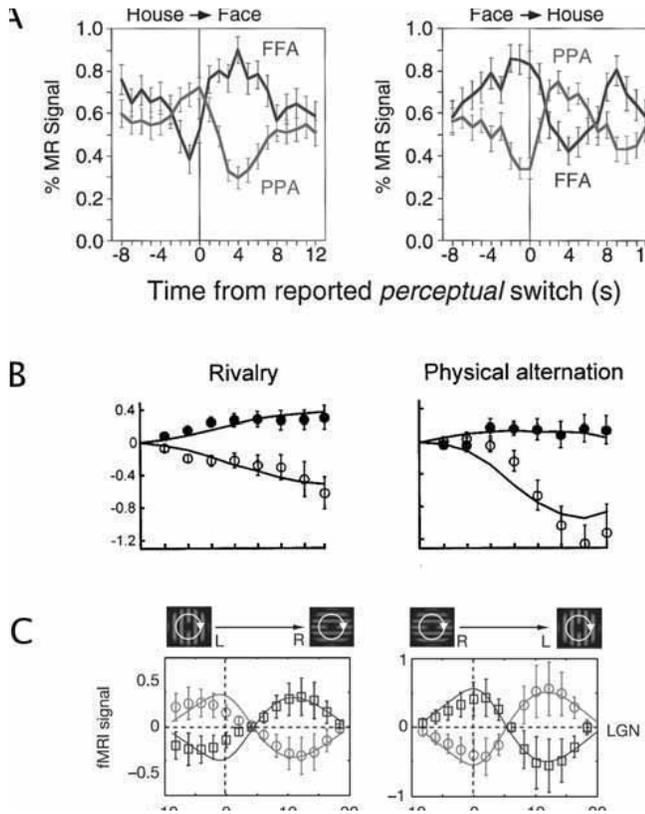

FIGURE 80.2 Fluctuations in activity in visual pathways associated with visual awareness during binocular rivalry. (A) Fusiform face area. Activity measured using functional MRI from human fusiform face area (FFA) and parahippocampal place area (PPA) is plotted as a function of time relative to a perceptual switch from house to face (left panel) or face to house (right panel). It is apparent that activity in the FFA is higher when a face is perceived during binocular rivalry than when it is suppressed, and activity in the PPA is similarly higher when a house is perceived than when it is suppressed. For further details see Tong, Nakayama, Vaughan, and Kanwisher (1998). (B) Binocular rivalry in primary visual cortex (V1). Activity measured using fMRI from human primary visual cortex is plotted as a function of time after a perceptual switch where the subsequent perception is of a high-contrast stimulus (solid symbols) or low-contrast stimulus (open symbols). The left-hand panel plots activity following a perceptual switch due to binocular rivalry, while the right-hand panel plots activity following a deliberate physical switch of monocular (nonrivalrous) stimuli. V1 activity therefore corresponds to perception during binocular rivalry, and the amplitude changes are similar to those seen during physical alternation of corresponding monocular stimuli. For further details see Polonsky, Blake, Braun, and Heeger, (2000). (C) Rivalry in the lateral geniculate nucleus (LGN). Activity measured using fMRI is plotted as a function of time for voxels in the LGN selective for left-eye stimuli (red symbols) or right-eye stimuli (blue symbols) around the time (vertical dotted line) of a perceptual switch between left- and right-eye views (left panel) or right- and left-eye views (right panel). Reciprocal changes in signal in the different eye-selective voxels as a function of perceptual state can be readily seen. For further details see Haynes, Deichmann, and Rees (2005). (See color plate 98.)

potential to reveal qualitative differences in neural processes underlying conscious and unconscious processing in a cortical area. Orientation and direction of motion of simple visual stimuli can be decoded (Haynes & Rees, 2005a; Kamitani & Tong, 2006), plus the identity of more complex objects (Haxby et al., 2001). If subjects are asked to attend one of two overlapping orientations or motion directions, then patterns of activity in early visual cortex can be used to predict which one is attended (Kamitani & Tong, 2005, 2006). Moreover, the local spatial pattern of activity in early retinotopic visual cortex can be used to dynamically decode and accurately predict perceptual state during binocular rivalry over extended periods of time (Haynes & Rees, 2005b). These data suggest that reliable decoding of the subjective contents of consciousness, at least under controlled viewing conditions, may be a realistic prospect. Moreover, the ability to provide information about the underlying specificities of the neuronal populations may now provide a future basis for characterizing whether conscious and unconscious stimuli elicit different types of activity in a single cortical region.

INVOLVEMENT OF FRONTAL AND PARIETAL CORTEX Although visual cortex plays a central role in representing the contents of visual consciousness, there is now considerable evidence that activity in frontal and parietal cortex is strongly correlated with changes in the contents of visual awareness (see figure 80.3). For example, activity during transitions in binocular rivalry, as well as other forms of bistable perception, is time-locked to frontal and parietal cortex activity (Kleinschmidt, Buchel, Zeki, & Frackowiak, 1998; Lumer, Friston, & Rees, 1998; Sterzer, Russ, Preibisch, & Kleinschmidt, 2002). Strikingly, frontal and parietal activity is also associated with spontaneous changes in the contents of consciousness in a variety of perceptual paradigms, such as stereo pop-out (Portas, Strange, Friston, Dolan, & Frith, 2000), the perception of fragmented figures (Eriksson, Larsson, Riklund Ahlstrom, & Nyberg, 2004), the detection of change in a visually presented object (Beck et al., 2001), conscious perception of flicker (Carmel, Lavie, & Rees, 2006), and successful conscious identification of visually masked words (Dehaene et al., 2001). Electrical activity over parietal sensors is associated with the detection of a simple threshold-level stimulus (Pins & Ffytche, 2003). Moreover, changes in the contents of consciousness during bistable perception are associated with distributed changes in synchronous electrical oscillations measured on the scalp (Srinivasan, Russell, Edelman, & Tononi, 1999; Struber & Herrmann, 2002; Tononi, Srinivasan, Russell, & Edelman, 1998).

Importantly, frontoparietal activity is not simply associated with the requirement that observers report their experience. When binocular rivalry occurs in the absence of

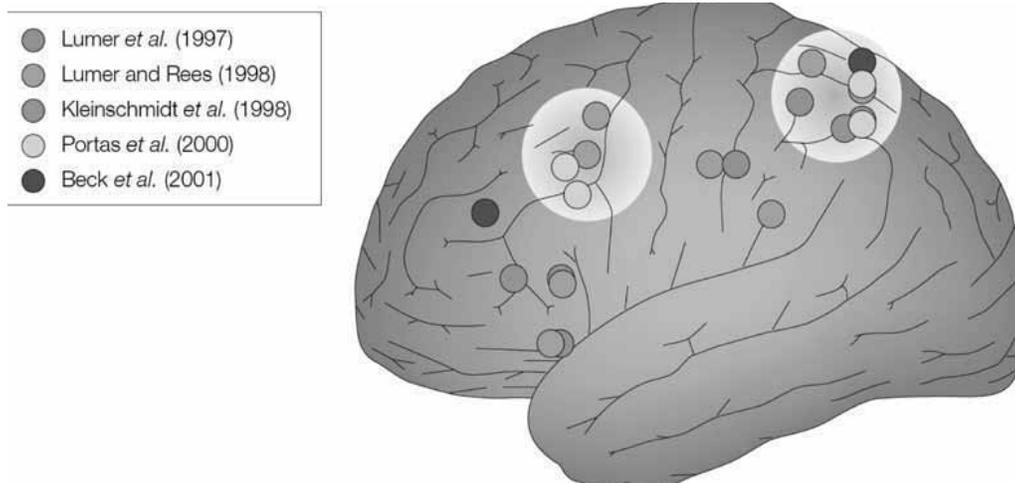

FIGURE 80.3 Parietal and prefrontal correlates of visual awareness. Foci of parietal and prefrontal activity measured using functional MRI and associated with switches in the contents of consciousness independent of changes in physical stimulation are plotted on an anatomical brain image in a standard stereotactic space. Studies shown identify the neural correlates of perceptual switches during rivalry (Lumer, Friston, & Rees, 1998; Lumer &

Rees, 1999), during bistable perception generally (Kleinschmidt, Buchel, Zeki, & Frackowiak, 1998), associated with stereo pop-out (Portas, Strange, Friston, Dolan, & Frith, 2000), or associated with change detection (Beck, Rees, Frith, & Lavie, 2001). Clustering of activated foci (white circles) are apparent in superior parietal and dorsolateral prefrontal cortex. (See color plate 99.)

behavioral reports, there is a close coupling between activity in early visual cortical areas representing the rivaling stimuli and multiple regions of frontal and parietal cortex previously associated with the report of conscious transitions (Lumer & Rees, 1999). Such frontal and parietal involvement in rivalry therefore appears independent of the requirement to make motor reports (though also see Lau, chapter 83, this volume).

INVOLVEMENT OF SPECIFIC PSYCHOLOGICAL PROCESSES
 Demonstrating that activity in specific brain areas is associated with visual awareness does not determine which psychological processes might give rise to awareness. Nevertheless, the common association of frontal and parietal activation with awareness has led to speculation that selective attention may be both necessary and sufficient for awareness of a stimulus to arise (e.g., Block, 2007). Indeed, failure to allocate attention to stimulus processing can lead to stimuli neither being perceived nor eliciting activity associated with their identity (Rees et al., 1999). However, more recently both behavioral and neuroimaging evidence converge to indicate that selective attention can facilitate processing and activity evoked by an invisible target (Bahrami, Lavie, & Rees, 2007; Kentridge, Heywood, & Weiskrantz, 2004; Sumner, Tsai, Yu, & Nachev, 2006; for a review see Koch & Tsuchiya, 2007). Even if attention is necessary, it therefore cannot be a sufficient precondition for visual awareness. Indeed, magnetoencephalographic signals show distinct and independent neural correlates of visual awareness and spatial attention at different frequencies in the gamma (30–150 Hz)

range (Wyart & Tallon-Baudry, 2008). In contrast to attention, the potential role of other psychological processes, such as memory, in modulating cortical activity associated with visual awareness has come under rather less scrutiny but may represent a potentially fertile area for future study. For example, mnemonic signals such as those observed during interruptions in bistable perception might play a fundamental role in stabilizing conscious visual percepts (Sterzer & Rees, 2008).

Causal factors and pathologies of vision

Noninvasive approaches such as fMRI and EEG/MEG in healthy human volunteers can reveal the correlation between neural activity and the contents of visual awareness. However, the existence of such an association does not imply a causative relationship between the two. In order to do so, neural activity must be manipulated either experimentally or through studying individuals with brain damage.

TRANSIENT DISRUPTION OF CORTICAL FUNCTION Transcranial magnetic stimulation (TMS) can be used to transiently stimulate or disrupt local cortical processing. In both healthy volunteers and individuals who are blind due to retinal damage, TMS applied to visual cortex can elicit phosphenes. This ability demonstrates that retinal activity is not necessary for conscious visual experience. Similarly, visual experiences significantly more complex than mere phosphene perception can be elicited by direct electrical stimulation of the ventral visual cortex in humans (H. Lee, Hong, Seo, Tac, & Hong,

2000), suggesting that activity in the lateral geniculate nucleus may also not be necessary for visual awareness. Whether activity in primary visual cortex is necessary is more controversial. For example, TMS applied to visual cortex does not elicit phosphenes when blindness results from damage to V1 (Covey & Walsh, 2000). However, even observers with V1 damage can experience phenomenal percepts (Weiskrantz, Rao, Hodinott-Hill, Nobre, & Covey, 2003), indicating that V1 is necessary for some types of visual percepts. One possibility is that a specific aspect of activity in V1, such as its character or timing (discussed earlier), plays an important role. Consistent with this, awareness of motion is impaired if feedback signals from V5/MT to V1 are disrupted by TMS (Pascual-Leone & Walsh, 2001; Silvanto, Covey, Lavie, & Walsh, 2005). Similarly, using TMS to disrupt processing of a metacontrast mask presented after a target can lead to unmasking and corresponding visibility of the original target (Ro, Breitmeyer, Burton, Singhal, & Lane, 2003). These data suggest that temporally late signals in V1 representing feedback from other ventral visual (or higher cortical) areas may be required for awareness. TMS also provides direct evidence for a role of frontal and parietal cortices in visual awareness, as detection of visual change is impaired when frontal or parietal cortex is transiently disrupted (Beck, Muggleton, Walsh, & Lavie, 2006; Turatto, Sandrini, & Miniussi, 2004).

HEMIANOPIA AND BLINDSIGHT Damage to primary visual cortex is typically associated with a lack of awareness for stimuli presented at corresponding points in the visual field. However, when patients with such cortical damage are asked to guess properties of stimuli that they deny being able to see when they are presented in a scotoma, a number show residual visual capacity in their blind field. These patients are able to perform certain discriminations and localizations better than chance in the acknowledged absence of awareness. This ability has become known as blindsight. The prevalence of such a phenomenon is unclear, but when systematic forced-choice testing with stimuli appropriate for the spatial and temporal characteristics of the residual vision found in blindsight has been applied to patients with visual field defects resulting from occipital damage, the majority demonstrate blindsight (Sahraie et al., 2006). Individuals with blindsight can still experience some types of nonveridical percept in their blind field, such as afterimages from unseen stimuli (Weiskrantz et al., 2003), but the absence of awareness associated with V1 damage points to a significant role for V1 in visual awareness. Indeed, ingenious exclusion tasks (where the participants are required to report stimuli that are *not* shown) have been used to demonstrate that blindsight is unlike normal visual awareness and does not simply reflect unreliable subjective reports (Persaud & Covey, 2008). Many different hypotheses have been proposed for why V1

damage leads to blindness, from the inability of weaker signals from extrageniculostriate pathways to engender awareness to V1 damage interfering with particular pathways or timing of signals necessary for awareness. The recent successful characterization of anatomical pathways underlying the residual vision in one blindsighted observer (Bridge, Thomas, Jbabdi, & Covey, 2008) points to the need to understand such deficits in the context of the connectivity of the visual system.

VISUAL NEGLECT AND VISUAL EXTINCTION Damage to frontal and parietal cortex is commonly associated with visual neglect and visual extinction, where patients do not perceive or respond to any type of visual stimulus placed in one half of the visual field (Driver & Mattingley, 1998). This deficit in conscious visual representation is consistent with a general involvement of these structures in representing many different types of conscious contents. Activation of visual cortex or subcortical structures by visual stimuli is insufficient for awareness in visual neglect (Driver, Vuilleumier, Eimer, & Rees, 2001). When visual stimuli are presented to patients with visual extinction, areas of both primary and extrastriate visual cortex that are activated by a seen left-visual-field stimulus are also activated by an unseen and extinguished left-visual-field stimulus (Rees et al., 2000, 2002; Vuilleumier et al., 2001) and also associated with enhanced covariation of activity between visual cortical areas representing the visual stimulus and undamaged parietal and prefrontal regions (Vuilleumier et al., 2001). The unconscious processing of an extinguished face stimulus extends even to face-selective cortex in the fusiform face area (Rees et al., 2002). These data confirm that activation of visual cortex is insufficient to result in awareness and strongly support a role for frontal and parietal structures in visual awareness (see figure 80.4).

Empirical and theoretical integration

The last decade of empirical study of the relationship between brain activity and visual awareness has given rise to an enormous amount of data, out of which certain common themes may be emerging. First, it appears that visual stimuli that do not reach awareness nevertheless undergo extensive processing in both dorsal and ventral visual pathways, although the nature and extent of processing at higher levels remain under debate. Second, neuropsychological and neuroimaging evidence strikingly converges to suggest an association of frontal and parietal activity with awareness, particularly of changes in the visual environment. Whether this reflects a particular cognitive process (such as attention) remains a matter of debate. Third, changes in coupling between different brain areas and in particular between frontal and parietal cortex with visual cortex appear to play

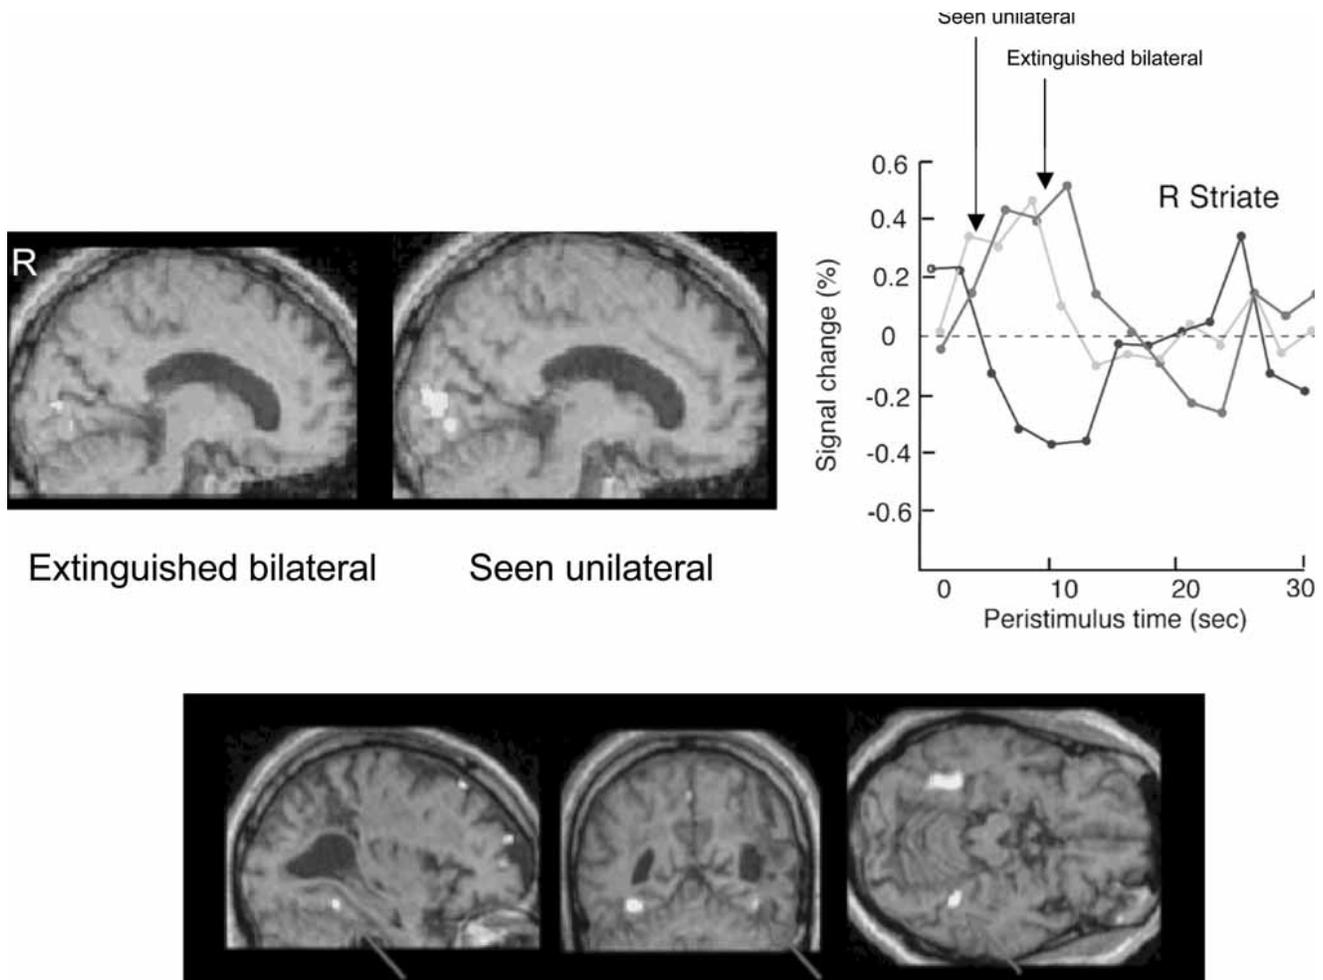

FIGURE 80.4 Activity in ventral visual cortex is not sufficient for awareness. *Upper left:* Activity evoked by an unseen and extinguished left-visual-field stimulus (see text for description of visual extinction) in striate and extrastriate cortex in a patient with parietal neglect. Differences in activity comparing bilateral extinguished with unilateral right stimulation is overlaid on two sagittal slices of a T1-weighted anatomical scan. For further details see Rees and colleagues (2000). *Upper right:* BOLD activity from the right striate (V1) focus of activation shown in the left panel is plotted as a function of peristimulus time for bilateral extinguished stimuli, unilateral left-visual-field stimuli, and unilateral right-visual-field stimuli. Note the similarity of the BOLD time courses for the bilateral extinguished stimuli (in which a stimulus is present in the left visual

field but not reported by the individual with parietal extinction) and for the left unilateral stimulation (in which a stimulus is both present in the left visual field and reported). This indicates that stimuli that do and do not reach awareness may produce similar levels of activation in similar cortical locations, in this case following parietal damage. *Lower panel:* Activity in the fusiform face area evoked by a face (versus a house) stimulus presented in the neglected left hemifield of a patient with parietal neglect and left visual extinction. Thus, after parietal damage, activation in the ventral visual pathway for unseen stimuli can be sufficient to distinguish the category of stimulus presented. See Rees and colleagues (2002) for further details. (See color plate 100.)

an important role in stimuli becoming reportable and merit further investigation.

These conclusions from the study of visual awareness bear upon theoretical models of consciousness in a number of important ways (see Tononi & Balduzzi, chapter 84, and Block, chapter 77, this volume). The involvement of areas outside the classical visual pathway is not easy to explain for theoretical approaches that posit that conscious perception of a given visual attribute resides in the extrastriate area specialized for that attribute. While the contents of visual awareness may be determined by the location of neural

activity in functionally specialized visual areas, this activity does not seem to be enough. Interaction with other areas, particularly parietal and prefrontal cortex, seems to be necessary. Theoretical approaches to consciousness as a whole that propose an interaction between processes specific to particular sensory domains with a “global workspace” (e.g., Dehaene, Kerszberg, & Changeux, 1998) or that highlight the role of interactions between distributed neuronal systems in general (Tononi & Edelman, 1998) appear to fit the empirical data more closely. Theoretical considerations are developed more fully elsewhere (see Tononi & Balduzzi).

Conclusion

The most parsimonious account of currently available data is that awareness of particular attributes or objects in the visual environment is contingent on the presence of an activated representation in primary visual cortex and ventral visual pathways corresponding to the attributes represented in awareness, together with activity in specific parietal (and perhaps) prefrontal structures. Activity in such a distributed network may be necessary for accurate report, which is at the heart of our attribution of consciousness to individuals. The challenge for the future is both conceptual and empirical. Conceptual and theoretical advances are required to make sense of the mass of the empirical data and integrate findings from multiple domains of inquiry. Empirical work should more precisely specify the interactions between and potential causal role for different brain areas. At the same time, a full understanding of the neural correlates of visual awareness will require detailed knowledge of the relationship between noninvasive population measures of neural activity such as fMRI and EEG/MEG used in humans and those single-neuron or neuronal population measures employed for studying the visual system in experimental animals.

81 The Role of Feedback in Visual Attention and Awareness

STEPHEN L. MACKNIK AND SUSANA MARTINEZ-CONDE

ABSTRACT The mammalian visual system includes numerous brain areas that are profusely interconnected. With few exceptions, these connections are reciprocal. Anatomical feedback connections in general outnumber feedforward connections, leading to widespread speculation that feedback connections play a critical role in visual awareness. However, evidence from physiological experiments suggests that feedback plays a modulatory role, rather than a driving role. Here we discuss theoretical constraints on the significance of feedback's anatomical advantage, and we describe theoretical limits on feedback's potential physiological impact. These restrictions confine the potential role of feedback in visual awareness and rule out some extant models of visual awareness that require a fundamental role of feedback. We propose that the central role of feedback is to maintain visuospatial attention, rather than visual awareness. Our conclusions highlight the critical need for experiments and models of visual awareness that control for the effects of attention. As a matter of clarity in this chapter: by "visual awareness" or "visibility" we mean the conscious perception that a stimulus is visible. Thus, for the purposes of this discussion, we use the terms *visual awareness*, *visibility*, and *consciousness* interchangeably.

Anatomical observations of feedback in the visual system

The visual areas of the brain are interconnected in a complex pattern of feedforward, lateral, and feedback pathways (Felleman & Van Essen, 1991). Feedback connections are ubiquitous throughout the cortex, and subcortical regions in ascending hierarchical pathways also receive a large amount of feedback from cortical areas (Erisir, Van Horn, & Sherman, 1997; Fitzpatrick, Usrey, Schofield, & Einstein, 1994; Guillery, 1969; Sherman & Guillery, 2002).

ANATOMY OF FEEDBACK IN THE LGN Corticogeniculate input is the largest source of synaptic afferents to the cat lateral geniculate nucleus (LGN). Whereas retinal afferents only encompass 25% of the total number of inputs to LGN interneurons, 37% of the synaptic contacts come from the cortex. In the case of relay cells, the respective percentages are 12% versus 58% (Montero, 1991). Similar estimates have been calculated in the primate, and the general agreement is that the cortical-to-retinal input ratio is between 1 : 2

and 1 : 6 in both cats and primates (Erisir et al., 1997; Fitzpatrick et al., 1994; Guillery, 1969; Sherman & Guillery, 2002; Van Horn, Erisir, & Sherman, 2000). Boyapati and Henry (1984) concluded that feedback connections from the cat visual cortex to the LGN concentrated a larger fraction of fine axons than feedforward geniculocortical connections, presumably resulting in comparatively slower conduction speeds.

These and other considerations concerning the synaptic size, efficacy, and contribution of feedback connections underscore the potential mistake in assuming that a numerically larger number of inputs means that those inputs are functionally most important (Sherman & Guillery, 2002).

ANATOMY OF FEEDBACK IN THE PRIMARY VISUAL CORTIX Cortical feedforward pathways usually project from the supragranular layers of visual areas early in the hierarchy (less than 10–15% of the connections may arise from deep layers) and terminate in layer 4 of areas later in the hierarchy. In contrast, feedback projections usually arise from the infragranular layers of later areas and terminate outside of layer 4 in the early areas (Barone, Batardiere, Knoblauch, & Kennedy, 2000; Felleman & Van Essen, 1991; Hilgetag, O'Neill, & Young, 1996a, 1996b; Maunsell & Van Essen, 1983).

Direct feedforward projections to primate area V1 (also called primary visual cortex, striate cortex, and Brodmann's area 17) originate from the pulvinar, LGN, claustrum, nucleus paracentralis, raphe system, locus coeruleus, and nucleus basalis of Meynert (Blasdel & Lund, 1983; Doty, 1983; Fitzpatrick et al., 1994; Hendry & Yoshioka, 1994; Lachica & Casagrande, 1992; Ogren & Hendrickson, 1976; Perkel, Bullier, & Kennedy, 1986; Rezak & Benevento, 1979). Direct feedforward projections from V1 extend to V2, V3, V5 or MT, MST, and FEF (Boussaoud, Ungerleider, & Desimone, 1990; Livingstone & Hubel, 1987; Lund, Lund, Hendrickson, Bunt, & Fuchs, 1975; Maunsell & Van Essen, 1983; Shipp & Zeki, 1989; Ungerleider & Desimone, 1986a, 1986b). Direct feedback projections to V1 originate from V2, V3, V4, V5 or MT, MST, FEF, LIP, and inferotemporal cortex (Barone et al., 2000; Perkel et al., 1986; Rockland, Saleem, & Tanaka, 1994; Shipp & Zeki,

STEPHEN L. MACKNIK and SUSANA MARTINEZ-CONDE *Barrow Neurological Institute, Phoenix, Arizona*

1989; Suzuki, Saleem, & Tanaka, 2000; Ungerleider & Desimone, 1986a, 1986b). Direct feedback projections from V1 extend to SC, LGN, pulvinar, and pons (Fitzpatrick et al., 1994; Fries, 1990; Fries & Distel, 1983; Gutierrez & Cusick, 1997; Lund et al., 1975).

Peters, Payne, and Budd (1994) showed that only 1–8% of the synaptic inputs into a layer 4C neuron from primate area V1 originate in the LGN. They concluded that “it is unlikely that the response properties of a particular cortical neuron are dominated by its input from a single geniculate neuron” (p. 215). However, this conclusion was based solely on the anatomical numbers of inputs, and not on their functional properties, which we discuss further in the next section.

Physiological observations of feedback in the visual system

METHODOLOGICAL SHORTCOMINGS IN PHYSIOLOGICAL STUDIES OF FEEDBACK Some visual physiology studies have found that feedback connections between the secondary and primary visual cortices enhance or decrease neuronal responsiveness without fundamentally altering response specificity (Martinez-Conde et al., 1999) (see figure 81.1). These studies were conducted by microinjecting small amounts of neuronal modulators into area 18 of the cat while recording from the corresponding retinotopic position in area 17. This method is accurate in its assessment of feedback effects because it sequesters the source of neuronal enhancement and suppression to a small focal region that cannot directly affect the neuronal responses of the neurons being recorded in the area of interest. Thus the only possible cause of the response modulation in area 17 was the feedback connection from area 18. Another positive aspect of this technique is that the effects are fully reversible, which is not a feature shared by the ablation (Super & Lamme, 2007) and lesion methods.

Other studies have proposed a more significant physiological role for feedback in the visual system. However, these studies have generally used alternative methods such as ablation, cooling, transcranial magnetic stimulation, and direct pharmacological manipulation of the neurons being recorded. Such techniques are usually disadvantageous in that they are nonfocal, nonreversible, and/or may have unknown or poorly understood nonspecific effects on the physiological milieu of the neurons being directly recorded (such as by changing the pH, osmolarity, temperature, or other effects). Nonfocal and/or nonreversible techniques may also affect the vasculature feeding the targeted neurons or fibers of passage with known or unknown connectivity (either direct or indirect) to the targeted neurons. Thus the results obtained are more difficult to interpret, as the responses of the targeted neurons may have been affected in ways unrelated to any putative role of feedback.

Also, as we will discuss more fully in a later section, it is critical that physiological measurements of feedback, as they relate to awareness, be conducted with careful controls for the effects of attention, as well as its underlying circuits. This is a necessary precaution, as the physiological process of attention is differentiable from that of awareness (Koch & Tsuchiya, 2007). For a comprehensive discussion of this issue, please see Koch (chapter 79, this volume).

WHAT DO WE MEAN BY FEEDBACK? For the purposes of this chapter, we restrict our definition of the word “feedback” to the long-range fibers that connect a higher brain area to a lower brain area, within an ascending sensory system. In this definition, the same information arrives to the same neural circuit at least twice: first as it feeds forward through the system and later again as it feeds back.

Other types of feedback loops in the brain are not discussed in this chapter. For instance, information may flow up from one thalamic nucleus to the cortex (i.e., from the LGN to area V1) and then back down to a different thalamic nucleus (i.e., the pulvinar) (Rockland, 1996). In this case, it could be said that the thalamus as a whole sends information to, and receives feedback from, area V1 (as Rockland describes it). However, the feedforward and feedback projections are mediated by two separate thalamic nuclei. Thus this type of circuit does not meet the definition of feedback used here.

Here we will discuss specifically those reciprocal connections between visual areas of the geniculate-cortical pathway. Thus the feedback we will consider entails connections from neurons processing more complex visual information (and having more complex receptive fields) to neurons processing less complex visual information (which have simpler and less selective receptive fields) (figure 81.2).

This chapter aims to describe the powerful constraints on the functional role of feedback, even within such an ordinary and basic neural system. Figure 81.2*A* illustrates the basic connectivity between an area of the geniculocortical pathway and the next area up in the hierarchy (i.e., the LGN and area V1). The lower, simpler level of processing feeds forward to the higher level. There, information is further processed by neural circuits with more complex receptive fields. The higher, more complex level then feeds back information to the simpler level. If such a feedback connection is functionally effective, the receptive fields from the lower level will acquire the specificity and complexity that characterize the higher-level receptive fields (figure 81.2*B*). This physiological prediction should apply to any feedback pathways that are both engaged and significant in strength.

PHYSIOLOGY OF FEEDBACK IN THE LGN Corticogeniculate connections to the LGN are retinotopically organized, and

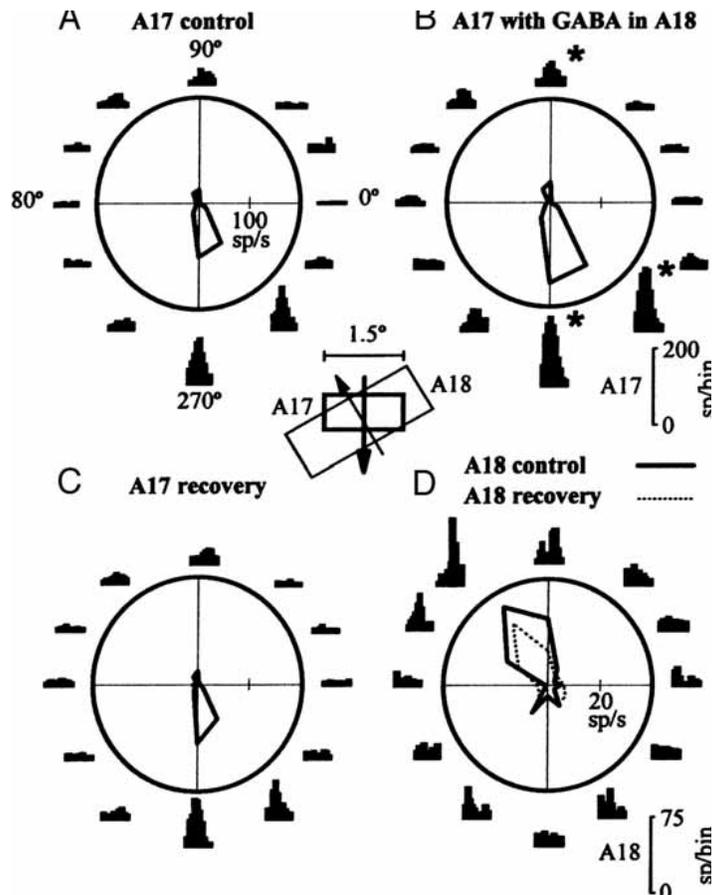

FIGURE 81.1 Reversible removal of feedback from area 18 to area 17 in the cat. (A) Orientation tuning curve of a cell from layers 2/3 of area 17. (B) Orientation tuning curve of the same cell during GABA application in area 18. Note that, although the firing rate of this area 17 neuron increases significantly, its orientation selectivity is virtually unchanged in the absence of feedback from area 18. Thus feedback modulates the magnitude of the neuronal responses but does not affect their functional specificity. (C) Ori-

tation tuning curve of the same cell after area 18 blockade. (D) Solid line, control tuning curve of an area 18 cell recorded simultaneously. Dotted line, tuning curve of the same cell after blockade. *Inset*: receptive fields of both cells. For clarity, only the preblockade post-stimulus time histograms (PSTHs) are shown in D. The number of spikes for PSTHs of areas 17 and 18 are indicated at *bottom* of B and D, respectively. Bin size: 100 ms. Time base: 1 s. (Reprinted from Martinez-Conde et al., 1999.)

they preferentially end on LGN layers with the same ocular dominance as the cortical cells of origin (Murphy & Sillito, 1996). Although only 12–58% (Montero, 1991) of the inputs to geniculate cells are retinal in origin, these synapses drive the primary responses of geniculate relay cells, whereas feedback inputs play a modulatory role (Sherman & Guillery, 1998, 2002).

PHYSIOLOGY OF FEEDBACK IN THE PRIMARY VISUAL CORTEX
Cortico-cortical feedback connections are also retinotopically specific (Salin, Girard, Kennedy, & Bullier, 1992). For instance, there is a functional projection from area 18 to area 17 neurons with similar retinotopic locations (Bullier, McCourt, & Henry, 1988; Martinez-Conde et al., 1999; Salin et al., 1992; Salin, Kennedy, & Bullier, 1995). Girard, Hupe, and Bullier (2001) found that feedforward and feedback connections between areas V1 and V2 of the monkey have similarly rapid conduction speeds.

In the cat visual cortex, electrical stimulation from areas 18 and 19 demonstrated 50% of monosynaptic connections with superficial layers of area 17, in regions with similar functional properties, such as retinotopic location (Bullier et al., 1988). Mignard and Malpeli (1991) also found that inactivation of area 18 in the cat led to decreased responses in area 17. Martinez-Conde and colleagues (1999) found that focal reversible inactivation of area 18 produced suppressed or enhanced visual responses in area 17 neurons with a similar retinotopy. In most area 17 neurons, orientation bandwidths and other functional characteristics remained unaltered, suggesting that feedback from area 18 modulates area 17 responses without fundamentally altering their specificity.

In the squirrel monkey, Sandell and Schiller (1982) found that most area V1 cells decreased their visual responses when area V2 was reversibly cooled, although a few cells became more active. Orientation selectivity remained

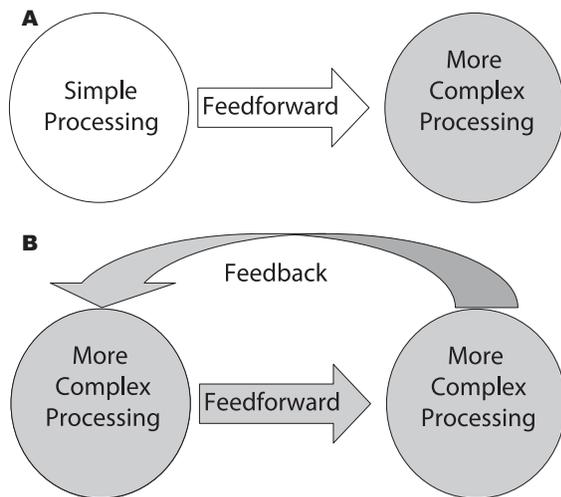

FIGURE 81.2 A generalized model of the effect of feedback in a hierarchy of simple to complex neural processing. (A) In a functional hierarchy, information processing becomes more complex as one ascends in the pathway. (B) When feedback is engaged, the lower levels of the hierarchy take on the more complex properties of the upper levels.

unchanged, although direction selectivity decreased in some instances. Bullier, Hupe, James, and Girard (1996) reported in the cynomolgous monkey that, following GABA inactivation of area V2, V1 neurons showed decreased or unchanged responses in the center of the classical receptive field, but increased responses in the region surrounding it. These results were supported by subsequent findings in areas V1, V2, and V3 following area MT inactivation (Hupe et al., 1998). More recently, Angelucci and colleagues (Angelucci & Bressloff, 2006; Angelucci, Levitt, & Lund, 2002) have suggested that area V1 extraclassical receptive field properties arise from area V2 feedback.

In summary, physiological studies as a whole suggest that feedback connections in the visual system may play a modulatory role, rather than a driving role, in shaping the responses of hierarchically lower areas. This evidence agrees with the “no-strong-loops” hypothesis formulated by Crick and Koch (1998b). The no-strong-loops hypothesis proposes that all strong connections in the visual system are of the feedforward type. That is, “the visual cortex is basically a feedforward system that is modulated by feedback connections,” which is “not to say that such modulation may not be very important for many of its functions” (p. 248). Crick and Koch argued that “although neural nets can be constructed with feedback connections that form loops, they do not work satisfactorily if the excitatory feedback is too strong.” Similarly, if feedback connections formed “strong, directed loops” in the brain, the cortex would as a result “go into uncontrolled oscillations.” Therefore, the relative number of feedback versus feedforward anatomical connections to any given visual area may be misleading as to the respective roles

of such connections. For instance, the fact that the cat LGN receives substantially larger numbers of synapses from the cortex than from the retina (Montero, 1991) does not necessarily mean that corticogeniculate connections are more important than retinogeniculate connections in determining the response characteristics of LGN neurons.

Although the role of feedback modulation in our visual perception remains unclear, one possibility is that feedback may be involved in attentional mechanisms (Martinez-Conde et al., 1999). We will discuss this idea more fully in the next section.

The role of feedback in attention

Based on the evidence we have reviewed, one potentially important role for feedback may be to carry attentional modulation signals. Other modulatory roles for feedback remain possible, but none are as clearly established. Thus it may be that the sole effect of all feedback connectivity is to facilitate and suppress attention. At first, given the massive amount of anatomical feedback versus feedforward connections, this possibility may seem unlikely. Indeed, the great extent of feedback connectivity suggests to some that feedback must have a large number of roles (Sherman & Guillery, 2002; Sillito & Jones, 1996). However, we will argue here that the great number of feedback connections may potentially be explained by the need for top-down attentional modulation alone. Ascending circuits in the visual system primarily form a labeled-line hierarchy, and so feedback connections necessarily require more wiring than feedforward connections to send back even the simplest signal.

To illustrate the logic of this argument, let us consider the anatomical connectivity between the LGN and V1 (figure 81.3). As previously described, LGN relay cells receive more numerous feedback connections from the cortex than feedforward inputs from the retina. However, because V1 receptive fields are orientation selective and LGN receptive fields are not, any functionally significant feedback from V1 to a given retinotopic location in the LGN must represent many, or all, orientations. (One should note that Vidyasagar & Urbas, 1982, found slight orientation biases in LGN receptive fields; these biases were much smaller than the strong orientation selectivity found in V1.) That is, for each unoriented feedforward connection from the LGN to V1, there *must be* many oriented feedback connections from V1 to the LGN, each with a different orientation, so that the sum of all feedback projections spans all the orientation space. Otherwise, if the orientation space of the feedback connections were not filled completely, LGN receptive fields would show a substantial orientation bias. Thus anatomical feedback connectivity must be large so as to represent the entire orientation space at each retinotopic location. However, because

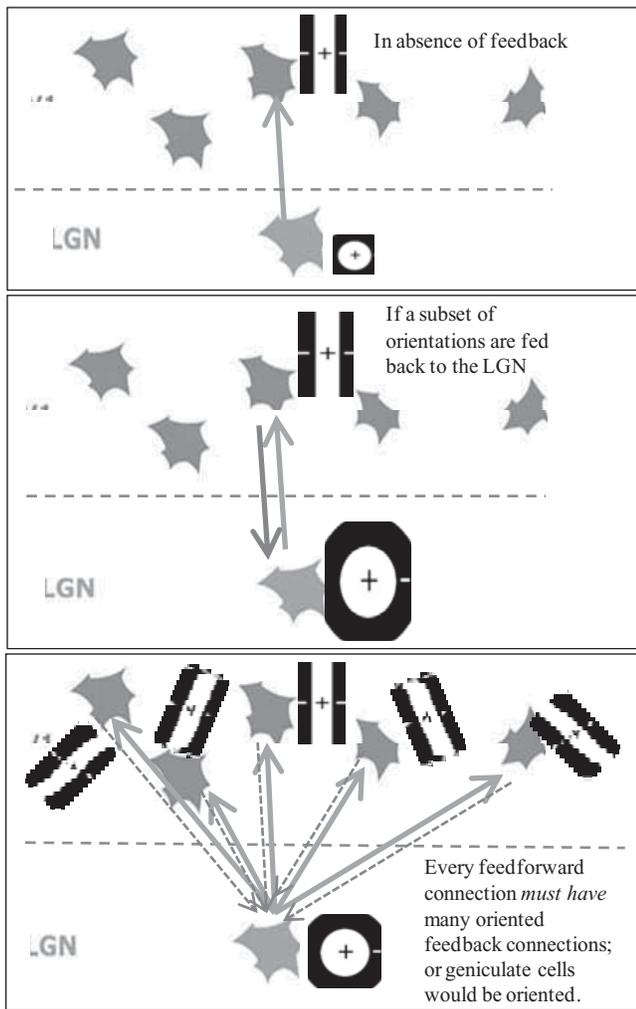

FIGURE 81.3 A model of the effects of feedback from area V1 on an LGN neuron. Numerous V1-oriented cells must feed back to every feedforward LGN cell in order to account for the lack of significant orientation bias in LGN receptive fields.

of their orientation selectivity, only a fraction of all feedback connections will be active at any given time, depending on the orientation of the visual stimulus, whereas the feedforward connections will be active irrespective of stimulus orientation. In summary, the massive feedback versus feedforward connectivity ratio can be misleading: this large ratio does not necessarily mean that feedback signals are more important or more physiologically relevant than feedforward signals. Because higher visual areas are more selective than lower visual areas, only a relatively small fraction of the feedback may be expected to be active at any given moment. Thus feedback connections may need to tile the entire space of receptive field properties of the higher level; otherwise, the feedback would impose high-level receptive field characteristics on the receptive fields of lower areas.

Figure 81.4 illustrates this idea in terms of the feedback from dichoptic to monoptic levels of the visual pathway. To

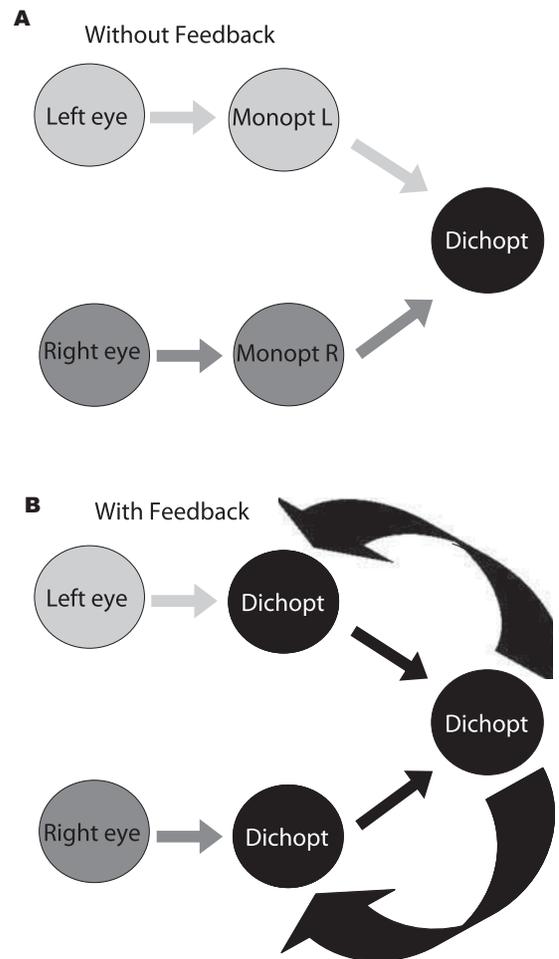

FIGURE 81.4 The effects of feedback from dichoptic levels to monoptic levels of visual processing. (A) A general model of early visual binocular integration in the absence of feedback connections. (B) If significant feedback existed between dichoptic levels of processing and earlier monoptic levels, the earlier levels should acquire the properties of the dichoptic levels (i.e., they should become dichoptic by virtue of the feedback). (Reprinted from Macknik, 2006.)

be clear about the jargon: “monocular” means “with respect to a single eye,” and “monoptic” means either “monocular” or “not different between the two eyes.” “Binocular” means “with respect to both eyes,” and “dichoptic” means “different in the two eyes.” Thus subcortical levels of the visual system are monoptic (because the cells are monocular), whereas cortical visual areas that have binocular circuits may potentially process dichoptic information.

To summarize: because receptive fields in ascending pathways become more selective, larger, and more complex in their properties as one rises through the higher levels of the brain’s hierarchies, anatomical feedback connections must be more numerous than feedforward connections. Otherwise, the hierarchical nature of the visual system would be diminished (figure 81.2). Moreover, the numerical

advantage of feedback over feedforward connections should be expected even if there is just a single functional role for feedback (i.e., attentional modulation).

If we combine these ideas with the Crick and Koch's non-strong-loops hypothesis and the physiological findings indicating that feedback plays a modulatory rather than a driving role, we may conclude that feedback inputs have more moderate physiological effects than feedforward inputs, despite being anatomically more numerous. This concept is supported by the known physiology: besides their lack of orientation selectivity, another feature that distinguishes LGN from V1 receptive fields is their smaller size (Allman, Miezin, & McGuinness, 1985; Desimone, Schein, Moran, & Ungerleider, 1985; Kastner, Nothdurft, & Pigarev, 1999; Knierim & Van Essen, 1991; Zeki, 1978a, 1978b). If feedback connections from V1 to the LGN were functionally as strong as their feedforward counterparts, LGN receptive fields would be as large as V1 receptive fields, but they are not. That is, because LGN receptive fields are smaller than V1 receptive fields, feedback from V1 to the LGN must be weaker than the retinal inputs.

It follows from these ideas that when feedback is operational, some receptive field properties, such as size, which continues to increase throughout the visual hierarchy (Allman et al., 1985; Desimone et al., 1985; Kastner et al., 1999; Knierim & Van Essen, 1991; Zeki, 1978a, 1978b) will be fed back from higher to lower levels. Thus we may predict that, if attention is carried by feedback connections, earlier receptive fields should increase in size when attention is

applied actively. This prediction has been confirmed experimentally (He, Cavanagh, & Intriligator, 1996; Williford & Maunsell, 2006). Chen and colleagues (2008) recently showed that attentional modulation of V1 neurons in the awake monkey is spatially specific: increasing task difficulty enhanced V1 neuronal firing rate at the focus of attention and suppressed it in surrounding regions, in support of Desimone and Duncan's (1995) center-surround model of attention (figure 81.5). Moreover, response enhancement and suppression were mediated by distinct neuronal populations that differed in direction selectivity, spike width, interspike-interval distribution and contrast sensitivity. This finding suggested that attentional feedback facilitates and suppresses distinct populations of neurons in the primary visual cortex.

To conclude, feedback connections may potentially have no other function than to modulate (facilitate or suppress) feedforward signals as a function of attentional load.

The role of visual masking, binocular rivalry, attention, and feedback in the study of visual awareness

Let us assume that visual awareness is correlated to brain activity within specialized neural circuits, and that not all brain circuits maintain awareness. It follows that the neural activity that leads to reflexive or involuntary motor action may not correlate with awareness because it does not reside within awareness-causing neural circuits (Macknik & Martinez-Conde, 2009).

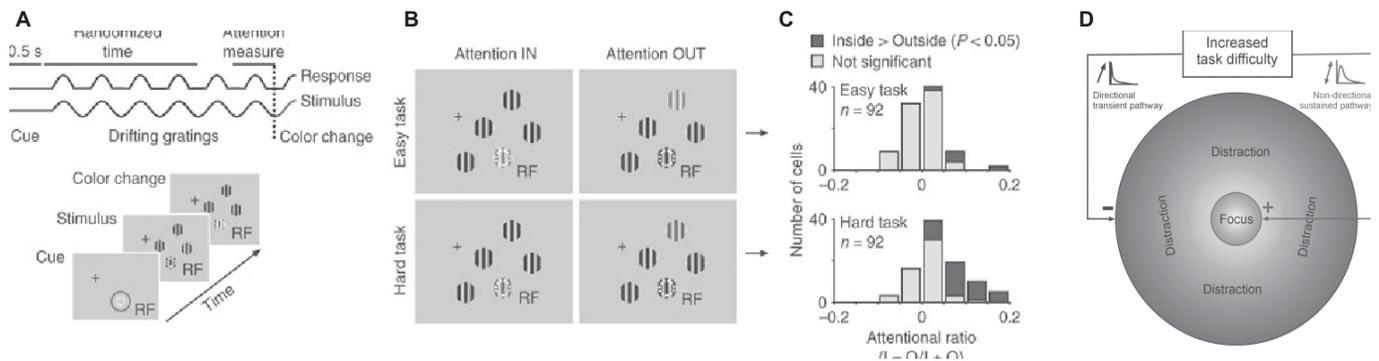

FIGURE 81.5 V1 attentional response modulation in awake monkey single cells during hard and easy tasks. (A) Temporal structure of a trial. Two rhesus monkeys were trained to fixate on a small cross while covertly attending to a spatial location that was cued at the beginning of each trial. The cue was a thin red ring with a diameter that was threefold larger than the diameter of the neuronal receptive field (RF). Following the cue, drifting gratings were presented simultaneously at five different spatial locations for 1.5–3 s. Following a randomized period of time, one of the gratings changed color/luminance, and the animal was tasked with detecting the change by releasing a bar within 0.5 s. The attentional modulations were measured at the last cycle of the drifting grating before the color change. (B) The color change could be easy or

hard to detect and could occur inside or outside of the receptive field. (C) The number of cells that were significantly modulated by attention (red) was much lower during the easy task (top) than during the hard task (bottom). A subset of 8 cells was significantly modulated by attention during both the easy and the hard task ($P < 0.05$). (D) An increase in task difficulty leads to an enhancement of V1 visual responses at the focus of attention and a suppression outside the focus. Difficulty-enhanced V1 neurons have poor directional selectivity and broad interspike interval distributions (sustained responses). Difficulty-suppressed V1 neurons are directional selective and have tight interspike interval distributions (transient responses). (Reprinted from Chen et al., 2008.)

Let us also propose that there is a “minimal set of neural conditions” necessary to achieve conscious visibility (see Chalmers, 2000, for an excellent review of this idea). Such conditions take the form of a specific type (or types) of neural activity within a subset of brain circuits. The minimal set of conditions will not be met if the correct circuits have the wrong type of activity (too much activity, too little activity, sustained activity when transient activity is required, etc). Moreover, if the correct type of activity occurs, but solely within circuits that do not maintain awareness, visibility will also fail. Finding the conditions in which visibility fails is critical to the research described here; although we do not yet know what the minimal set of conditions is, we can nevertheless systematically modify potentially important conditions (change neural circuits, modify levels of activity) and see if they result in stimulus invisibility. If so, the modified condition would be part, potentially, of the minimal set of neural conditions necessary to maintain visibility.

To establish the minimal set of conditions for visibility we need to answer at least four questions (Macknik, 2006). The questions and their (partial) answers are as follows:

1. What stimulus parameters are important to visibility?
 - A. The spatiotemporal edges (also curves and corners) of stimuli are the most important parameters to stimulus visibility (Macknik, Martinez-Conde, & Haglund, 2000; Troncoso, Macknik, & Martinez-Conde, 2005; Troncoso et al., 2007).
2. What types of neural activity best maintain visibility (transient versus sustained firing, rate codes, bursts of spikes, etc.—that is, what is the neural code for visibility)?
 - A. Transient bursts of spikes best maintain visibility (Macknik & Livingstone, 1998; Macknik et al., 2000; Martinez-Conde, Macknik, & Hubel, 2000, 2002). See figure 81.6.
3. What brain areas must be active to maintain visibility?
 - A. Visual areas downstream of V2, lying within the occipital lobe, must be active to maintain visibility of simple unattended targets (Macknik, 2006; Macknik & Martinez-Conde, 2004a; Tse, Martinez-Conde, Schlegel, & Macknik, 2005).
4. What specific neural circuits within the relevant brain areas maintain visibility?
 - A. The specific circuits that maintain visibility are currently unknown, but their responsivity is modulated by lateral inhibition (Macknik, 2006; Macknik & Livingstone, 1998; Macknik & Martinez-Conde, 2004a, 2004b; Macknik et al., 2000).

We must also determine the set of standards that will allow us to conclude that any given brain area, or neural circuit within an area, is responsible for generating a conscious

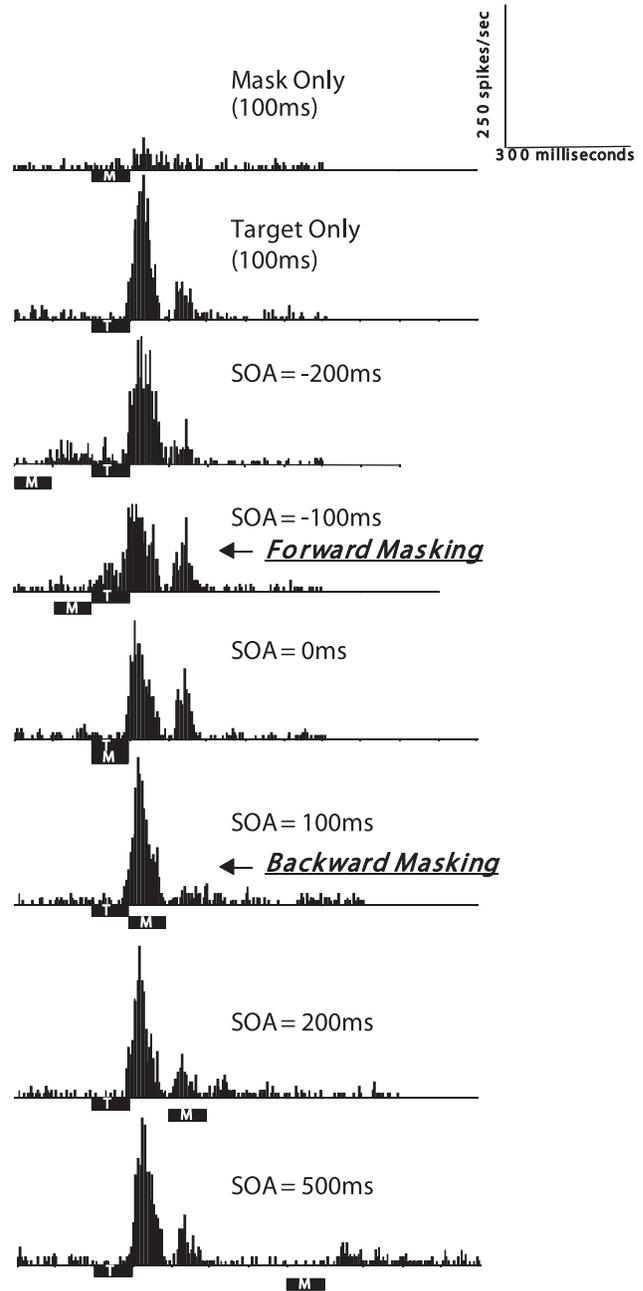

FIGURE 81.6 Multiunit recording from upper layers of area V1 in an anesthetized rhesus monkey. Black boxes below each histogram represent the time course of the mask (*M*) and target (*T*). Notice that under conditions that best correlate with human forward masking (interstimulus interval [ISI] of 0 ms, here corresponding to stimulus onset asynchrony [SOA] of -100 ms), the main effect of the mask is to inhibit the transient onset-response to the target. Similarly, in the condition that produces maximum backward masking in humans (stimulus termination asynchrony [STA] of 100 ms, here corresponding to SOA of 100 ms), the afterdischarge is specifically inhibited. Each histogram is an average of 50 trials with a bin width of 5 ms. (Reprinted from Macknik & Livingstone, 1998.)

experience. Parker and Newsome developed a “list of idealized criteria that should be fulfilled if we are to claim that some neuron or set of neurons plays a critical role in the generation of a perceptual event” (Parker & Newsome, 1998, p. 230). If one replaces the words “perceptual event” with “conscious experience,” Parker and Newsome’s list can be used as an initial foundation for the neurophysiological requirements needed to establish whether any given neuron or brain circuit may be the neural substrate of awareness (Macknik & Martinez-Conde, 2007). Parker and Newsome’s list (pp. 230–231) follows:

1. The responses of the neurons and of the perceiving subject should be measured and analyzed in directly comparable ways.
2. The neurons in question should signal relevant information when the organism is carrying out the chosen perceptual task. Thus the neurons should have discernible features in their firing patterns in response to the different external stimuli that are presented to the observer during the task.
3. Differences in the firing patterns of some set of the candidate neurons to different external stimuli should be sufficiently reliable in a statistical sense to account for, and be reconciled with, the precision of the organism’s responses.
4. Fluctuations in the firing of some set of the candidate neurons to the repeated presentation of identical external stimuli should be predictive of the observer’s judgment on individual stimulus presentations.
5. Direct interference with the firing patterns of some set of the candidate neurons (e.g., by electrical or chemical stimulation) should lead to some form of measurable change in the perceptual responses of the subject at the moment that the relevant external stimulus is delivered.
6. The firing patterns of the neurons in question should not be affected by the particular form of the motor response that the observer uses to indicate his or her percept.
7. Temporary or permanent removal of all or part of the candidate set of neurons should lead to a measurable perceptual deficit, however slight or transient in nature.

However, visual circuits that may pass muster with Parker and Newsome’s guidelines may nevertheless fail to maintain awareness, as we shall explain. To guide the search for the neural correlates of consciousness (NCC), the minimal neuronal mechanisms jointly sufficient for a particular percept (Crick & Koch, 1995), some additional standards must be added.

The first additional standard concerns the use of illusions as the tool of choice to test whether a neuronal population or circuit may maintain awareness. Visual illusions, by definition, dissociate the subject’s perception of a stimulus from its physical reality. Thus visual illusions are powerful devices in the search for the NCC (Myerson, Miezins, & Allman,

1981), as they allow us to distinguish the neural responses to the physical stimulus from the neural responses that correlate to perception. Our brains ultimately construct our perceptual experience, rather than reconstruct the physical world (Macknik & Haglund, 1999). Therefore an awareness-maintaining circuit should express activity that matches the conscious percept, irrespective of whether it matches the physical stimulus. Neurons (circuits, brain areas) that produce neural responses that fail to match the percept provide the most useful information because they can be ruled out, unambiguously, as part of the NCC. As a result, the search for the NCC can be focused to the remaining neural circuits. Conversely, neurons that do correlate with perception are not necessarily critical to awareness, as they may simply play a support role (among other possibilities) without causing awareness themselves.

The second additional standard derives from a major contribution of Crick and Koch’s: the distinction between explicit and implicit representations in the study of visual awareness (Crick & Koch, 1998a). In an explicit representation of a stimulus feature, there is a set of neurons that represents that feature without substantial further processing. In an implicit representation, the neuronal responses may account for certain elements of a given feature; however, the feature itself is not detected at that level. For instance, all visual information is implicitly encoded in the photoreceptors of the retina. The orientation of a stimulus, however, is not explicitly encoded until area V1, where orientation-selective neurons and functional orientation columns are first found. Crick and Koch propose that there is an explicit representation of every conscious percept.

Here we offer the following corollary to Crick and Koch’s idea of explicit representation: Before one can test a neuronal population or circuit for its role in the NCC, the specific neurons (or the population/circuit being tested) must be shown to explicitly process the test stimulus. That is, the neurons must respond to the test stimulus or show selective tuning to some range of features of the stimulus. This corollary constrains the design of neurophysiological experiments aimed to test the participation of specific neurons, circuits, and brain areas in the NCC. For instance, if one found that retinal responses do not correlate with auditory awareness, such a discovery would not carry great weight. The neurons in the eye do not process auditory information, and so it is not appropriate to test their correlation to auditory perception. However, this caveat also applies to more nuanced stimuli. What if V1 activity was tested for its correlation to the perception of faces versus houses? Faces and houses are visual stimuli, but V1 has never been shown to process faces or houses explicitly, despite the fact that visual information about faces and houses must implicitly be represented in V1. Therefore, one cannot test V1’s role in the NCC using houses versus faces and expect to come to any meaningful

conclusion. Because that form of information is not explicitly processed in V1, it would not be informative as to V1's role in the NCC if V1 neurons failed to modulate their response when the subject was presented with faces versus houses. It follows that some stimuli are incapable of localizing awareness within specific neural circuits, because no appropriate control exists to test for their explicit representation. For this reason, binocular rivalry stimuli pose a special problem in localizing the circuits that maintain visual awareness. Binocular rivalry (Wheatstone, 1838) is a dynamic percept that occurs when two disparate images that cannot be fused stereoscopically are presented dichoptically to the subject (i.e., each image is presented independently to each of the subject's eyes). The two images (or perhaps the two eyes) appear to compete with each other, and the observer perceives repetitive undulations of the two images, so that only one of them dominates perceptually at any given time. (If the images are large enough, then binocular rivalry can occur in a piecemeal fashion, so that parts of each image are contemporaneously visible.)

Binocular rivalry has been used as a tool to assess the NCC, but it has generated controversy because of conflicting results (Macknik & Martinez-Conde, 2004a; Tse et al., 2005). Some human fMRI studies report that BOLD activity in V1 correlates with awareness of binocular rivalry percepts (Lee, Blake, & Heeger, 2005; Polonsky, Blake, Braun, & Heeger, 2000; Tong & Engel, 2001). In contrast, other human fMRI studies (Lumer, Friston, & Rees, 1998), as well as neuronal recording studies in nonhuman primates (Leopold & Logothetis, 1996), report that activity in area V1 does not correlate with visual awareness of binocular rivalry percepts. One possible reason for this discrepancy is that none of these studies determined that the visual areas tested contained the interocular suppression circuits necessary to mediate binocular rivalry. That is, since binocular rivalry is a process of interocular suppression, the neural circuits underlying the perception of binocular rivalry must be shown to produce interocular suppression—explicitly. Otherwise, it cannot be demonstrated that binocular rivalry is a valid stimulus for testing the NCC in those areas. Thus awareness studies using binocular rivalry are valid only in areas that have been shown to maintain interocular suppression. If binocular rivalry fails to modulate activity within a visual area, one cannot know, by using binocular rivalry alone, if the perceptual modulation failed because awareness is not maintained in that area or because the area does not have circuits that drive interocular suppression. This is more than just a theoretical possibility: as we will describe, we have shown in the human and the macaque monkey that the initial binocular neurons of the early visual system (areas V1 and V2) are binocular for excitation but monocular for inhibition. That is, they fail to process interocular suppression explicitly (Macknik & Martinez-Conde, 2004a; Tse

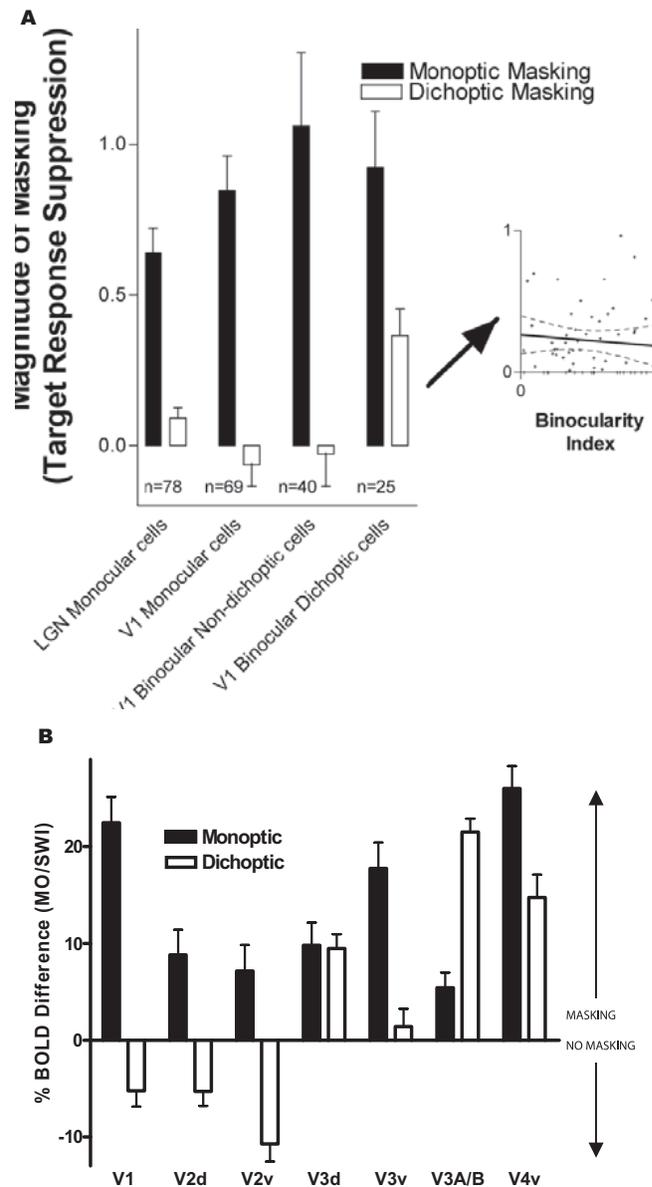

FIGURE 81.7 (A) Summary statistics of monoptic versus dichoptic masking responses in the LGN and area V1 of the macaque monkey. Monoptic (black bars) and dichoptic (white bars) masking magnitude as a function of cell type: LGN, V1 monocular, V1 binocular (nonresponsive to dichoptic masking), and V1 binocular (responsive to dichoptic masking) neurons. Inset shows the linear regression of dichoptic masking magnitude in V1 binocular neurons as a function of their degree of binocularity (all neurons plotted were significantly binocular as measured by their relative responses to monocular targets presented to the two eyes sequentially): BI of 0 indicates that the cells were monocular, while a BI of 1 means both eyes were equally dominant. (Reprinted from Macknik & Martinez-Conde, 2004a.) (B) Monoptic and dichoptic masking magnitude as a function of occipital retinotopic brain area in the human. Negative values indicate decreased visual masking (increased target visibility), whereas values ≥ 0 indicate increased masking (decreased target visibility). (Reprinted from Tse, Martinez-Conde, Schlegel, & Macknik, 2005.)

et al., 2005) (figure 81.7). There is no control condition with which to establish whether binocular rivalry fails because of a (mundane) lack of interocular suppression or (more interestingly) fails because of a lack of awareness maintaining circuits. One could address this issue by using binocular rivalry in tandem with a different stimulus to test for the explicit representation and strength of interocular suppression, such as visual masking stimuli. In visual masking, a monoptic form of the illusion is available, and so one can distinguish failures of interocular suppression from failures of visual awareness. But if one were to use masking stimuli to assess interocular suppression in a given visual area, then the role of such area in maintaining visibility and awareness would have also been established (in the absence of binocular rivalry stimulation), thus obviating the need for subsequent testing with binocular rivalry stimuli. Because one must rely on non-binocularly-rivalrous stimuli to determine the explicit representation and strength of interocular suppression in a given area, it is not possible to unambiguously interpret the neural correlates of perceptual state using binocular rivalry *alone* in any visual area, irrespective of the strength of the binocular rivalry response.

Our visual masking studies have shown that binocular neurons in areas V1 (the first stage in the visual hierarchy where information from the two eyes is combined) and V2 of humans and monkeys can integrate excitatory responses from the two eyes (Macknik & Martinez-Conde, 2004a; Tse et al., 2005) (figure 81.7). However, these same neurons do not express interocular suppression between the eyes. That is, binocular neurons in V1 are largely binocular for excitation while nevertheless being monocular for suppression (that is, input from one eye will not suppress the firing rate of a V1 or V2 cell that is primarily tuned for input from the opposite eye). Because most early binocular cells do not explicitly process interocular suppression, these neurons cannot explicitly process binocular rivalry. Further, binocular rivalry cannot distinguish between the role of interocular suppression and the role of awareness at any level of the visual system. Therefore no conclusions can be reached about the localization of the NCC to specific parts of the visual system based on binocular rivalry studies alone. If a given visual area does not correlate to binocular rivalry, it may simply mean that interocular suppression is not at play in that area, rather than that area is not maintaining awareness. However, these findings also beg the question of why some studies have found binocular rivalry modulation in low-level visual areas (Haynes, Driver, & Rees, 2005; Lee et al., 2005; Polonsky et al., 2000; Tong & Engel, 2001; Wunderlich, Schneider, & Kastner, 2005). One possible reason for this paradox is that these studies failed to control for the effects of attentional feedback, thus confounding apparent modulation to interocular suppression with attentional modulation. Because the subjects in these studies needed to

attend to the binocular rivalry stimuli, attention itself, rather than binocular rivalry, may have produced the retinotopic activation found.

Monoptically and dichoptically presented visual-masking illusions (such as forward and backward masking and the standing wave) can differentiate between interocular suppression and awareness, and thus they are immune to these shortcomings. Therefore visual masking is an ideal illusion to isolate the NCC. Further, visual-masking illusions allow us to examine the brain's response to the same physical target under varying levels of visibility (unlike in binocular rivalry, where one only measures which of two rivalrous percepts was dominant at any given time, without consideration of how visible that percept was). Thus by quantifying the perceptual and physiological effects of visible versus invisible (masked) targets we will determine many, if not all, of the conditions that cause visibility.

We propose that, to test for explicit processing in neuronal populations or circuits, one should use a visual illusion, such as visual masking, that can be presented in at least two modes of operation: one mode to ensure that the neural circuit in question is able to process the stimulus explicitly and another mode to test the correlation to awareness. In visual masking, the monoptic mode establishes that the neural circuit in consideration explicitly processes visual-masking stimuli, and then the dichoptic mode can be used to probe the NCC.

Choosing an appropriate stimulus that is processed at multiple levels of the visual system is key to localizing awareness. However, one must take care to control for other potential experimental confounds. Lamme and colleagues used visual-masking stimuli to examine the NCC and concluded that stimulus-derived late responses (i.e., afterdischarges) are due to feedback from higher areas (Lamme, Zipser, & Spekreijse, 2002) and that this feedback is critical to maintaining awareness (figure 81.8). But if the late responses are due to feedback and not to feedforward circuits, their timing should be stable with respect to stimulus duration. That is, if late responses are due to feedback, target duration should not affect their latency, because the feedback would be driven by the target's onset-response as it rises through the visual hierarchy (figure 81.9A). On the contrary, if the late responses are caused by the target's termination in a feedforward fashion, then target duration would critically affect their latency (figure 81.9B). Figure 81.10 shows that, as the stimulus duration increases, so does the latency of the afterdischarge, against the predictions from Lamme's feedback model (Macknik & Martinez-Conde, 2004b). The model is further ruled out on psychophysical grounds, as the perceptual strength of masking varies with target duration (Macknik & Livingstone, 1998).

Despite these arguments, Lamme's group has maintained that late responses are due to feedback. In a recent study

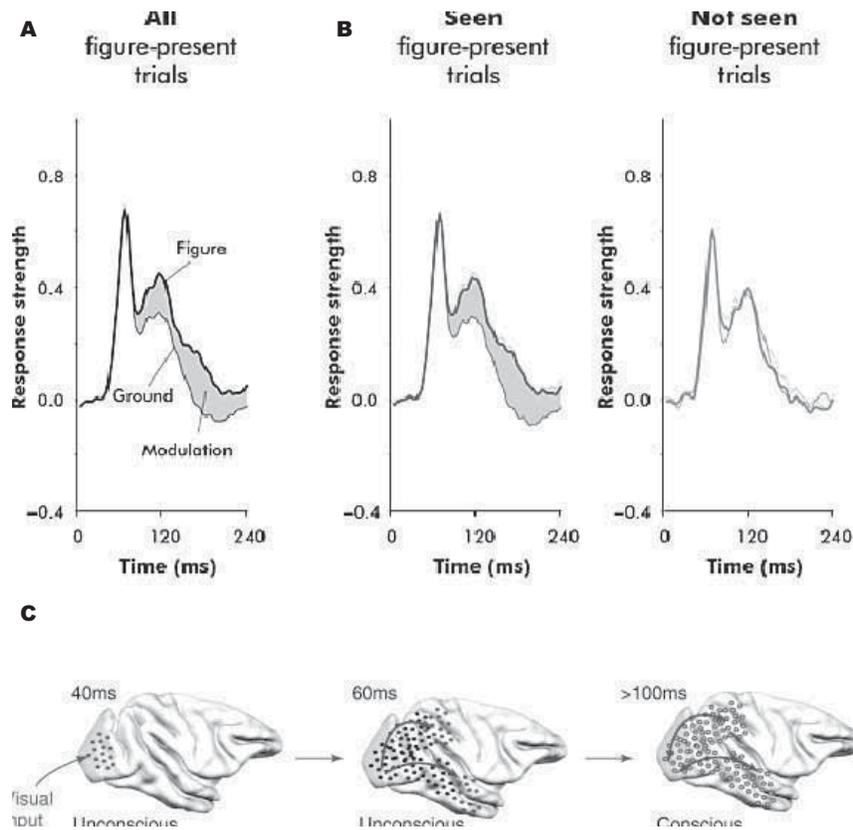

FIGURE 81.8 Alternative model of visual backward masking and awareness that require recurrent feedback. (A) Population response strength in awake monkey V1 to a figure-present (thick line) and ground (no figure-present, thin line) stimulus. (B) Responses to figure and ground conditions in which the figure was seen (left) and not seen (right). Notice that in the not-seen trials the late response

does not differ for figure and ground conditions. (Reprinted from Super, Spekreijse, & Lamme, 2001.) (C) Model suggesting that the visibility-correlated late response in panels A and B is due to recurrent feedback from higher level cortices (activated by the feed-forward onset response). (Reprinted from Lamme, 2003.)

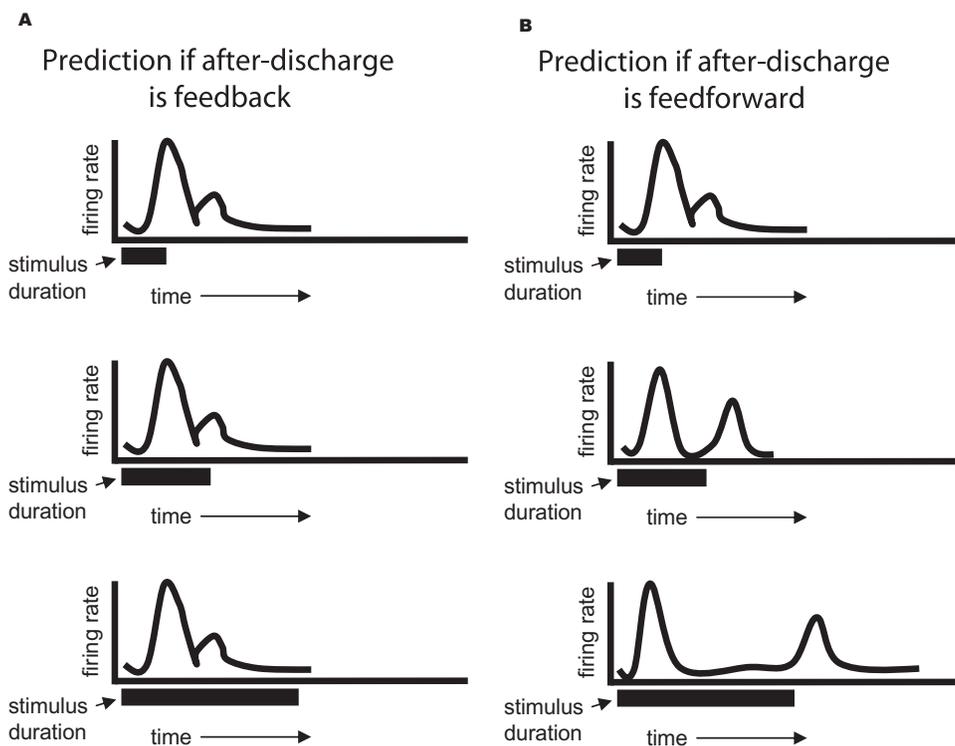

FIGURE 81.9 Predicted temporal dynamics of neuronal responses (as a function of stimulus duration) if the afterdischarge is (A) due to recurrent feedback driven by the stimulus onset or (B) driven by the termination of the stimulus in a feedforward manner.

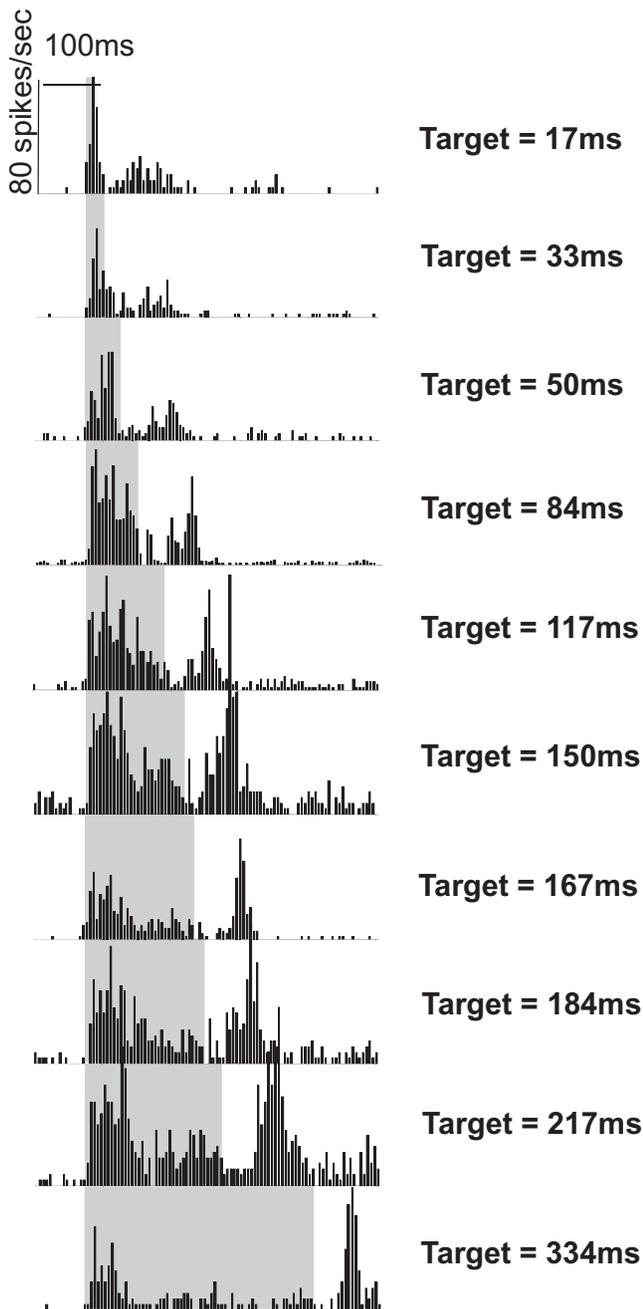

FIGURE 81.10 Typical responses from a single neuron in monkey area V1 to a target of various durations. The latency and magnitude of the afterdischarge grow as the target duration increases. (Reprinted from Macknik & Martinez-Conde, 2004a.)

they surgically removed the entire extrastriate visual cortex of a monkey (V3, V3A, V4, MT, MST, DP, LOP, LIPd, and 7a), a procedure which led to a reduction of area V1 late responses (Super & Lamme, 2007). However, surgical ablations are irreversible by definition: one cannot reverse the procedure to show that reinstating the ablated tissue cancels out the effect. Moreover, the surgical removal of the extrastriate cortex involves the resection of a large portion of the cerebral cortex, thus causing massive traumatic brain

damage, including substantial damage to the cortical vascular systems as well as fibers of passage and nearby neural structures such as the optic radiations. Therefore it is unclear exactly what processes may or may not have been affected by such a drastic ablation.

Conclusions

We have reviewed the literature on the anatomy and physiology of feedback in the visual system and concluded that feedback connections may be the source of attentional facilitation and suppression, and that other proposed roles for feedback are not as clearly supported. We have also proposed that the large ratio of feedback to feedforward connections does not necessarily indicate a significant physiological role for feedback, but may instead be a requirement of any feedback pathway operating within a hierarchical neural system, such as the visual hierarchy. This statement would be true even if feedback subserves only a single role, such as top-down attentional modulation.

Finally, we have discussed the strengths of visual masking in the study of visual awareness, as compared to binocular rivalry, and have concluded that visual masking is a sound paradigm in awareness studies, whereas binocular rivalry has serious shortcomings as a tool to localize the NCC. Using visual masking as a tool, we have developed several new standards that must be met to determine the role of neural circuits, neurons, and brain areas in maintaining consciousness.

We have emphasized the need to control for the effects of attention as an important strategy in designing experiments that localize awareness. Attention can enhance or suppress the magnitude of neural responses to a given stimulus (Chen et al., 2008; Desimone & Duncan, 1995; McAdams & Maunsell, 1999; Moran & Desimone, 1985; Spitzer, Desimone, & Moran, 1988; Williford & Maunsell, 2006), and thus it may facilitate or suppress its perceptual awareness. However, attention is a distinct process from awareness itself (Koch & Tsuchiya, 2007; Merikle, 1980; Merikle & Joordens, 1997; Merikle, Smilek, & Eastwood, 2001). For instance, low-level bottom-up highly salient stimuli (such as flickering lights or loud noises) can lead to awareness and draw attention, even when the subject is actively attending to some other task, or not attending to anything (i.e., when the subject is asleep). It follows that experiments to isolate the NCC should control for the effects of attention.

Therefore, we add the following three standards for testing a neural circuit's contribution to awareness to Parker and Newsome's list:

8. The candidate neurons should be tested with an illusion that allows one to dissociate the physical stimulus from its perception. If the candidate set of neurons is capable of

maintaining awareness, the neural responses should match the subjective percept, rather than the objective physical stimulus.

9. The candidate neurons must explicitly process the type of information or stimulus used to test them.

10. The responses of the neurons, and of the perceiving subject, should be measured with experimental controls for the effect of attention.

ACKNOWLEDGMENTS We thank Mona Stewart, Hector Rieiro, and Jorge Otero-Millan for their technical assistance. This study was funded by the Barrow Neurological Foundation, National Science Foundation, Arizona Biomedical Research Institute, and Science Foundation Arizona.

82 Emotion and Consciousness

MICHAEL KOENIGS AND RALPH ADOLPHS

ABSTRACT Emotional feelings, such as happiness and sadness, are a fundamental feature of human conscious experience, yet the neuroanatomical pathways that give rise to the conscious experience of emotion remain unclear. In this chapter we review data and theories that address the neural basis of the conscious experience of emotion. In particular, we highlight the insula's role in mapping the physiological state of the body as a potential substrate for the conscious experience of emotion. In addition, we discuss research supporting the assertion that emotional information need not be conscious to have significant effects on brain activity and behavior. We conclude with speculative thoughts about the relationship among interoception, emotion, and self-awareness.

“Consciousness” refers to subjective experience. At any given waking moment we are conscious *of* something. In other words, there are contents of consciousness—what it is that we are experiencing. The contents of consciousness can include things we see, hear, smell, taste, and touch. It is easy to become confused about what exactly it is that human conscious experience refers to, or whether such reference is veridical (see box 82.1 for some clarifications), but in this chapter we do not intend to discuss any of these issues. Instead, we focus on our commonsense understanding of what it means to be “conscious of” something, a sense that is shared in common between humans and many other animals. For conscious experiences in this everyday sense, there are solid neurobiological accounts of how a sensory stimulus (such as light) is processed by the nervous system: a specialized sensory apparatus (such as the retina) transduces physical energy to nerve impulses, and through afferent relays (such as thalamic nuclei) the information is mapped in modality-specific areas of the cerebral cortex (such as primary visual cortex). The cortical processing of sensory information is thought to give rise to the conscious experience of the sensation. The chapters in this volume by Koch (chapter 79) and Rees (chapter 80) address this issue in detail and discuss which cortical regions appear to contribute directly to the contents of consciousness. The neuroscience approach here has been straightforward: in which neural structures can we record signals (e.g., single-unit activity, BOLD response in fMRI studies) that correlate better with

reports of conscious experience than with physical properties of the sensory stimuli alone?

But there are kinds of conscious experiences that seem different from the preceding examples and for which the neural pathways are less well understood. For example, the subjective experiences of joy and sorrow are no less real than the subjective experience of the blueness of the sky, but there seem to be more unanswered questions regarding the neurobiological mechanism for the experience of emotion than for the experience of vision. In the visual system the retina transduces light waves to neural impulses that code visual information—but is there an analogous point of origin for neural impulses that code emotional information? In the visual system there are visual cortices that are necessary for the conscious experience of sight—but are there analogous “emotional cortices” that are necessary for the conscious experience of emotion?

In this chapter we will review data and theories that address the neural basis of the conscious experience of emotion. In addition, we will discuss research supporting the assertion that emotional information need not be conscious to have significant effects on brain activity and behavior, just as is the case for nonconscious sensory processing. We will conclude with some more speculative thoughts on the relationship between emotion and consciousness, suggesting not only that emotion provides a possible content for consciousness, but that such content in fact provides an essential ingredient for all conscious experience.

Conscious experience of emotion

Before turning to a discussion of neuroscientific research relating emotion and consciousness, we first clarify some terminology. Depending on whom one asks—philosophers, psychologists, neuroscientists, or neurologists, for example—one may hear substantially different conceptions of both “emotion” and “consciousness.” With respect to consciousness, we will make a distinction between the level (state) of consciousness and the contents of consciousness. The level of consciousness can be categorical (e.g., conscious versus unconscious) or graded (e.g., degrees of wakefulness and alertness); this is the aspect of consciousness that is impaired, as explained by Schiff in chapter 78 in this volume. As described previously, the contents of consciousness refer specifically to “what” it is that we are aware of in our conscious

MICHAEL KOENIGS University of Wisconsin, Madison, Wisconsin
RALPH ADOLPHS California Institute of Technology, Pasadena, California

Box 82.1 What are we conscious of?

A primary point of puzzlement, and material for a large literature in philosophy of mind and epistemology, is one illustrated in the following example. Suppose you are at this moment seeing a red sunset. What is it that you are directly conscious of? One answer, and the one we give as premise to this chapter, is to say that you are conscious of the sunset out there in the world. A different answer is to say that you are conscious of something in your mind or your brain. After all, you can experience a red sunset while dreaming or imagining it, and for all you know that could be the case even when you are convinced that you are really seeing it.

It is perhaps telling that no animal other than humans is capable of entertaining this doubt (we believe). It is also telling that nothing in the brain has the physical properties of being red or sunsetlike (although its representational properties may be such). While we can of course be mistaken about the state of the world on the basis of our conscious experience, we reject the extreme idea that we could be mistaken in a global and systematic way, a view called *solipsism*. In order for our conscious experiences to have any meaning, any content, they need to be anchored to the world in the general case (although, again, we can of course be mistaken on individual occasions—but such mistakes could only occur against a background of generally getting it right).

So what exactly is it that specific regions of the brain contribute to conscious experience? In our view, it is misleading to speak of regions of the brain as “having,” “producing,” or “causing” conscious experience. They contribute to it, certainly, but the way in which they do so should keep track of the right level at which to attribute conscious experience. When you experience the red sunset, no part of your brain has that experience—you, the person, does. The parts of your brain that contribute to the conscious experience all work together to make you conscious of the red sunset and able to tell us about it. We are, therefore, not conscious of neural activity, but rather conscious *with* it.

experience (a red sunset, a Bach concerto, a particular perfume, or an emotion). It is this aspect of consciousness (the contents of consciousness) whose relationship to emotion we will primarily discuss in this chapter. In this context we will distinguish between conscious and nonconscious processing of emotion, by which we mean whether or not an otherwise conscious individual (statewise) is specifically aware of particular emotional information (contentwise).

With respect to emotion, we will use a distinction between “emotion” and “feeling” that was articulated more than a century ago in the James-Lange theory of emotion (James, 1884; Lange, 1887) and later elaborated by Antonio Damasio (Damasio, 1994, 1999). In this framework, “emotion” refers to the physiological and musculoskeletal changes in the body (encompassing the body proper as well as physiological modulatory changes in the brain) that occur in response to an emotionally salient stimulus (e.g., changes in heart rate,

posture, facial expression, alertness, and attention). “Feelings” refer to the conscious experience of emotion (e.g., the subjective experience of fear, sadness, or happiness). It follows that “emotions” can be observed objectively in the third person—for example, changes in heart rate can be measured with an EKG—whereas “feelings” are only available subjectively in the first person and thus can only be measured strictly through self-report (although they can of course be correlated with emotion and with neural responses). This usage of terms is by no means universal; while “feeling” is generally understood to mean the conscious experience of emotion, the usage of “emotion” is more vague and in many frameworks includes feelings. Furthermore, the word “feeling” has been used by many philosophers and scientists to denote any conscious, phenomenal state without necessarily implying emotional processing (e.g., “the feeling of seeing red”). In this chapter, we will use “feeling” to specifically denote the conscious experience of emotion, rather than the experience of conscious states in general. Figure 82.1 provides some further clarification of ways in which emotion, feeling, and related terms can be used.

A perennial debate about emotion and feeling as we have defined them is whether one causes the other. Intuitively, one might think that feelings cause emotions—you feel sad and consequently exhibit various autonomic and behavioral changes (you cry, etc.). William James famously inverted this intuitive causal order. According to James, we have autonomic emotional responses first, and these cause us to feel the emotion: you first run away from a bear and then feel afraid. Modern analyses of the relationship have acknowledged both versions. We now know that there can be very rapid emotional responses that precede feelings (and in fact can occur in the absence of our conscious awareness of the stimuli that triggered the emotion; see next subsection) in the way that James envisioned. But we also know that

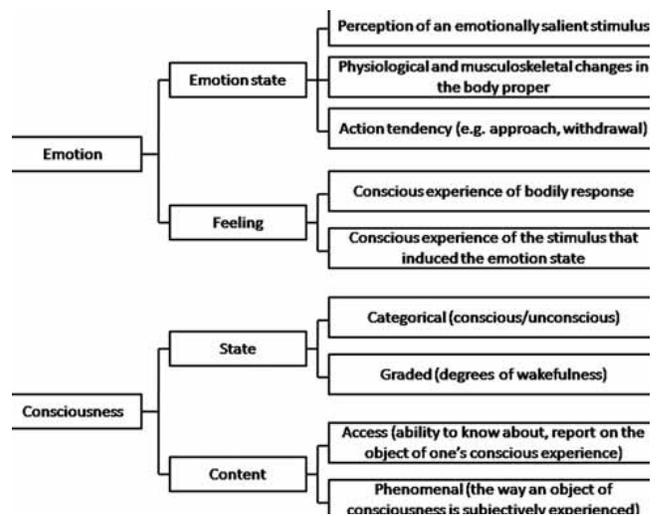

FIGURE 82.1 Clarification of terminology.

feelings influence emotions. The causal relationship is bidirectional.

Still, we ask the same question about feelings as about conscious experiences of other kinds: what are the necessary and sufficient neural substrates wherein neuronal activity covaries with the content of emotional conscious experience? We next review evidence for the idea that particular interoceptive sensory cortices are involved in feelings. Rather than making us aware of objects out there in the world (teloreception) or events at the interface of our body with the external environment (exteroception), interoception makes us aware of what is going on within the body proper (cf. box 82.1).

SOMATIC CHANGES AS A SUBSTRATE FOR FEELINGS We think of physiological changes in the viscera and musculoskeletal system (which, together with changes in the brain itself, constitute emotions in our terminology) as the stimuli that determine the content of the conscious experience of emotion (in much the same way that light determines the content of the conscious experience of vision). Continuing the analogy with teloreceptive conscious experience, there must exist in the nervous system some mechanism for transducing these internal physiological changes into afferent neural impulses that are ultimately mapped in the brain in such a way that they generate the conscious experience of the emotion (the feeling). This type of afferent pathway does in fact exist; it has been dubbed the *interoceptive system* or the *homeostatic afferent system* (Craig, 2003) (figure 82.2). The essential function of this system is to monitor the physiological condition of the body. The peripheral nerve fibers of this system innervate virtually all tissues of the body, including skin, muscle, and internal organs. The specialized nerve endings of these fibers are sensitive to a variety of physiological parameters, such as temperature, mechanical stress, hormonal activity, pH, osmolarity, and metabolic activity. Neural impulses representing this physiological information ascend through a multisynaptic pathway. The peripheral fibers (small-diameter afferents) initially synapse in lamina I of the spinal and trigeminal dorsal horns. These cells project to the nucleus of the solitary tract and the parabrachial nucleus in the brain stem, as well as to the thalamus (specifically, the posterior part of the ventromedial nucleus of the thalamus, or VMpo, and the medial dorsal nucleus, or MD). The nucleus of the solitary tract and parabrachial nucleus make their own projections to the thalamus (specifically, the basal part of the ventromedial nucleus of the thalamus, or VMb, and MD). Thus three regions of the thalamus (VMpo, VMb, and MD) relay afferent homeostatic information to cortex. The primary cortical target of both VMpo and VMb is the dorsal insula. After the initial topographic projection from VMpo and VMb to dorsal insula, the afferent homeostatic information is remapped in the anterior insula. The primary cortical target of MD (the anterior cingulate cortex) also

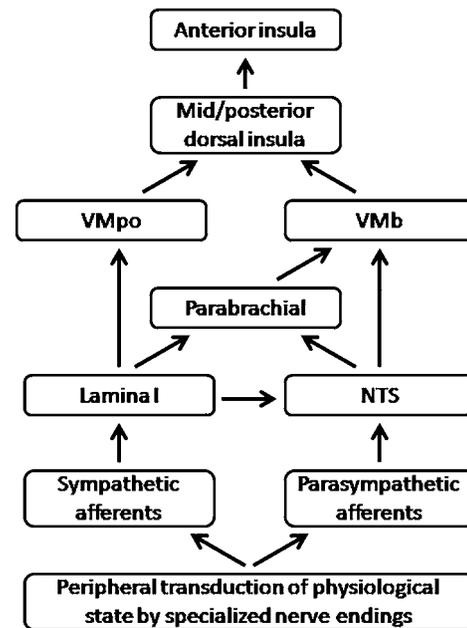

FIGURE 82.2 Schematic of homeostatic afferent system. NTS, nucleus of the solitary tract; VMpo, ventromedial thalamic nucleus (posterior portion); VMb, ventromedial thalamic nucleus (basal portion). (Adapted from Craig, 2003.)

projects to anterior insula. It is theorized that this cortical mapping (and remapping) of physiological/homeostatic information in anterior insula yields the conscious perceptions (“feelings”) of bodily state, such as pain, hunger, and thirst (Craig, 2003). An additional and more speculative idea (Craig, 2003) is that awareness of one’s own bodily feelings through this remapping may be a pathway unique to primates, or even *Homo sapiens*.

Inspired by the ideas of William James, Baruch Spinoza, and others (who were only able to conjecture at the time, ignorant of modern neuroscience findings), Antonio Damasio developed a theory of emotion and consciousness that highlights the recursive central mapping of peripheral physiological changes as the basis for subjective feeling and sentience (Damasio, 1994, 1999). Damasio’s ideas predate those of Craig and in fact much neuroscience evidence; they were formulated in large part on his work with patients who had damage to the ventromedial prefrontal cortex—a region of the brain intimately connected with the insula and involved in interactions between emotion, decision making, and social behavior. Together, Damasio’s and Craig’s proposals relieve the question of a neural substrate for feelings from historical vagueness and provide specific hypotheses that it should depend on interoceptive representations.

Recent neuroscientific data support a basic tenet of Damasio’s and Craig’s theories, specifically, that a central dynamic mapping of the viscera in the anterior insula is critically involved in emotion and feeling. A variety of functional imaging studies associate activation of the anterior

insula with the subjective experience of emotion and/or homeostatic stress. Examples of stimuli inducing anterior insula activation include unpleasant taste (Small et al., 2003; Zald, Lee, Fluegel, & Pardo, 1998), disgusting smells (Heining et al., 2003; Wicker et al., 2003), pictures of disgusting food (Calder et al., 2007), capsaicin pain (Iadarola et al., 1998), thermal pain (Brooks, Zambreanu, Godinez, Craig, & Tracey, 2005), thirst (Farrell et al., 2006), air hunger (Evans et al., 2002), and unfair treatment (Sanfey, Rilling, Aronson, Nystrom, & Cohen, 2003). Perhaps the most direct evidence linking the subjective feeling of emotion with the neurobiological mechanisms of interoception was provided by Hugo Critchley and colleagues (Critchley, Wiens, Rotshtein, Ohman, & Dolan, 2004). In this study, participants underwent functional magnetic resonance imaging while they attempted to determine whether their heartbeat was in sync with a series of auditory tones (a test of interoceptive awareness). Accuracy on the interoceptive heartbeat detection test was correlated with the activity and gray matter volume of the right anterior insula. Furthermore, participants' self-report ratings of day-to-day anxiety correlated with heartbeat detection accuracy and anterior insula activity. These findings suggest that anterior insula mediates both interoceptive awareness and emotional feeling states.

Just as higher-order visual cortices can mediate aspects of visual consciousness in the absence of a visual stimulus (e.g., in hallucinations, dreaming, and imagery), so can the insula mediate feelings that are decoupled from interoception. Its activity, and that of higher-order regions in the prefrontal cortex to which the insula projects, such as the anterior cingulate cortex, can be modulated by hypnosis (Rainville, Hofbauer, Bushnell, Duncan, & Price, 2002) and placebo effect (Petrovic, Kalso, Petersson, & Ingvar, 2002). If the insula is indeed critical for conscious emotional feelings, it is germane to consider how the properties of insula neurons may support this aspect of consciousness. In other domains of conscious experience (e.g., vision), researchers have theorized about the importance of thalamocortical loops, reciprocal feedback, and intercortical synchrony. Do insula neurons exhibit analogous profiles with respect to their connections with thalamus (e.g., VMpo and VMB) and other cortical areas (e.g., anterior cingulate)?

Although the mapping of emotion-related visceral changes in the insula is intuitively appealing and solidly grounded in neuroanatomical and physiological evidence, one must be wary of oversimplifying the neurobiological mechanism of feeling emotion. There is ample evidence to suggest that the mapping of visceral changes in the insula is neither necessary nor sufficient for the feeling of emotion. First of all, the basic James-Lange notion that emotional feelings necessarily follow from stereotyped changes in peripheral physiology (e.g., you feel sad because you cry) is challenged by reports of patients exhibiting pathological laughter and crying (PLC),

which is a disorder of emotional expression in which the patient may laugh or cry (or rapidly switch between the two) in the absence of an appropriately motivating stimulus and without the affiliated feeling of happiness or sadness, respectively. Typically, PLC follows some neurological insult, such as tumor or cerebrovascular lesion. However, the lesions associated with PLC typically involve descending pathways in the internal capsule and brain stem, thus leaving intact the ascending pathways for representing peripheral physiological changes. The fact that salient and stereotyped changes in respiratory, orofacial, and muscular activity (laughing and crying) are entirely dissociable from the normally associated feelings indicates that one does not necessarily follow from the other. Second, it seems that the insula is involved in processing a limited range of emotion. As described earlier, the insula seems to respond preferentially to negatively valenced or noxious stimuli. In many studies insula activation is associated with basic motivational/appetitive states like hunger, thirst, and pain, which are typically considered more "physical" than primarily "affective" states. With respect to the basic emotions (e.g., fear, happiness, sadness, disgust, surprise, anger), insula activity appears to be most reliably associated with disgust, which has a prominent ingestive component that other basic emotions do not. Furthermore, there is no evidence indicating that focal lesions of the insula have pervasive effects on the experience of emotion. One study reports a reduction in the urge to smoke among patients with insula damage (Naqvi, Rudrauf, Damasio, & Bechara, 2007), but again, this is an effect on a motivational/appetitive state rather than a primarily emotional state. Thus the insula's role in the conscious experience of emotion may be restricted to negatively valenced or ingestion-related contexts. Human emotional experience, however, spans a much broader range. In the following sections, we discuss the neural architecture supporting more complex aspects of human emotional experience.

EMOTION AND SOCIAL COGNITION One quintessential feature of human emotion is its prominence in social interaction. A subtle shift in gaze, posture, facial expression, or tone of voice by one person can engender marked changes in the emotional state of another. A fundamental question in the neuroscience of emotion, consciousness, and social behavior is how our conscious feeling state is impacted by the emotional states of others. An elementary step in this process is the recognition and discrimination of emotional states in others. Indeed, there has been a sustained effort to identify areas of the brain that discriminate between different expressions of emotion. For humans, facial expression is a principal means of communicating emotional state. Convergent lines of research implicate the amygdala as a key neural structure for the recognition of facial expressions

of emotion. The seminal report in this regard is that of SM, a woman who suffered extensive but remarkably selective damage to the amygdala bilaterally (Adolphs, Tranel, Damasio, & Damasio, 1994). SM evinces a marked impairment in the ability to recognize fear from facial expressions. Subsequent studies of patients with amygdala damage have replicated this deficit in the recognition of facial expressions of fear (Adolphs et al., 1999; Broks et al., 1998), but have also demonstrated deficits in the recognition of other basic emotions such as sadness, anger, and disgust (Adolphs & Tranel, 2004; Adolphs et al., 1999; Schmolck & Squire, 2001), as well as social emotions such as guilt, admiration, and flirtatiousness (Adolphs, Baron-Cohen, & Tranel, 2002) and the judgment of trustworthiness from faces (Adolphs, Tranel, & Damasio, 1998). Functional imaging studies of healthy individuals corroborate the conclusions of the patient studies; the amygdala is reliably activated during viewing of facial expressions of fear (Breiter et al., 1996; Morris et al., 1996). The amygdala's role in recognition of emotion from stimuli other than facial expressions is less clear. There are studies implicating the amygdala in recognition of emotion from auditory stimuli (Gosselin, Peretz, Johnsen, & Adolphs, 2007; Phillips et al., 1998) and body postures (de Gelder, Snyder, Greve, Gerard, & Hadjikhani, 2004; Hadjikhani & de Gelder, 2003), but there are also lesion studies that failed to find impairments in emotion recognition from such stimuli following amygdala lesions (Adolphs & Tranel, 1999; Atkinson, Heberlein, & Adolphs, 2007).

However, in order for one person's conscious feeling state to be impacted by the observed emotional state of another, the nervous system must do more than simply discriminate facial expressions of emotion. There must be an additional mechanism by which the observed emotion confers a change in the emotional state of the observer. One influential theoretical framework, known as *simulation theory*, holds that the observation and experience of certain emotions engage the

same neural substrates. Simulation theory is based in part on electrophysiological recordings in monkeys, which have demonstrated the existence of brain cells ("mirror neurons") that fire both when the monkey performs a particular motor action and when a monkey observes the same action (Rizzolatti, Fadiga, Gallese, & Fogassi, 1996). As it relates to emotion, simulation theory has garnered empirical support through behavioral and functional imaging studies in humans. For example, Dimberg and colleagues demonstrated that when people are unconsciously exposed to emotional faces, they exhibit distinct facial muscle reactions that correspond to the subliminally presented emotional faces (Dimberg, Thunberg, & Elmehed, 2000). A complementary functional imaging study showed that some areas of the brain are activated both when a subject observes and consciously imitates facial expressions of emotion (Carr, Iacoboni, Dubeau, Mazziotta, & Lenzi, 2003). Furthermore, the anterior insula, which is known to be active during the experience of disgusting tastes and smells, is also active when viewing facial expressions of disgust in others (Phillips et al., 1997; Wicker et al., 2003). And Singer and colleagues found that certain areas of the brain, including anterior insula and rostral anterior cingulate cortex, are activated both when an individual experiences physical pain and when the individual is aware that a loved one is experiencing physical pain (Singer et al., 2004). Taken together, these studies support the notion that the neurobiological basis for human empathy relies, at least in part, on shared neural substrates for the experience and observation of emotion.

Nonconscious processing of emotion

In order to fully understand the neural underpinnings of the conscious experience of emotion, one must also consider the nonconscious aspects of emotional processing. There is ample evidence indicating that emotionally salient information in the environment can indeed have an impact on both

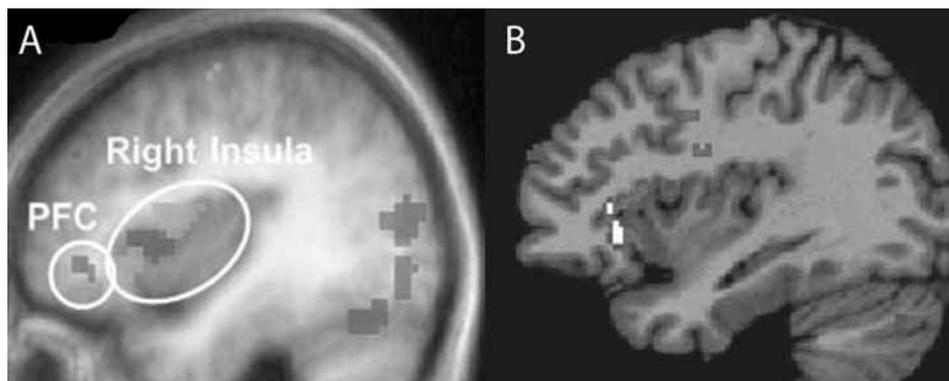

FIGURE 82.3 Functional MRI data supporting simulation theory. (A) Brain areas active during the observation of pain in another (red) and the feeling of pain in oneself (green) (Singer et al., 2004). (B) Brain areas active during the observation of disgust in another (blue) and the feeling of disgust in oneself (red); overlap in white (Wicker et al., 2003). (See color plate 101.)

brain and behavior without necessarily being consciously perceived.

NONCONSCIOUS PROCESSING OF EMOTIONAL VISUAL STIMULI

Functional imaging studies have demonstrated measurable neural responses to emotional stimuli in the absence of conscious perception of the stimuli. As described previously, the amygdala is reliably activated when viewing facial expressions of emotion, particularly fear. Whereas initial studies displayed stimuli for at least several seconds to ensure conscious perception (Breiter et al., 1996; Morris et al., 1996), subsequent studies employed subliminal presentation paradigms to determine whether the amygdala's responsiveness to emotional faces was inextricably linked to conscious awareness of the faces. Using a backward masking procedure in which a briefly presented emotional face (fearful or happy) was immediately replaced by a neutral face, Whalen and colleagues found greater amygdala activation in response to the masked fearful faces compared to the masked happy faces, even when subjects reported being unaware of the emotional faces (Whalen et al., 1998). In studies that suppressed the conscious perception of presented faces (Jiang & He, 2006; Williams, Morris, McGlone, Abbott, & Mattingley, 2004), the amygdala was again activated for fearful faces even when the faces were not consciously perceived. To determine the neural pathway that mediates the amygdala's response during the subliminal presentation of fearful faces, Morris and colleagues examined functional connectivity data in an fMRI study of backward-masked fear-conditioned faces (Morris, Ohman, & Dolan, 1999). In response to unseen faces (compared to seen faces), there was increased connectivity between the amygdala and the subcortical visual system (pulvinar and superior colliculus) and decreased connectivity between the amygdala and cortical visual areas (e.g., fusiform gyrus). These results suggest that the amygdala's response to nonconscious emotionally salient information is mediated by a subcortical (colliculothalamic) pathway. This conclusion is supported by the study of a patient (GY) who is blind in half of his visual field as a result of cortical damage involving primary visual areas. Despite his report of not being able to consciously "see" any faces in his blind hemifield, GY is able to discriminate, above chance, the faces' emotional expressions (de Gelder, Vroomen, Pourtois, & Weiskrantz, 1999). Furthermore, GY exhibits amygdala activity in response to fearful and fear-conditioned faces presented in his blind hemifield, and this amygdala activity correlates with activity in his intact subcortical pathway.

AUTONOMIC RESPONSES AS INDICES OF NONCONSCIOUS EMOTION

Psychophysiological and behavioral studies provide further evidence for nonconscious emotional processing. Skin conductance response (SCR) is an index of

autonomic nervous system activity that has been widely used as a measure of emotional arousal. The advantage of this technique for measuring emotional arousal is that it is "objective" in the sense that it does not depend on a subjective self-report. This feature of SCR is particularly useful for assessing emotional responsiveness in certain types of brain-damaged patients, who may lose access to declarative knowledge (and conscious self-report) for certain classes of stimuli or in certain contexts. For example, damage to occipitotemporal cortex may result in a condition known as prosopagnosia, which is an inability to recognize previously familiar faces, such as friends or family, despite intact basic visual perceptual abilities. Tranel and Damasio studied a group of six prosopagnosics to determine whether the patients' SCRs could discriminate between familiar and unfamiliar faces even if the patients could not discriminate the faces at a conscious level (Tranel & Damasio, 1985). This hypothesized dissociation is exactly what Tranel and Damasio found; although none of the prosopagnosics had any conscious sense of familiarity for any of the faces, each patient produced significantly larger SCRs for the faces of well-known family and friends than for the faces of strangers.

In addition, SCR data have been used to demonstrate that emotional responses can be acquired independently of conscious awareness of the emotion-inducing stimuli. In one of a series of such studies, Ohman and Soares collected SCR data from spider- and snake-phobic individuals as they were subliminally presented backward-masked pictures of spiders and snakes (Ohman & Soares, 1994). Despite reporting no conscious awareness of the phobia-relevant pictures, the phobic subjects still produced large SCRs. In a related study, Ohman and Soares tested nonphobic individuals on a conditioning paradigm in which masked pictures of snakes and spiders were repeatedly paired with an electric shock (Ohman & Soares, 1998). Again, despite no conscious recognition of the conditioned stimuli, subjects developed large conditioned SCRs.

The independence of emotional responsiveness from conscious awareness has been further supported by lesion patient data. Bechara and colleagues studied a patient with dense anterograde amnesia following bilateral hippocampal damage, using a conditioning paradigm in which a previously "neutral" stimulus (a particular visual slide or auditory tone) was repeatedly paired with a sudden, loud burst of noise (Bechara et al., 1995). Like normal healthy adults, the amnesic patient developed large SCRs in response to the conditioned stimuli. But unlike healthy adults, who could readily describe the association between the conditioned and unconditioned stimuli, the amnesic patient had no conscious knowledge of the association.

More elaborate studies of brain-injured patients have highlighted the role of nonconscious emotional processes in

overt behavior. One such study (Tranel & Damasio, 1993) featured patient B, who suffered severe amnesia with prosopagnosia following extensive bilateral cortical and subcortical damage resulting from herpes simplex encephalitis. Anecdotal observation of patient B suggested that he had a preference for a particular caregiver, despite having no declarative memory of the person, such as name, appearance, personality characteristics, hours of work, or specific interactions. To formally test the idea that patient B had developed a nonconscious affective behavioral preference, Tranel and Damasio devised an experiment in which patient B was exposed to three different caregivers: a “good guy,” who was friendly and always granted requests; a “bad guy,” who was responsible for tedious and unpleasant tasks; and a “neutral guy,” who was neither overly friendly nor unpleasant. After a week of exposure to the different caregivers, patient B denied any conscious recognition of any of the three persons and could offer no declarative information about any of them, even with extensive prompting. However, in a two-alternative forced-choice test in which a picture of each caregiver was paired with a picture of a visually similar stranger, patient B exhibited a strong preference for the “good guy,” a strong aversion for the “bad guy,” and no preference or aversion for the “neutral guy.” In addition, patient B had much larger SCRs for the “good guy” and the “bad guy” than for the “neutral guy” and strangers. These data clearly demonstrate that affective behavioral preference is not necessarily mediated by conscious recognition of the alternatives.

NONCONSCIOUS EMOTION IN DECISION MAKING The conclusion concerning affective preference unmediated by conscious awareness is further supported by a series of studies on the Iowa Gambling Task, or IGT (Bechara, Damasio, Damasio, & Anderson, 1994). In this task, the subject must choose between one of four decks of cards, with each card denoting a net gain or loss of money. The key manipulation is that the decks are preprogrammed so two decks are “good” in the long run, resulting in net gain, and two decks are “bad” in the long run, resulting in net loss. Through the variable experiences of reward and punishment with each deck, most normal people eventually develop a strong preference for the good decks. Bechara and colleagues later demonstrated that over the course of the task normal subjects develop SCRs prior to card selection, and that these “anticipatory SCRs” were greater when preceding choices for the bad decks (Bechara, Tranel, Damasio, & Damasio, 1996). In a subsequent study, Bechara and colleagues intermittently queried subjects throughout the task to assess the subjects’ conscious declarative knowledge of the decks’ relative net values (Bechara, Damasio, Tranel, & Damasio, 1997). Intriguingly, some normal subjects were never able to explicitly describe the relative long-term outcomes of each

deck, but still generated anticipatory SCRs and chose advantageously. Conversely, several patients with blunted emotional responsiveness due to ventromedial prefrontal lesions never generated anticipatory SCRs and continued to choose disadvantageously throughout the task, even in cases where they could articulate the relative net values of each deck. Thus the critical determinant of affective preference may not be conscious consideration of likely outcomes, but a nonconscious somatic signal derived from prior experiences with reward and punishment.

The assertion of the importance of nonconscious (or at least not necessarily conscious) somatic signals in decision making has been debated. Subsequent studies of the IGT have directly addressed the issue of conscious and nonconscious processing. In a study that involved more sensitive and detailed assessments of conscious knowledge of deck contingencies during the task, Maia and McClelland found that subjects were able to provide task-relevant quantitative knowledge earlier in the task than Bechara and colleagues had claimed, and furthermore that this conscious knowledge correlated positively with task performance (Maia & McClelland, 2004). In addition, a patient study shows that amnesics with impaired declarative recall typically perform the IGT at chance levels (Gutbrod et al., 2006). These findings suggest that conscious processing of previous reward/punishment experiences may indeed be the critical determinant of IGT performance. However, a later study introduced a manipulation in which subjects were explicitly told that the good and bad decks were reversed at one point during the task, and after that point there would be no ongoing feedback of gains and losses (Stocco & Fum, 2008). If subjects had conscious knowledge of the deck contingencies at the point of reversal, they would switch their selections accordingly. Despite demonstrating a behavioral preference for the good decks prior to the explicit reversal, subjects did not reliably shift card selection following the reversal, thereby indicating that conscious explicit knowledge of relative deck values was not the crucial determinant of successful task performance.

A recent study proposes a reconciliation of these apparently conflicting results (Persaud, McLeod, & Cowey, 2007). In this study, awareness of relative deck values was assessed with a postselection wagering scheme. In other words, subjects could make a side bet on whether each selection would pay off. If subjects were consciously aware that a deck was likely to yield a positive result, they would wager more money on a selection from that deck. Persaud and colleagues observed that when using Bechara’s testing scheme, which involved intermittent open-ended questions about the game, the subjects’ wagering gains lagged behind their IGT gains, indicating that subjects were improving on the IGT without conscious awareness of deck contingencies. However, when Persaud and colleagues used Maia and McClelland’s

testing scheme, which involved detailed quantitative questions about the game, the subjects' wagering gains matched their IGT gains, indicating that IGT performance was coupled with conscious knowledge about the game. These results suggest that conscious awareness is not necessary for improved decision making on the IGT, but that conscious awareness can be induced by directed questioning, and that this increased awareness is beneficial for performance.

Summary and closing thoughts

We finish by returning to ideas articulated by Damasio in his writings. According to this view, the body provides the substrate for conscious experience through its interaction with external objects. The self (in the sense of the material organism) is represented by "first-order" maps of afferent homeostatic activity, which are impacted by external objects and/or mental images. The physiological changes comprising emotion are one source of fluctuation in the first-order maps. In turn, higher-order maps in the brain represent the act of first-order somatic mapping by the nervous system. In this way, the organism becomes aware of itself interacting with the environment and experiencing emotion. The result is a conscious experience associated with a sense of self. The brain stem nuclei and white matter tracts that constitute the initial stages of all interoceptive channels are therefore also a prime region for which to hypothesize deficits in consciousness following lesions. While the impairments in consciousness (e.g., coma, persistent vegetative state) that can result from brain stem lesions are usually interpreted as arising from damage to ascending arousal systems, Damasio provides an alternative idea. The upper brain stem (at or above the level at which somatic information from the head is conveyed to the trigeminal nucleus) is the only place where a single lesion could interrupt all ascending interoceptive information (cervical spinal cord transection, for instance, still leaves intact information from the head coming in through the trigeminal nerve, as well as information from the body by way of the vagus nerve). In this view, the complete loss of ascending interoceptive information would render one unconscious.

83 Volition and the Function of Consciousness

HAKWAN LAU

ABSTRACT What are the psychological functions that can only be performed consciously? People have intuitively assumed that many acts of volition are not influenced by unconscious information. These acts range from simple examples such as making a spontaneous motor movement to higher cognitive control. However, the available evidence suggests that under suitable conditions, unconscious information can influence these behaviors and the underlying neural mechanisms. One possibility is that stimuli that are consciously perceived tend to yield strong signals in the brain, which makes us think that consciousness has the function of such strong signals. However, if we could create conditions where the stimuli could yield strong signals but not the conscious experience of perception, perhaps we would find that such stimuli are just as effective in influencing volitional behavior. Future studies that focus on clarifying this issue may tell us what the defining functions of consciousness are.

Many acts of volition seem to require conscious effort. We consciously initiate spontaneous motor movements. We cancel planned actions at will. We deliberately avoid particular actions. We intentionally shift our action plans in order to pursue different goals. Sometimes, theorists say, these are the functions of consciousness, as if evolution has equipped us with the gift of consciousness just to perform these acts. Without consciousness, presumably, we would only be able to perform much simpler actions that are no more sophisticated than embellished reflexes.

In this chapter we review available evidence to see if these intuitive claims are empirically supported. Recent studies in cognitive neuroscience suggest that many of these complex processes can actually be performed without consciousness. Or at least, many of them can be directly influenced by unconscious information. This evidence calls into question the true function of consciousness, if it is not to enable us to deliberate our actions. We end by discussing what is logically required for an experiment to demonstrate the true function of consciousness.

Spontaneous motor initiation

Motor actions that are made not in immediate or direct response to external stimuli can be said to be spontaneously

initiated. These are also sometimes called self-paced or self-generated actions. For instance, one may choose to casually flex one's wrist while sitting in a dark room, out of one's own free choice and timing, not to react to anything in particular. Some philosophers have argued that in cases like that, it should seem obvious that the action is caused by one's conscious intention (Searle, 1983). Whereas one may argue that fast reactions to external stimuli may be driven by unconscious reflex (e.g., a runner leaping forward upon hearing the starting shot), spontaneous actions do not seem to have any immediate cause but the conscious intention itself.

However, it has been shown that there is preparatory activity in the brain that starts as early as 1–2 seconds before spontaneous actions are executed. This piece of one of the most perplexing findings in cognitive neuroscience was originally reported by Kornhuber and Deecke in the 1960s (Kornhuber & Deecke, 1965). They placed electrodes on the scalp to measure electroencephalography (EEG) while subjects made spontaneous movements at their own timing. The EEG data that were time-locked to the point of motor execution (as measured by muscle contraction indicated by electromyography, EMG) were averaged over many trials, thereby producing an event-related potential (ERP) known as the *Bereitschaftspotential* (BP) or readiness potential (RP). The readiness potential is slowly rising, peaking at around the point of action execution, and starting from 1 to 2 seconds before that (figure 83.1). The readiness potential is most pronounced at electrodes near the vertex (Cz in the EEG coordinate system), which is directly above the medial premotor areas (including the supplementary motor area, SMA, presupplementary motor area, pre-SMA, and cingulate motor areas below them). It is generally believed that one major source of the readiness potential lies in the medial premotor areas (Ball et al., 1999; Erdler et al., 2000; Weilke et al., 2001; Cunnington, Windischberger, Deecke, & Moser, 2003).

The demonstration of the readiness potential calls into question whether spontaneous movements are really caused by the preceding conscious intentions. Intuitively, conscious intentions seem to cause motor actions almost immediately—it seems to take much less time than 1–2 seconds. This could mean that the brain starts to prepare for the actions long before we consciously initiate them.

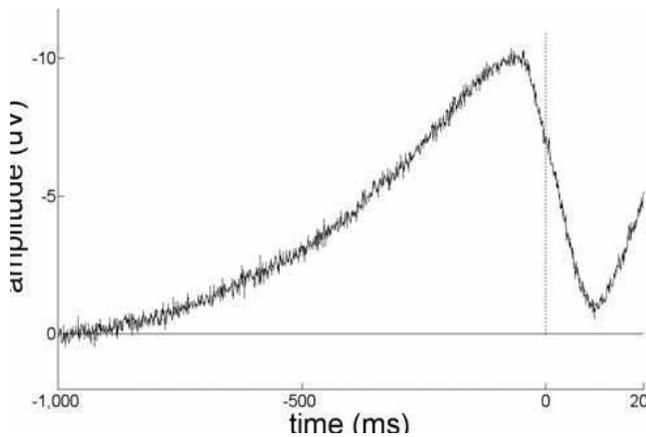

FIGURE 83.1 A schematic depiction of the readiness potential (RP) preceding spontaneous movements. The RP is usually recorded at the top of the scalp, above medial frontal premotor areas. It gradually ramps up, beginning about 1–2 seconds before movement and peaking around the time of movement execution (marked as time = 0).

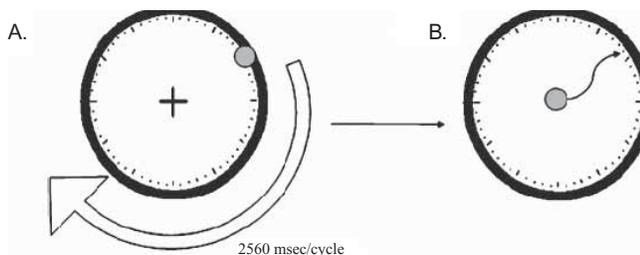

FIGURE 83.2 The Libet clock paradigm. (A) The subject views a dot rotating slowly (2.56 seconds per cycle) around a clock face and waits for an urge to move to arise spontaneously. When the urge arrives, the subject makes a movement (e.g., a key press). (B) After making the movement, the subject estimates the earliest time at which the intention to move was experienced. To carry out this time estimate, the subject either verbally indicates the location of the dot where the intention was first felt or moves a cursor to that location (as in this example). In a common control condition, the subject uses the clock to estimate the time of movement rather than the onset of intention. (Edited and adapted from Lau, Rogers, & Passingham, 2007.)

Benjamin Libet and colleagues empirically studied the timing of the conscious intention in relation to the readiness potential and the action (Libet, Gleason, Wright, & Pearl, 1983). To measure the onset of conscious intention, he invented a creative but controversial paradigm that is sometimes called the *Libet clock paradigm*. In those studies, subjects watched a dot revolving around a clock face at a speed of 2.56 seconds per cycle, while they flexed their wrist spontaneously (figure 83.2). After the action was finished, subjects were required to report the location of the dot when they “first felt the urge” to produce the action, that is, the onset of intention. The subject might say it was at the 3 o’clock or 4 o’clock position when they first felt the intention, for

instance. This way the subjects could time and report the onset of their intention, and the experimenter could then work out when the action was actually produced, and hence the temporal distance between the two. Libet and colleagues reported that subjects on average report the onset of intention to be about 250 ms before motor execution.

Many people feel uncomfortable with the fact that the onset of the readiness potential seems to be so much earlier than the onset of intention, and some have tried to explain away the gap. Libet and colleagues have tried to study the onset of the readiness potential more carefully, discarding trials that might have been “contaminated” by preplanning of action well before the action (for instance, by counting to 10 and then triggering the movement), as reported by the subjects. By only looking at the trials where the actions were supposed to be genuinely spontaneous, Libet and colleagues reported that the onset of the readiness potential is only about 500 ms before action execution (Libet, Gleason, et al., 1983). However, this is still clearly earlier than the reported onset of intention. And by discarding so many trials, it may be that the analysis just lacked the power to detect an earlier onset.

Some have argued that the onset of readiness potential might be an artifact due to the averaging needed to produce the ERP (Miller & Trevena, 2002). However, Romo and Schultz (1987) have recorded from neurons in the medial premotor areas while monkeys made self-paced movements. It was found that some neurons in this region in fact fired as early as 0.6–2.6 seconds before movement onset. From the reported results it was also clear that this pattern of early firing for these neurons was consistent across trials. One other recent study has reported that the spatial pattern of fMRI activity from this region, at up to 5 seconds before action, can statistically predict the timing of action above chance level (Soon, Brass, Heinze, & Haynes, 2008).

Others have argued that the readiness potential may not reflect the specific and causal aspects of motor initiation. However, as mentioned earlier, it is likely that the readiness potential partly originates from the medial premotor areas. Lesion to these areas can abolish the production of spontaneous actions (Thaler, Chen, Nixon, Stern, & Passingham, 1995). These areas also contain neurons that code specific action plans (Shima & Tanji, 1998; Tanji & Shima, 1996). Further, when people use the Libet clock paradigm to time their own intentions, there is attentional modulation of activity in the medial pre-SMA (Lau, Rogers, Haggard, & Passingham, 2004), as if people were reading information off the area that is likely to be a source of the readiness potential.

The Libet clock method has also received considerable criticism. It involves timing across modalities and could be susceptible to various biases (Libet, 1985; Gomes, 2002; Joordens, van Duijn, & Spalek, 2002; Klein, 2002; Trevena & Miller, 2002). However, it is unlikely that all these biases

are in the direction that would help to narrow the gap between the onsets of the readiness potential and intention. Some have actually suggested that the different biases may point to different directions and thus just cancel each other out (Klein 2002). Also, in the original experiments by Libet and colleagues, there were control conditions that tested for the basic accuracy of the clock. They asked subjects to use the clock to time either the onset of movement execution, or in another condition to time the onset of tactile stimuli presented externally by the experimenter. Since the actual onsets of these events are objectively measurable, they could estimate the subjective error of onset reports produced by the clock method. They found the error to be on the order of about 50 ms; for example, people misestimate the time of action execution to be 50 ms earlier than it actually is. This size of error is considerably smaller than the gap between the onsets of the readiness potential and intention.

The basic results of Libet and colleagues have also been replicated in several different laboratories (e.g., Lau et al., 2004; Haggard & Eimer, 1999; Soon et al., 2008). In general, the same pattern is found, that the onset of intention is either around or later than 250 ms before action execution, which seems to confirm our intuition that conscious intentions seem to be followed by motor actions almost immediately. In fact, given that the readiness potential starts as early as 1–2 seconds before action execution, it is hard to imagine how the onset of intention could coincide with or precede the readiness potential, unless one thinks of intention as a kind of prior intention (Searle, 1983), like the general plan that is formed at the beginning of the experimental session when the subject agrees to produce some actions in the next half hour or so. We shall discuss this kind of higher-cognitive “intention” later in the chapter. However, the intention we are concerned with here is the immediate “urge” to produce the motor action (Libet, Wright, & Gleason, 1982).

Taken together, the evidence suggests that conscious intention—that is, the immediate feeling of motor initiation—is unlikely to be the “first unmoved mover” in triggering spontaneous motor movements. It is likely to be preceded by unconscious brain activity that may contribute to action initiation. What, then, is conscious intention for?

Conscious veto?

Libet’s interpretation of the timing-of-intention results is that although intention may not be early enough to be the first cause of action, the fact that it occurs before action execution means that it could still be part of the causal chain. Maybe the decision to move is initiated unconsciously, but the awareness of intention may allow us to “veto”—that is, to cancel—the action.

This seems to be a possibility. Libet, Wright, and Gleason (1983) as well as other researchers (Brass & Haggard, 2007)

have performed experiments where subjects prepare for an action and then cancel it at the last moment, just before it is executed. The fact that we have the ability to “veto” an action seems beyond doubt. The question, however, is whether having the conscious intention is critical. Can the choice of veto be preceded by unconscious activity, just as the intention to act is preceded by the readiness potential? Or maybe sometimes actions are unconsciously vetoed, even without our awareness?

Some recent evidence suggests that the conscious intention may not facilitate a veto. As mentioned earlier, when people were using the Libet clock to time the onset of their intentions, there was attentional modulation of activity in the pre-SMA (Lau et al., 2004). These data have been subsequently further analyzed (Lau, Rogers, & Passingham, 2006), and it has been shown that subjects who showed a large degree of attentional modulation also tended to report the onset of intention to be early. One interpretation could be that attention biases the judgment of onset to be earlier. It was found in another experiment that this was also true when people used the Libet clock to time the onset of the motor execution. The higher the level of fMRI activity modulated by attention, the earlier subjects reported the onset to be, even though on average subjects reported the onsets to be earlier than they actually were, a result which means that a bias to the negative (i.e., early) direction produced more erroneous rather than more precise reports. In general, the principle of attentional prior entry (Shore, Spence, & Klein, 2001) suggests that attention to an event speeds up its perception and negatively biases the reported onset. If this were true in the case of the Libet experiments, it could mean that attention might have exaggerated the 250-ms onset; that is, had subjects not been required to attend to their intentions in order to perform the timing tasks, the true onset of conscious intention might well have been much later than 250 ms prior to action execution. This possibility calls into question whether we have enough time to consider the veto.

Another study reported that some patients with lesion to the parietal cortex reported the onset of intention to be late as 50 ms prior to action execution (Sirigu et al., 2004). If the awareness of intention allows one to veto actions, one might expect these patients to have much less time to consciously evaluate spontaneous intentions and cancel the inappropriate ones. This could be quite disastrous to daily life functioning. Yet there were no such reports about these patients.

Finally, in another study (Lau, Rogers, & Passingham, 2007), single pulses of transcranial magnetic stimulation (TMS) were sent to the medial premotor areas (targeting the pre-SMA). Again, subjects were instructed to produce spontaneous movements and to time the onset of intentions and movement execution using the Libet clock. Surprisingly,

although TMS was applied *after* motor execution, it had an effect on the reported onsets. No matter whether TMS was applied immediately after action execution or with a 200-ms delay, the stimulation exaggerated the temporal distance between the reported onsets of intention and movement, as if people reported a prolonged period of conscious intending. One interpretation may be that TMS injected noisy activity into the area and the intention monitoring mechanism did not distinguish this from endogenously generated activity that is supposed to represent intention. However, what is crucial is the fact that the reported onsets can be manipulated even after the action is finished. This seems to suggest that our awareness of intention may be constructed after the facts, or at least not completely determined before the action is finished. If conscious intentions are not formed before the action, they certainly cannot play any role in facilitating veto, let alone causing it.

This interpretation may seem wild, but it is consistent with other proposals. For instance, on the basis of many ingenious experiments manipulating a subject's sense of agency, Wegner (2002) has suggested that the conscious will is an illusion. The sense of agency is often inferred post hoc, based on many contextual factors. Wegner cites experiments to support these claims. One example is a study on "facilitated communication" (Wegner, Fuller, & Sparrow, 2003). Subjects (playing the role of "facilitators") were asked to place their fingers on two keys of a keyboard, while a confederate (playing the role of "communicator") placed his or her fingers on top of those of the subject. Subjects were given headphones with which they listened to questions of varying difficulty. Confederates were given headphones as well, and subjects were led to believe that the confederates would be hearing the same questions, although in fact the confederates heard nothing. Subjects were told to detect subtle, unconscious movements in the confederate's fingers following each question. When such movements were detected, the subject was to press the corresponding key in order to answer on the confederate's behalf. It was found that subjects answered easy questions well above chance levels. If they had performed the task strictly according to the instructions, however, they should have performed at chance. Therefore, subjects must have been directing their own key presses. Nonetheless, they attributed a significant causal role for the key presses to the confederate. The degree to which subjects answered easy questions correctly was not correlated with the degree to which they attributed causal responsibility to confederates, suggesting that the generation of action and attribution of action to an agent are independent processes.

To summarize, although theorists have speculated that the awareness of intention may play some role in allowing us to cancel or edit our actions, considerable doubt has been cast by recent empirical evidence.

Exclusion and inhibition

Another kind of situation that seems to require conscious deliberation involves the need to avoid a particular action or response. This is related to "vetoing" as described previously, except that the action being inhibited is not necessarily self-paced and may be specified externally. One example would be to perform stem completion while avoiding a particular word. So, for instance, the experimenter may ask the subjects to produce any word starting with the letter *d* (i.e., completing a "stem") but avoid the word *dinner*. So subjects can produce *dog*, *danger*, *dear*, and so on, but if they produce the word *dinner*, it will be counted as an error. This is called the exclusion task (Jacoby, Lindsay, & Toth, 1992).

One interesting aspect of the exclusion task is that people can perform well only if they clearly see and remember the target of exclusion (i.e., the word *dinner* in the foregoing example). If the target of exclusion is presented very briefly and followed by a mask, such that it was only very weakly perceived, people may fail to exclude it (Debnar & Jacoby, 1994; Merikle, Joordens, & Stolz, 1995). In fact, they tend to produce exactly the word they should be avoiding with higher likelihood than if they were not presented with the word at all. It has been argued that this exclusion failure phenomenon is the hallmark of unconscious processing (Jacoby et al., 1992). The weak perception of the target probably produced a representation for the word, but because the signal is not strong enough to reach the level of conscious processing, subjects are unable to inhibit the corresponding response.

In addition to the intuitive appeal, the notion that consciousness is required for exclusion is also supported by a case study of a blindsight patient (Persaud & Cowey, 2008). Subject GY has a lesion to the left primary visual cortex (V1) and reports that most of his right visual field is subjectively blind. However, in a forced-choice situation he can discriminate simple stimuli well above chance level in his "blind" field (Weiskrantz, 1986, 1997). In one study he was required to perform an exclusion task (Persaud & Cowey, 2008)—that is, to say the location (up or down) where the target was *not* presented. Whereas he could do this easily in the normal field, he failed the task when stimuli were presented to his blind field. Note that he was significantly worse than chance in the blind field, as if the unconscious signal drove the response directly and inflexibly, defying exclusion control. This result seems to support the account that consciousness is required for exclusion.

The general idea that inhibition requires consciousness seems to be supported by other studies too, including those that do not employ the exclusion paradigm. One study tested subjects' ability to ignore distracting moving dots while doing a central task that has nothing to do with the distracters (Tsushima, Sasaki, & Watanabe, 2006). It was

found that if the motion of the distracter was above the perceptual threshold, people could ignore the dots and inhibit the distraction successfully. Somewhat paradoxically, when the motion was below perceptual threshold, people could not ignore the dots and were distracted. The results from brain imaging seem to suggest that when the motion of the stimuli was strong, it activated the prefrontal cortex and triggered it to suppress the motion signal. When the motion of the stimuli was below perceptual threshold, however, the signal failed to trigger the inhibitory functions in the prefrontal cortex, and therefore the motion signal was not suppressed and thus remained distracting.

However, the notion that flexible control or inhibition of perceptual signal requires consciousness is not without its critics (Snodgrass 2002; Haase & Fisk, 2001; Visser & Merikle, 1999). One problem becomes clear when we consider the motion distracter example. “Conscious signal” here seems to be the same thing as a strong signal, driven by larger motion strength in the stimuli. Obviously, signals have to be strong enough to reach the prefrontal cortex in order to trigger the associating execution functions. Do unconscious stimuli fail to be excluded because we are not conscious of them, or is it just because the signal is not strong enough? Or, are the two explanations one and the same? Not all studies are subject to this argument. For instance, in the blindsight study (Persaud & Cowey, 2008), the subject failed to exclude in the blind field even when the contrast level would have given a performance that was similar to that in the normal visual field. So if we take forced-choice performance as an index of signal strength, the signal from the blind field was not weak in this sense. However, in most other cases we often take awareness to be the same as good performance. Are we justified in doing so? This is an important issue, and we will come back to it in the final section of the chapter.

Other researchers have reported evidence that seems to support unconscious inhibition. For instance, in one study (Snodgrass & Shevrin, 2006) people were asked to detect visually presented words. In certain conditions, some subjects showed detection performance that was significantly *worse* than chance. These words were presented so briefly that typically detection performance would be near chance. We usually take chance level as the objective threshold for conscious perception. Below-chance-level performance could be taken as evidence that the subjects did not consciously perceive the words. And yet, if they had no information at all regarding the words, performance should just be exactly at chance rather than below. It seems that these subjects were actively suppressing the words.

These are unusual cases and are somewhat hard to interpret. We take chance level as the objective threshold for conscious perception because when people perform at chance, it indicates that they do not have explicit information regarding the target of perception. However, if people

perform significantly below chance, it means that somehow they have information regarding the detection, which violates the very logic we adopt to label perception unconscious. But in any case, the stimuli were supposed to be really weak, and it is intriguing that some subjects seem to be automatically suppressing the words. Are we to take these somewhat unusual cases as evidence to reject the notion that exclusion or inhibition requires consciousness? It seems that, logically, if we claim that a certain function *requires* consciousness, we should predict there will never be a case where one could perform such a function unconsciously. How seriously are we to take this logic and reject functions as requiring consciousness by a single experiment? We will return to this argument in the last section of the chapter.

Top-down cognitive control

So far we have discussed acts of volition that are relatively simple, like starting a motor movement or avoiding a particular action. Sometimes we also voluntarily prepare for a set of rules or action plans in order to satisfy a more abstract goal in mind. For instance, a telephone ring may usually trigger a particular action, for example, picking up the phone. However, when one visits friends at their homes, one may deliberately change the mapping between the stimulus (telephone ring) and action; that is, it would be more appropriate to sit still or ask the host to pick up the phone, rather than pick it up oneself. This volitional change of stimulus-response contingency is an example of top-down cognitive control.

It has been suggested that top-down cognitive control may require consciousness (Dehaene & Naccache, 2001). The idea is that unconscious stimuli can trigger certain prepared actions, as demonstrated in studies in subliminal priming (Kouider & Dehaene, 2007). However, the preparation or setting up of the stimulus-response contingency may require consciousness.

However, recent studies suggest that this conclusion might not be true, in the sense that unconscious information seems to be able to influence or even trigger top-down cognitive control too (Mattler, 2003; Lau & Passingham, 2007). In one study subjects had to prepare to do a phonological or semantic judgment, based on the orientation of a figure they saw (figure 83.3). In every trial, if they saw a square, they had to prepare to judge whether an upcoming word has two syllables (e.g., *table*) or not (e.g., *milk*). If they saw a diamond, they had to prepare to judge whether an upcoming word refers to a concrete object (e.g., *chair*) or an abstract idea (e.g., *love*). In other words, they had to perform top-down cognitive control based on the instruction figure (square or diamond). However, before the instruction figure was presented, there was actually an invisible prime figure, which could also be a diamond or a square. It was found that the prime could

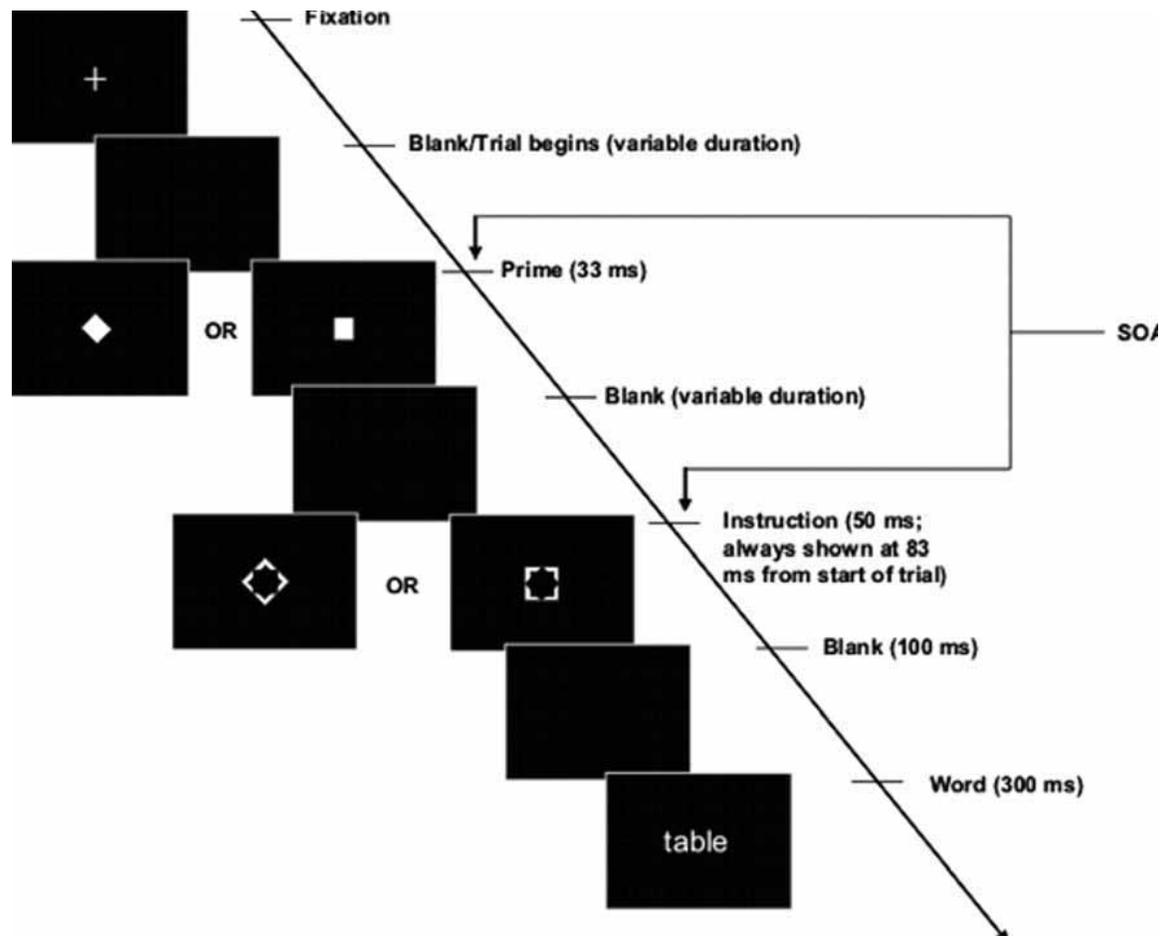

FIGURE 83.3 Experimental paradigm of Lau and Passingham (2007). Subjects view briefly presented words and perform either a phonological task (is the word one syllable or two syllables?) or a semantic task (does the word name something concrete or abstract?). Before word presentation, subjects are instructed which task to perform on a given trial by a visual symbol (a square for the phonological task or a diamond for the semantic task). The symbolic instruction itself acts as a metacontrast mask for an earlier prime, also a square or a diamond. Because the prime is briefly presented and masked, it is not consciously perceived. On half of the trials, the prime is congruent with the instruction, and on the other half,

impair subjects' performance when it suggested the alternative (i.e., wrong) task to the subjects (incongruent condition). One could argue that this result occurred only because the prime distracted the subjects on a perceptual level and did not really trigger cognitive control. However, the experiment was performed in the fMRI scanner, and the brain recordings suggest that when being primed to perform the wrong task, subjects used more of the wrong neural resources too (Lau & Passingham, 2007). That is, areas that are more sensitive to phonological or semantic processing showed increased activity when the explicit instruction figure made subjects perform the phonological and semantic tasks, respectively. The invisible primes also seem to be able to trigger activations in task-sensitive areas. This result seems

incongruent. Behavioral and imaging results suggest that the unconscious primes affected top-down task switching. When primes were incongruent with instructions, accuracy fell, reaction time increased, and brain regions corresponding to the task indicated by the prime were partially activated (all relative to the prime-congruent condition). But when the stimulus onset asynchrony (SOA) between prime and instruction was lowered, such that primes became visible, the priming effect was not evident. This double dissociation suggests that the interference of incongruent primes on task switching cannot be attributed to conscious processing. (Adapted from Lau & Passingham, 2007.)

to suggest that they can influence or exercise top-down cognitive control.

Another study examines how unconscious information affects our high-level objectives by focusing on how the potential reward influences our level of motivation (Pessiglione et al., 2007). Subjects squeezed a device to win a certain amount of money. The harder they squeezed, the more money they would win. However, the size of the stake in question for a particular trial was announced in the beginning by presenting the photo of a coin. The coin could either be a British pound (~2 U.S. dollars) or a penny (~2 U.S. cents), and it signified the monetary value of the maximal reward for that trial. Not surprisingly, people squeezed harder when the stakes were high, but interestingly, the same

pattern of behavior was observed even when the figure of the coin was masked such that subjects reported not seeing it. This finding suggests that unconscious information can influence our level of motivation as well.

If unconscious information alone is sufficient to exercise all these sophisticated top-down control functions, why do we need to be conscious at all?

How can we find the true function of consciousness?

The foregoing is not meant to be an exhaustive review of all studies on the potential functions of consciousness. We selected some examples from a few areas that are particularly related to volition and discussed the role that consciousness may play. There may, of course, be other psychological functions that require consciousness.

Yet one cannot help feeling that there seems to be some inherent limitation to this whole enterprise of research. If we claim that a certain function requires consciousness, strictly speaking, the interpretation could be that the function should never be able to be performed unconsciously. Of course, one could make the weaker claim that a certain function is usually or most suitably performed consciously, and when consciousness fails, unconscious processing can act as a backup. This is similar to arguing that one function of having legs is to facilitate locomotion; if we lose our legs, we could still move around, albeit poorly. However, let us assume that one is to make the stronger prediction that such functions should never be able to be performed unconsciously. In principle, it would only take a single experiment to falsify that. This assumption explains why this review may seem biased in that we focus on studies that show the power of the unconscious, rather than studies demonstrating functions that definitely require consciousness. In principle, falsifying the claim that a certain function requires consciousness is straightforward. But this is not the case for demonstrating functions that would always require consciousness.

One can, of course, try to show that subjects could normally do a task if the relevant information is consciously perceived. And then one tries to “knock out” the conscious perception for such information and show that the task could no longer be performed, or that it is performed at an additional cost, that is, slower or with more errors. But how would one know that in “knocking out” the conscious perception, one does not “knock out” too much? One typically suppresses conscious perception by visual masking, by using brief presentation, by distracting the subject, by applying transcranial magnetic stimulation, by pharmacological manipulations, and so on. But all of these could potentially impair the unconscious as well as the conscious signal. Could it be that in cases where the perception has been rendered unconscious, the signal is just no longer strong enough to drive the function in question? This interpretation

would mean that, in principle, it would be possible for a future study to find the optimal procedure or setup to just render the information unconscious, without reducing the signal strength too much. And in that case the subjects may be able to perform the task in question. That result would falsify our claim.

Consequently, in looking for functions that require consciousness, we need to adopt some different strategies. One potentially useful approach is to try to demonstrate something akin to a “double dissociation.” When conscious perception is suppressed, we often find that a sophisticated function (e.g., top-down cognitive control) can no longer be performed, though some simpler function (e.g., priming for a prepared motor response) may still be activated by unconscious information. From the foregoing discussion, one could see that this outcome may not be as surprising or informative as it seems. It could be just that the unconscious signal is too weak to drive the relatively sophisticated function. A demonstration of the opposite would, however, be much more convincing: If after suppression of conscious perception, the subjects can still perform a rather sophisticated function but fail to perform a simple function, that finding would suggest that the simple function really requires consciousness. In this case, it could not be that the suppression of conscious perception has taken away too much of the signal strength, because if that were the case then the subjects should not be able to perform the relatively sophisticated function (figure 83.4). Understanding this “double dissociation”

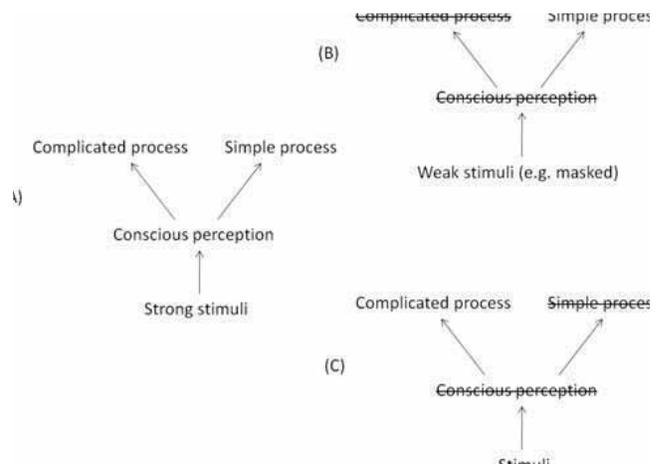

FIGURE 83.4 (A) The normal situation for conscious perception. Stimuli are strong enough to drive processes of different complexity. (B) A typical situation for unconscious perception. Stimuli are weak such that complicated processes are no longer activated, though simple processes can still be triggered. It could be argued that this result is not surprising, since we may expect that complicated processes require a stronger signal. (C) A potentially more informative situation. If one could find a stimulus that is not consciously perceived, yet is sufficiently strong to trigger a complicated process, then the relatively simple process that the stimulus does not drive would seem to critically depend on consciousness.

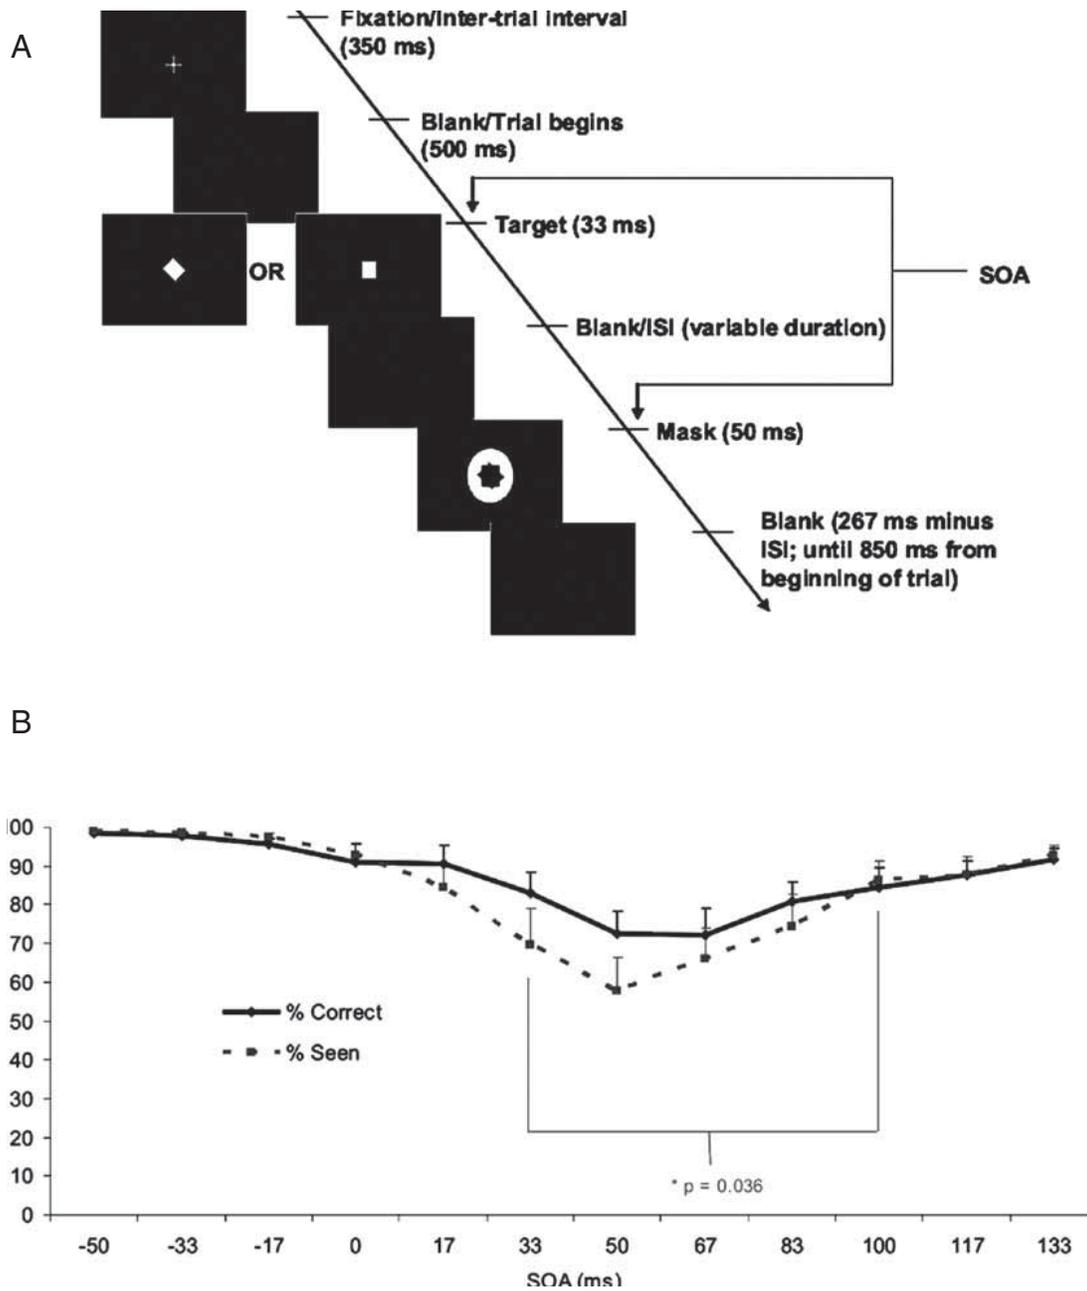

FIGURE 83.5 Inducing “relative blindsight” in normal observers using metacontrast masking. (A) Metacontrast masking paradigm. The subject is presented with a visual target (in this case, either a square or diamond). Afterward, a metacontrast mask is presented. The mask differentially affects discrimination accuracy and visual awareness of the target as a function of stimulus onset asynchrony (SOA). (B) Discrimination accuracy and visual awareness as a function of metacontrast mask SOA. The metacontrast mask creates a characteristic U-shaped function of performance versus SOA. At shorter and longer SOAs, discrimination accuracy is high, but it dips at intermediate SOAs. The same is true for visual awareness, but the shape of the awareness-masking function is not perfectly

symmetrical with respect to the performance-masking function. That is, there are certain SOAs at which forced-choice performance is matched but visual awareness differs significantly (e.g., as illustrated in the SOAs of 33 ms and 100 ms). Such performance-matched conditions could be used to investigate the functions of consciousness. If some task can be performed better in the condition of higher subjective visibility, it can plausibly be said to require visual awareness. Because forced-choice discrimination accuracy is matched across the two conditions, the superior performance of the task in the high-visibility condition cannot be attributed to a difference in signal strength. (Adapted from Lau & Passingham, 2006.)

approach helps us see the logic behind how we could deal with signal strength as a confounding variable. However, one problem is that it is unclear what is the most convincing way to define “sophisticated/complicated” functions versus “simple” functions.

An alternative approach may be to directly match for signal strength between the conscious and the unconscious conditions. This might seem difficult because conscious signals may seem to be strong in general. However, as discussed earlier, blindsight subjects can perform forced-choice discrimination on visual stimuli well above chance, even when they claim that conscious awareness is missing. Forced-choice performance is often taken as an objective estimate of signal strength; the detection theoretical measure d' is mathematically just the signal-to-noise ratio. In blindsight subject GY, where only half of the visual field lacks awareness, we can imagine presenting weak stimuli to the normal visual field such that forced-choice performance would match that in the blind field (Weiskrantz, Barbur, & Sahraie, 1995). This way we can test whether certain functions cannot be performed based on information presented to the blind field, a procedure which may shed light on when consciousness is required.

One may argue that blindsight patients are rare and that the way their brains process visual information may not generalize to intact brains. However, there are other paradigms where in normal subjects one could match for forced-choice performance and yet produce a difference in the level of conscious awareness. For instance, in one study (Lau & Passingham, 2006) metacontrast masking was used to create similar conditions where forced-choice discrimination accuracy for the visual targets was matched, and yet the subjective reports of how often subjects saw the identity of the targets differed (figure 83.5). One could imagine presenting these stimuli to subjects and seeing whether they drive a certain function with different effectiveness. If the subjects perform better in the condition where subjective conscious awareness of the stimuli is more frequent, one could argue that this function is likely to depend critically on consciousness.

Conclusion

Acts of volition are accompanied by a sense of conscious effort or intention. The fact that we feel the conscious effort is not in doubt. What is less clear is whether the processes underlying the conscious experience directly contribute to the execution of the actions, in a way that is not accomplished by unconscious processes just as effectively. The general picture seems to be that many sophisticated functions can be performed unconsciously or driven by unconscious information.

Does this conclusion mean that consciousness has no special function at all? The answer is not yet clear. It is likely that some psychological functions require consciousness. That is, there may be some functions that can only be performed poorly with unconscious information. Or, there may even be functions that can never be performed unconsciously. But experiments have not yet been able to convincingly pin them down.

Future research will have to overcome the following problem. If we assume that conscious perception is always accompanied by stronger and longer-lasting signals that are more effective than unconscious signals in propagating themselves throughout the brain, then consciousness would certainly be associated with the functions of these strong signals. However, in studies of blindsight (Weiskrantz et al., 1995), as well as in normals (Lau & Passingham, 2006), it has been shown that signal strength as indicated by forced-choice performance is not always one and the same as conscious awareness. Therefore, future studies may need to focus on identifying the functions that really cannot be performed unconsciously, even when the signal strength is sufficiently strong. This approach may help to reveal the true function of consciousness.

84 Toward a Theory of Consciousness

GIULIO TONONI AND DAVID BALDUZZI

ABSTRACT Cognitive neuroscience provides us with both clues and paradoxes about the neural substrate of consciousness. For example, we know that certain corticothalamic circuits are essential for conscious experience, whereas cerebellar circuits are not, despite their huge numbers. We also know that consciousness wanes during slow-wave sleep and generalized seizures, despite levels of neural activity that are comparable to wakefulness. To understand why this is so, empirical observations must be related to a theory that says, in a principled manner, what consciousness is and how it can be generated. This chapter introduces the integrated information theory. Starting from phenomenology and making a critical use of thought experiments, the theory claims that consciousness *is* integrated information. Specifically, (1) the quantity of consciousness is given by the amount of integrated information generated by a complex of elements, and (2) the quality of experience, such as the “redness” of red, is given by the set of informational relationships within that complex. Integrated information (symbol, Φ) is defined as the amount of information generated by causal interactions within a complex of elements, above and beyond the information generated independently by its parts. Qualia space (symbol, Q) is a space where each axis represents a possible state of the complex, each point is a probability distribution of its states, and arrows between points represent the informational relationships generated by causal interactions among its elements. Together, the set of informational relationships within a complex specifies a shape in Q that in turn specifies a particular experience. Several observations concerning the neural substrate of consciousness fall naturally into place within the integrated information framework.

Consciousness poses two related problems (Tononi, 2001). The first is to understand what features of the brain determine the extent to which consciousness is present. For example, why are certain corticothalamic circuits important for conscious experience, whereas cerebellar circuits are not, though the number of neurons in the two structures is comparable and their neurobiological organization is similarly complicated? And why is consciousness strikingly reduced during deep slow-wave sleep or during absence seizures, despite high levels of neuronal firing?

The second problem of consciousness is to understand what features of the brain determine the specific way consciousness is experienced—what is responsible for, say, the

“redness” of red? We know that the activity of specific cortical areas contributes specific dimensions of conscious experience—auditory cortex to sound, visual cortex to shapes and colors. Why is this so? Solving the first problem means that we would know to what extent a physical system can generate consciousness—the *quantity* or level of consciousness. Solving the second problem means that we would know what kind of consciousness it generates—the *quality* or content of consciousness.

Earlier chapters in part X have reviewed empirical evidence on the neural correlates of consciousness (Crick & Koch, 2003; Koch, 2004). Here we focus instead on the theoretical foundations of consciousness science. Specifically, we discuss the integrated information theory of consciousness (Tononi, 2004), according to which brain mechanisms generate experience to the extent that they generate integrated information. In what follows, we first consider phenomenological thought experiments indicating that subjective experience has to do with the generation of integrated information; we then consider ways of defining and measuring integrated information; next, we show how basic facts about consciousness and the brain can be accounted for in terms of integrated information; finally, we examine some ideas about how the second problem of consciousness can be addressed.

The first problem: What determines the quantity of consciousness?

Everyday experience indicates that consciousness has a physical substrate and that the physical substrate must be working in the proper way for us to be fully conscious—it is enough to fall asleep, receive a blow on the head, or take certain drugs such as anesthetics, to affect our consciousness dramatically. These observations raise the question of what are the necessary and sufficient conditions that determine whether consciousness is present and to what extent. The question is a general one with multiple implications. For example, is a person with akinetic mutism—awake with eyes open, but mute, immobile, and unresponsive—conscious or not? How much consciousness is there during sleepwalking or psychomotor seizures? Are newborn babies conscious,

GIULIO TONONI AND DAVID BALDUZZI Department of Psychiatry, University of Wisconsin, Madison, Wisconsin

and to what extent? Are animals conscious? If so, are some animals more conscious than others? Could we one day build conscious artifacts using nonneural ingredients (Koch & Tononi, 2008), or at least augment our own consciousness with implanted chips?

CONSCIOUSNESS AS INTEGRATED INFORMATION The *integrated information theory (IIT)* of consciousness claims that, at the fundamental level, consciousness *is* integrated information, and that its quality is given by the informational relationships generated by a complex of elements. These claims stem from realizing that information and integration are the essential properties of our own experience. This fact may not be immediately evident, perhaps because, being endowed with consciousness most of the time, we tend to take its gifts for granted. To regain some perspective, it is useful to resort to two thought experiments, one involving a photodiode and the other a digital camera.

Information Consider the following: You are facing a blank screen that is alternately on and off, and you have been instructed to say “light” when the screen turns on and “dark” when it turns off. A photodiode—a simple light-sensitive device—has also been placed in front of the screen. It contains a sensor that responds to light with an increase in current and a detector connected to the sensor that says “light” if the current is above a certain threshold and “dark” otherwise. The first problem of consciousness reduces to this: when you distinguish between the screen being on or off, you have the subjective experience of seeing light or dark. The photodiode can also distinguish between the screen being on or off, but presumably it does not have a subjective experience of light and dark. What is the key difference between you and the photodiode?

According to the IIT, the difference has to do with how much information is generated when that distinction is made. Information is classically defined as reduction of uncertainty: the more numerous the alternatives that are ruled out, the greater the reduction of uncertainty, and thus the information. It is usually measured using the entropy function, which is the logarithm of the number of alternatives (assuming they are equally likely). For example, tossing a fair coin and obtaining heads corresponds to $\log_2(2) = 1$ bit of information, because there are just two alternatives; throwing a fair die yields $\log_2(6) = 2.59$ bits of information, because there are six alternatives.

Let us now compare the photodiode with you. When the blank screen turns on, the mechanism in the photodiode tells the detector that the current from the sensor is above rather than below the threshold, so it reports “light.” In performing this discrimination between two alternatives, the detector in the photodiode generates $\log_2(2) = 1$ bit of information. When you see the blank screen turn on, however, the situa-

tion is quite different. Though you may think you are performing the same discrimination between light and dark as the photodiode, you are in fact discriminating among a much larger number of alternatives, thereby generating many more bits of information.

This point is easy to see. Just imagine that, instead of turning light and dark, the screen were to turn red, then green, then blue, and then display, one after the other, every frame from every movie that was ever produced. The photodiode, inevitably, would go on signaling whether the amount of light for each frame is above or below its threshold: to a photodiode, things can only be one of two ways, so when it reports “light,” it really means just “this way” versus “that way.” For you, however, a light screen is different not only from a dark screen, but also from a multitude of other images, so when you say “light,” it really means this specific way versus countless other ways, such as a red screen, a green screen, a blue screen, this movie frame, that movie frame, and so on for every movie frame (not to mention for any sound, smell, thought, or any combination of the above). Clearly, each frame looks different to you, implying that some mechanism in your brain must be able to tell it apart from all the others. So when you say “light,” whether you think about it or not (and you typically will not), you have just made a discrimination among a very large number of alternatives, and thereby generated many bits of information.

This point is so deceptively simple that it is useful to elaborate a bit on why, although a photodiode may be as good as we are in detecting light, it cannot possibly see light the way we do—in fact, it cannot possibly “see” anything at all. Hopefully, by realizing what the photodiode lacks, we may appreciate what allows us to consciously “see” the light.

The key is to realize how the many discriminations that we can do, and that the photodiode cannot, affect the *meaning* of the discrimination at hand, the one between light and dark. For example, the photodiode has no mechanism to discriminate colored from achromatic light, even less to tell which particular color the light might be. As a consequence, all light is the same to it, as long as it exceeds a certain threshold. So for the photodiode “light” cannot possibly mean achromatic as opposed to colored, not to mention any particular color. Also, the photodiode has no mechanism to distinguish between a homogeneous light and a bright shape—any bright shape—on a darker background. So for the photodiode light cannot possibly mean full field as opposed to a shape—any of countless particular shapes. Worse, the photodiode does not even know that it is detecting a visual attribute—the “visualness” of light—as it has no mechanism to tell visual attributes from nonvisual ones, such as sounds or smells, not to mention which particular sounds or smells, and so on. As far as it knows, the photodiode might

just as well be a thermistor—it has no way of knowing whether it is sensing light versus dark or hot versus cold.

In short, the only specification a photodiode can make is whether things are this or that way: any further specification is impossible because it does not have mechanisms for it. Therefore, when the photodiode detects “light,” such “light” cannot possibly mean what it means for us—it does not even mean that it is a visual attribute. By contrast, when we see “light,” we are implicitly being much more specific: we simultaneously specify that things are this way rather than that way (light as opposed to dark), that whatever we are discriminating is not colored (in any particular color), does not have a shape (any particular one), is visual as opposed to auditory or olfactory, sensory as opposed to thoughtlike, and so on. To us, then, light is much more meaningful precisely because we have mechanisms that can discriminate this particular state of affairs we call “light” against a large number of alternatives.

According to the IIT, it is all this added meaning, provided implicitly by *how* we discriminate pure light from all these alternatives, that increases its level of consciousness. This central point may be appreciated either by “subtraction” or by “addition.” By subtraction, one may realize that our being conscious of “light” would degrade more and more—would lose its noncoloredness, its nonshapedness, would even lose its visualness—as its meaning is progressively stripped down to just “one of two ways,” as with the photodiode. By addition, one may realize that we can only see “light” as we see it, as progressively more and more meaning is added by specifying how it differs from countless alternatives. Either way, the theory says that, the more specifically one’s mechanisms discriminate between what pure light is and what it is not—the more they specify what light means—the more one is conscious of it.

Integration Information—the ability to discriminate among a large number of alternatives—is thus essential for consciousness. However, information always implies a *point of view* or perspective (Metzinger, 2003), and we need to be careful about what that point of view might be (information for whom?) To see why, consider another thought experiment, this time involving a digital camera—say, one whose sensor chip is a collection of a million binary photodiodes, each sporting a sensor and a detector. Clearly, taken as a whole, the camera’s detectors could distinguish among $2^{1,000,000}$ alternative states, an immense number, corresponding to 1 million bits of information. Indeed, the camera would easily respond differently to every frame from every movie that was ever produced. Yet few would argue that the camera is conscious. What is the key difference between you and the camera?

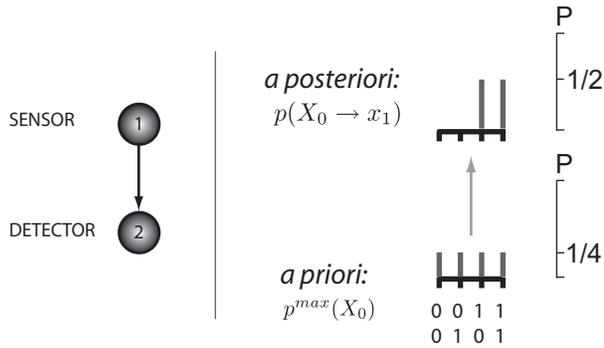

According to the IIT, the difference has to do with integrated information. From the point of view of an external

observer, the camera may be considered as a single system with a repertoire of $2^{1,000,000}$ states. In reality, however, the chip is not an integrated entity: since its 1 million photodiodes have no way to interact, each photodiode performs its own local discrimination between a low and a high current, completely independent of what every other photodiode might be doing. In reality, the chip is just a collection of 1 million independent photodiodes, each with a repertoire of 2 discriminable states. In other words, there is no intrinsic point of view associated with the camera chip as a whole. This point is easy to see: if the sensor chip were cut into 1 million pieces each holding its individual photodiode, the performance of the camera would not change at all.

By contrast, you discriminate among a vast repertoire of states as an integrated system, one that cannot be broken down into independent components each with its own separate repertoire. Phenomenologically, every experience is an integrated whole, one that means what it means by virtue of being one and that is experienced from a single point of view. For example, the experience of a red square cannot be decomposed into the separate experience of red and the separate experience of a square. Similarly, experiencing the full visual field cannot be decomposed into experiencing separately the left half and the right half: such a possibility does not even make sense to us, since experience is always whole. Indeed, the only way to split an experience into independent experiences seems to be to split the brain in two, as in patients who underwent the section of the corpus callosum to treat severe epilepsy (Gazzaniga, 2005). Such patients do indeed experience the left half of the visual field independently of the right side, but then the surgery has created two separate consciousnesses instead of one. Mechanistically then, underlying the unity of experience must be causal interactions among certain elements within the brain. This means that these elements work together as an integrated system, and it is for this reason that their performance breaks down if they are disconnected, unlike the camera.

MEASURING INTEGRATED INFORMATION This phenomenological analysis suggests that to generate consciousness, a physical system must be able to discriminate among a large repertoire of states (information) *and* it must be unified; that is, it should do so as a single system, not decomposable into a collection of causally independent parts (integration). But how can one measure integrated information? As we shall explain, the central idea is to quantify the information generated by a system, above and beyond the information generated independently by its parts (Balduzzi & Tononi, 2008; Tononi, 2001, 2004).

Information First, we need to evaluate how much information is generated by the system. Consider the system of two binary units in figure 84.1, which can be thought of as an

$$ei(X_0 \rightarrow x_1) = H[p(X_0 \rightarrow x_1) || p^{max}(X_0)] = 1 \text{ bit}$$

FIGURE 84.1 Effective information. A “photodiode” consisting of a sensor and detector unit. The detector unit turns on if the sensor’s current is above a threshold. Here both units are on (binary 1, indicated in gray). For the entire system (sensor unit, detector unit) there are four possible states: (00,01,10,11). The a priori distribution $p^{max}(X_0) = (\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$ is the maximum entropy distribution on the four states. Given that the detector is on, the mechanism specifies that the sensor must have been on, thus ruling out two of the four possible states (00,01). The a posteriori distribution is therefore $p(X_0 \rightarrow x_1) = (0, 0, \frac{1}{2}, \frac{1}{2})$. Note that the prior state of the detector makes no difference to the current state of the system, so the states (10,11) are indistinguishable to the mechanism. Relative entropy (Kullback-Leibler divergence) between two probability distributions p and q is $H[p|q] = \sum_i p_i \log_2(p_i/q_i)$ so that effective information (the entropy of the a posteriori relative to the a priori distributions) associated with output $x_1 = 11$ is 1 bit.

idealized version of a photodiode composed of a sensor S and a detector D . The system is characterized by a state it is in, which in this case is 11, and by a mechanism. This is mediated by a connection (arrow) between the sensor and the detector that implements a causal interaction: in this case, the elementary mechanism of the system is that the detector checks the state of the sensor and turns on if the sensor was on, and off otherwise (more generally, the specific causal interaction can be described by an input-output table).

A priori, a system of two binary elements could be in any of four possible states (00,01,10,11) with equal probability: $p = (\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$. Formally, this a priori (potential) repertoire is represented by the maximum entropy or uniform distribution of possible system states, which expresses complete uncertainty. However, given the mechanism of the system and the state it is in (in this case $x_1 = 11$), uncertainty is reduced—namely, the uncertainty about the previous state of the system. A posteriori, a system with this mechanism being in state 11 specifies that the previous system state x_0 must have been either 11 or 10, rather than 00 or 01, corresponding to $p = (0, 0, \frac{1}{2}, \frac{1}{2})$ (in this system, there is no mechanism to specify the detector state, which remains uncertain). For-

mally, then, the mechanism and the state 11 specify an a posteriori distribution or repertoire of system states that could have caused (led to) x_1 , while ruling out (giving probability zero to) states that could not. In this way, the system’s mechanism and state constitute information (about the system’s previous state) in the classic sense of reduction of uncertainty or ignorance. More precisely, the system’s mechanism and state generate 1 bit of information by distinguishing between things being one way (11 or 10, which remain indistinguishable to it) rather than another way (00 or 01, which also remain indistinguishable to it).

In general, the information generated when a system characterized by a certain mechanism in a particular state can be measured by the relative entropy H between the a posteriori and the a priori repertoires (“relative to” is indicated by $||$), also known as effective information (ei):

$$ei(X_0 \rightarrow x_1) = H[p(X_0 \rightarrow x_1) || p^{max} X_0]$$

Relative entropy, also known as Kullback-Leibler divergence, is a difference between probability distributions (Cover & Thomas, 2006): if the distributions are identical, relative entropy is zero; the more different they are, the higher the relative entropy. (Note that two different distributions over the same states have relative entropy >0 even if they have the same entropy.) Figuratively, the system’s mechanism and state (01) generate information by sharpening the uniform distribution into a less uniform one—this is how much uncertainty is reduced. Clearly, the amount of effective information generated by a system is high if it has a large a priori repertoire and a small a posteriori repertoire, since a large number of initial states are ruled out. By contrast, the information generated is little if the system’s repertoire is small or if many states could lead to the current outcome, since few states are ruled out. For instance, if noise dominates, so that any state could have led to the current one, no alternatives are ruled out, and no information is generated.

Since effective information is implicitly specified once a mechanism and state are specified, it can be considered to be an “intrinsic” property of a system. To calculate it explicitly, from an extrinsic perspective, one can perturb the system in all possible ways (i.e., try out all possible input states, corresponding to the maximum entropy distribution or a priori repertoire) to obtain a forward repertoire of output states given the system’s mechanism, and finally calculate, using Bayes’ rule, the a posteriori repertoire given the system’s state (Balduzzi & Tononi, 2008).

Integration Second, we need to find out how much of the information generated by a system is integrated information—that is, how much information is generated by a single entity, as opposed to a collection of independent parts. The key idea here is to consider the parts of the system independently, ask how much information they generate by them-

selves, and compare it with the information generated by the system as a whole.

This can be done by resorting again to relative entropy to measure the difference between the probability distribution generated by the system as a whole (a posteriori of the system) with the probability distribution generated by the parts considered independently (the product of the a posteriori repertoire of the parts). Integrated information is indicated with the symbol ϕ (the vertical bar “I” stands for information, the circle “O” for integration (Tononi, 2004; Tononi & Sporns, 2003):

$$\phi(x_1) = H \left[p(X_0 \rightarrow x_1) \parallel \prod_{M^k \in \mu^{min}} p(M_0^k \rightarrow \mu_1^k) \right]$$

That is, the a posteriori repertoire for each part is specified by causal interactions internal to each part, considered as a system in its own right, while external inputs are treated as a source of extrinsic noise. The comparison is made with the particular decomposition of the system into parts that leaves the least information unaccounted for. This *minimum information partition* or \mathfrak{p}^{min} decomposes the system into its *minimal parts* (see Balduzzi and Tononi, 2008, for details).

To see how this system works, consider two of the million photodiodes in the digital camera (figure 84.2, *left*). By turning on or off depending on its input, each photodiode generates 1 bit of information, just as we saw before. Considered independently, then, 2 photodiodes generate 2 bits of information, and 1 million photodiodes generate 1 million bits of information. However, as shown in the figure, the product of the a posteriori distributions generated independently by the parts is identical to the a posteriori distribution for the system. Therefore, the relative entropy between the two distributions is zero: the system generates no integrated information [$\phi(x_1) = 0$] above and beyond what is generated by its parts.

Clearly, for integrated information to be high, a system must be connected in such a way that a lot of information is generated by causal interactions *among* its elements, rather than *within* its parts. Thus a system can generate integrated information only to the extent that it cannot be decomposed into informationally independent parts. A simple example of such a system is shown in figure 84.2 (*right*). In this case, the interaction between the minimal parts of the system generates information above and beyond what is accounted for by the parts by themselves, and $\phi(x_1) > 0$. In short, integrated information captures the information generated by causal interactions in the whole, over and above the information generated independently by the parts.

Complexes Finally, by measuring ϕ values for all subsets of elements within a system, we can determine which subsets form *complexes*. Specifically, a complex X is a set of elements

that generate integrated information ($\phi > 0$) that is not fully contained in some larger set of higher ϕ (figure 84.3). A complex, then, can be properly considered to form a single entity having its own, intrinsic “point of view” (as opposed to being treated as a single entity from an outside, extrinsic point of view). Since integrated information is generated *within* a complex and not outside its boundaries, experience is necessarily private and related to a single point of view or perspective (Tononi, 2004; Tononi & Edelman, 1998). A given physical system, such as a brain, is likely to contain more than one complex, many small ones with low ϕ values, and perhaps a few large ones (Tononi, 2004; Tononi & Edelman, 1998). In fact, at any given time there may be a single *main complex* of comparatively much higher ϕ that underlies the dominant experience (a main complex is such that its subsets have strictly lower ϕ). As shown in figure 84.3, a main complex can be embedded into larger complexes of lower ϕ : a complex can be causally connected, through *ports-in* and *ports-out*, to elements that are not part of it. According to the IIT, such elements can influence indirectly the state of the main complex without contributing directly to the conscious experience it generates (Balduzzi & Tononi, 2008; Tononi, 2004).

ACCOUNTING FOR NEUROBIOLOGICAL OBSERVATIONS Can this approach account, at least in principle, for some of the basic facts about consciousness that have emerged from decades of clinical and neurobiological observations? Measuring ϕ and finding complexes is not easy for realistic systems, but it can be done for simple networks that bear some structural resemblance to different parts of the brain (Balduzzi & Tononi, 2008; Tononi, 2004).

For example, by using computer simulations, it is possible to show that high ϕ requires networks that conjoin functional specialization (due to its specialized connectivity, each element has a unique functional role within the network) with functional integration (there are many pathways for interactions among the elements; figure 84.4A). In very rough terms, this kind of architecture is characteristic of the mammalian corticothalamic system: different parts of the cerebral cortex are specialized for different functions, yet a vast network of connections allows these parts to interact profusely. And indeed, as much neurological evidence indicates (Posner & Plum, 2007; Schiff, chapter 78, this volume), the corticothalamic system is precisely the part of the brain that cannot be severely impaired without loss of consciousness.

Conversely, ϕ is low for systems that are made up of small, quasi-independent modules (figure 84.4B; Balduzzi & Tononi, 2008; Tononi, 2004). This may be the reason why the cerebellum, despite its large number of neurons, does not contribute much to consciousness: its synaptic organization is such that individual patches of cerebellar cortex tend

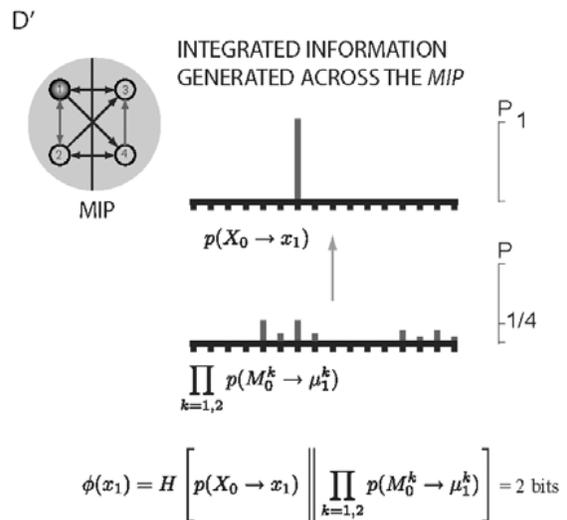

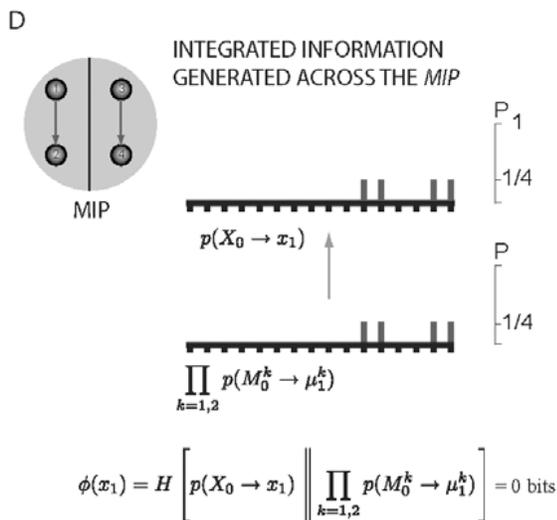

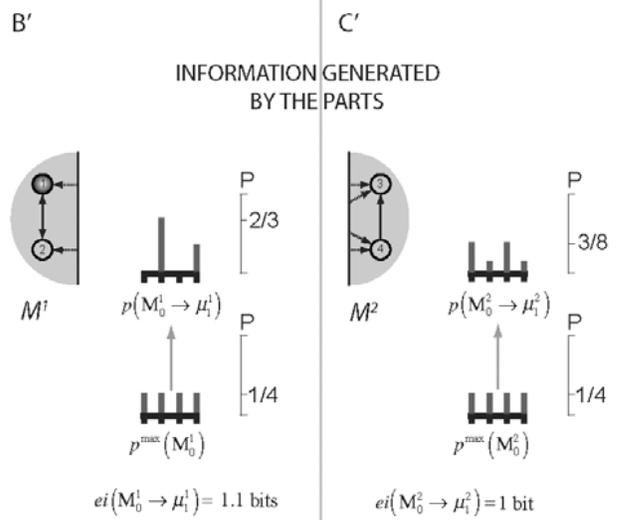

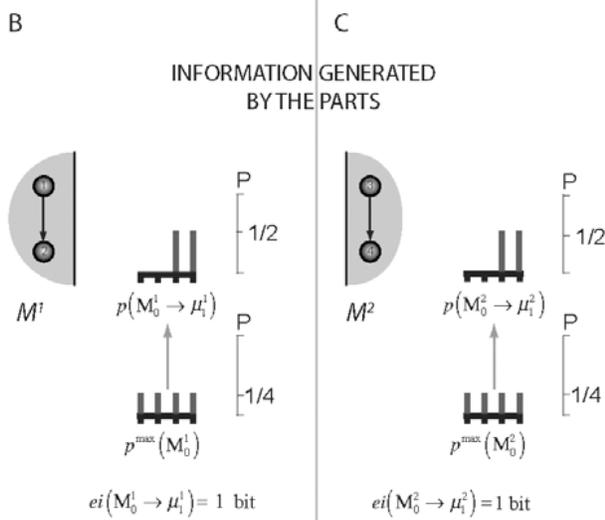

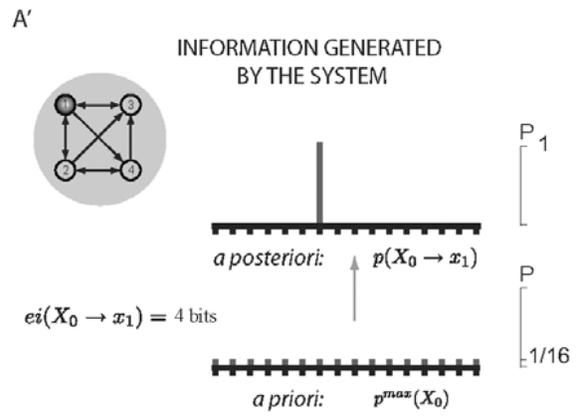

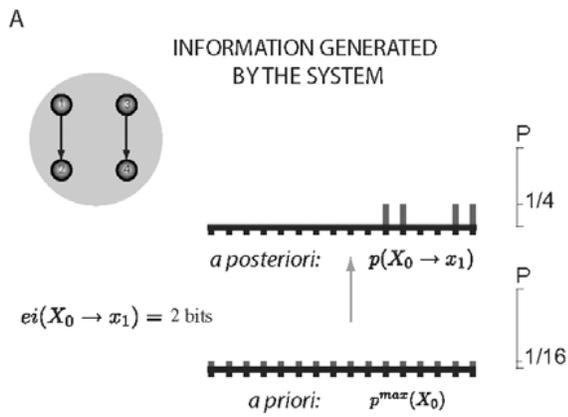

FIGURE 84.2 Integrated information. (*Left-hand side*) Two photodiodes in a digital camera. (*A*): the system as a whole generates 2 bits of effective information by specifying that n_1 and n_3 must have been on. (*B,C*): The information generated by the system as a whole is completely accounted for by the information generated independently by its parts. The minimum information partition (MIP) is the decomposition of a system into (minimal) parts that leaves the least information unaccounted for. (*D*) The a posteriori repertoire of the whole is identical to the combined a posteriori repertoires of the parts (the product of their respective probability distributions), so that relative entropy is zero. The system generates no information above and beyond the parts, so it cannot be considered a single entity. (*Right-hand side*) An integrated system. Elements in the system

are on if they receive 2 or more spikes. The system is in state $x_1 = 1000$. (*A'*) The mechanism specifies a unique prior state that causes (leads to) state x_1 , so the system generates 4 bits of effective information. All other initial states are ruled out, since they cause different outputs. (*B'C'*) Effective information generated by the two minimal parts, considered as systems in their own right. External inputs (dotted arrows) are treated as extrinsic noise and averaged over. (*D'*) The information generated by the whole (black arrows) over and above the parts (gray arrows). This is computed as the entropy of the a posteriori repertoire of the whole relative to the combined a posteriori repertoires of the parts: $\phi(x_1) = 2$ bits. The system generates information above and beyond the parts, so it can be considered a single entity (a complex).

to be activated independently of one another, with little interaction between distant patches (Bower, 2002; Cohen & Yarom, 1998).

Computer simulations also show that units along multiple, segregated incoming or outgoing pathways are not incorporated within the repertoire of the main complex (figure 84.4C; Balduzzi & Tononi, 2008; Tononi, 2004). This may be the reason why neural activity in afferent pathways (perhaps as far as V1), though crucial for triggering this or that conscious experience, does not contribute directly to conscious experience; nor does activity in efferent pathways (perhaps starting with primary motor cortex), though it is crucial for reporting each different experience.

The addition of many parallel cycles also generally does not change the composition of the main complex, although

ϕ values can be altered (figure 84.4D). Instead, cortical and subcortical cycles or loops implement specialized subroutines that are capable of influencing the states of the main corticothalamic complex without joining it. Such informationally insulated cortical-subcortical loops could constitute the neural substrates for many unconscious processes that can affect and be affected by conscious experience (Baars, 1988; Tononi, 2004), such as those that enable object recognition, language parsing, or translating our vague intentions into the right words.

At this stage, it is hard to say precisely which cortical circuits may work as a large complex of high ϕ and which instead may remain informationally insulated. Does the dense mesial connectivity revealed by diffusion spectral imaging (Hagmann et al., 2008) constitute the “backbone” of a corticothalamic main complex? Do parallel loops through basal ganglia implement informationally insulated subroutines? Are primary sensory cortices organized like massive afferent pathways to a main complex higher up in the cortical hierarchy (Koch, 2004)? Is much of prefrontal cortex organized like a massive efferent pathway? Do certain cortical areas, such as those belonging to the dorsal visual stream, remain partly segregated from the main complex? Unfortunately, answering these questions and properly testing the predictions of the theory requires a much better understanding of cortical neuroanatomy than is presently available.

Other simulations show that the effects of cortical disconnections are readily captured in terms of integrated information (Tononi, 2004): a “callosal” cut produces, out of a large complex corresponding to the connected corticothalamic system, two separate complexes, in line with many studies of split-brain patients (Gazzaniga, 2005). However, because there is great redundancy between the two hemispheres, their ϕ value is not greatly reduced compared to when they form a single complex. Functional disconnections may also lead to a restriction of the neural substrate of consciousness, as is seen in neurological neglect phenomena, in psychiatric conversion and dissociative disorders, and possibly during dreaming and hypnosis. It is also likely that

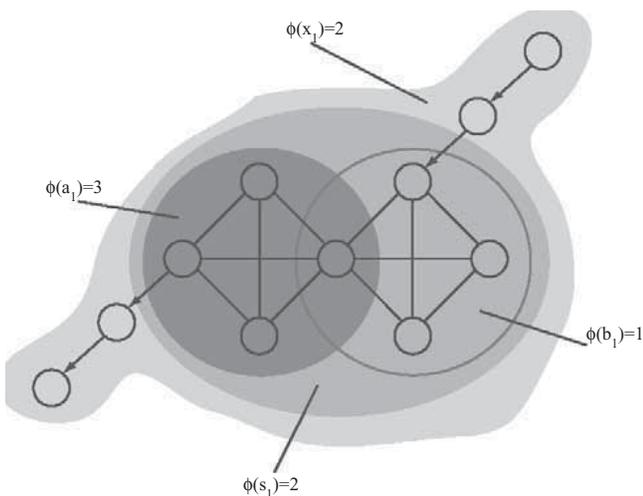

FIGURE 84.3 Complexes. Elements fire in response to an odd number of spikes; links without arrows are bidirectional. The system is decomposed into three of its complexes, shown in shades of gray. Observe that (1) complexes can overlap; (2) a complex can interact causally with elements not part of it; and (3) groups of elements with identical architectures generate different amounts of integrated information, depending on their ports-in and ports-out (compare subset a , the dark-gray filled-in circle, with the left side of subset b , the right-hand circle).

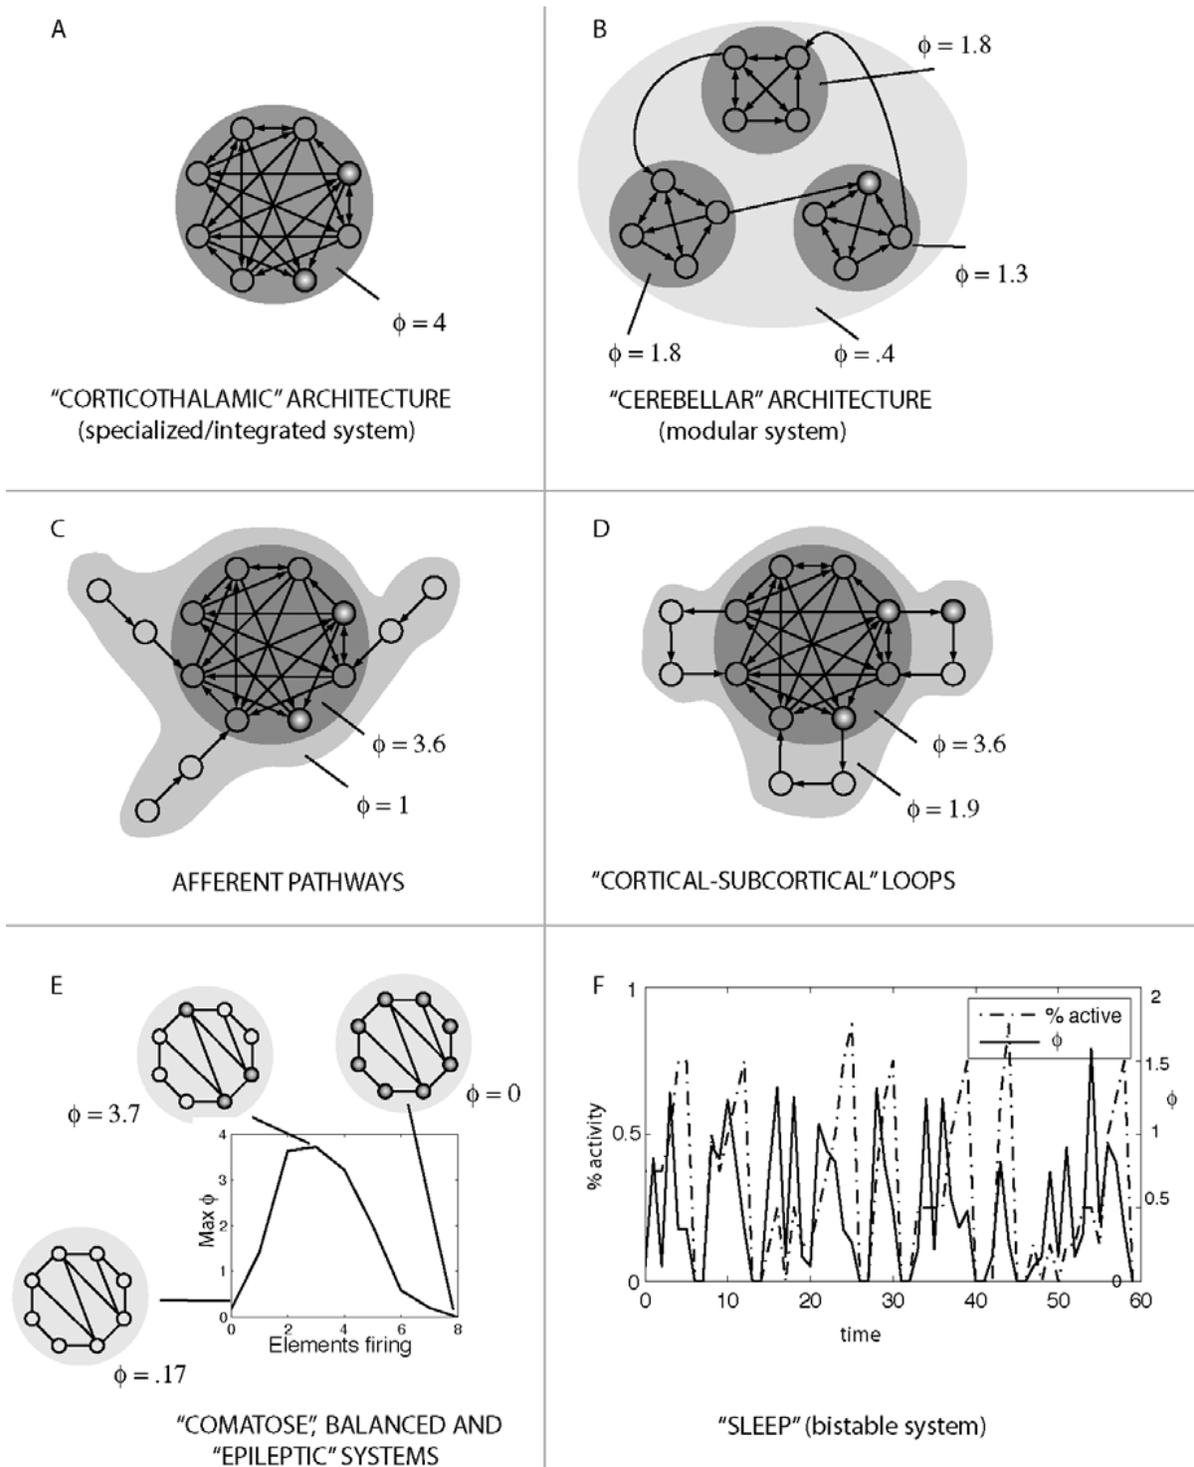

FIGURE 84.4 Relating integrated information to neuroanatomy and neurophysiology. Elements fire in response to two or more spikes (except elements targeted by a single connection, which copy their input); links without arrows are bidirectional. (A) Computing ϕ in simple models of neuroanatomy suggests that a functionally integrated and functionally specialized network—like the corticothalamic system—is well suited to generating high values of ϕ . (B,C,D) Architectures modeled on the cerebellum, afferent

pathways, and cortical-subcortical loops give rise to complexes containing more elements, but with reduced ϕ compared to the main corticothalamic complex. (E) ϕ peaks in balanced states; if too many or too few elements are active, ϕ collapses. (F) In a bistable ("sleeping") system (same as in E), ϕ collapses when the number of firing elements (dotted line) is too high, remains low during the DOWN state, and only recovers at the onset of the next UP state.

certain attentional phenomena may correspond to changes in the composition of the main complex underlying consciousness (Koch & Tsuchiya, 2007; Koch, chapter 79, this volume). The attentional blink, where a fixed sensory input may at times make it to consciousness and at times not, may also be due to changes in functional connectivity: access to the main corticothalamic complex may be enabled or not based on dynamics intrinsic to the complex (Dehaene, Sergent, & Changeux, 2003). Similarly, binocular rivalry may be related, at least in part, to dynamic changes in the composition of the main corticothalamic complex caused by transient changes in functional connectivity (Lumer, 1998). Computer simulations confirm that functional disconnection can reduce the size of a complex and reduce its capacity to integrate information (Tononi, 2004). Although it is not easy to determine, at present, whether a particular group of neurons is excluded from the main complex because of hard-wired anatomical constraints or is transiently disconnected as a result of functional changes, the set of elements underlying consciousness is not static, but forms a “dynamic complex” or “dynamic core” (Tononi & Edelman, 1998).

Computer simulations also indicate that the capacity to integrate information is reduced if neural activity is extremely high and near-synchronous, because of a dramatic decrease in the repertoire of discriminable states (figure 84.4E; Balduzzi & Tononi, 2008). This reduction in degrees of freedom could be the reason why consciousness is reduced or eliminated in absence seizure and other conditions during which neural activity is both high and synchronous.

The most common example of a marked change in the level of experience is the fading of consciousness that occurs during certain periods of sleep. Subjects awakened in deep NREM sleep, especially early in the night, often report that they were not aware of themselves or of anything else, though cortical and thalamic neurons remain active. Awakened at other times, mainly during REM sleep or during lighter periods of NREM sleep later in the night, they report dreams characterized by vivid images (Hobson & Pace-Schott, 2002; Hobson, Pace-Schott, & Stickgold, 2000). From the perspective of integrated information, a reduction of consciousness during early sleep would be consistent with the bistability of cortical circuits during deep NREM sleep. Because of changes in intrinsic and synaptic conductances triggered by neuromodulatory changes (e.g., low acetylcholine), cortical neurons cannot sustain firing for more than a few hundred milliseconds, and invariably enter a hyperpolarized down state. Shortly afterward, they inevitably return to a depolarized up state (Steriade, Timofeev, & Grenier, 2001). Indeed, computer simulations show that values of ϕ are low in systems with such bistable dynamics (figure 84.4F; Balduzzi & Tononi, 2008). Consistent with these observations, studies using TMS in conjunction with high-density EEG show that early NREM sleep is associated

either with a breakdown of the effective connectivity among cortical areas, and thereby with a loss of integration (Massimini et al., 2007, 2005), or with a stereotypical global response suggestive of a loss of repertoire and thus of information (Massimini et al., 2007). Similar changes are seen in animal studies of anesthesia (Hudetz & Imas, 2007; Imas, Ropella, Ward, Wood, & Hudetz, 2005; Kroeger & Amzica, 2007).

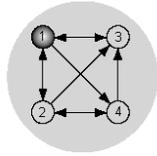

Finally, consciousness not only requires a neural substrate with appropriate anatomical structure and appropriate physiological parameters: it also needs time (Bachmann, 2000). The theory predicts that the time requirements for the generation of conscious experience in the brain emerge directly from the time requirements for the buildup of an integrated repertoire among the elements of the corticothalamic main complex so that discriminations can be highly informative (Tononi, 2004; Balduzzi & Tononi, submitted). To give an obvious example, if one were to perturb half the elements of the main complex for less than a millisecond, no perturbations would produce any effect on the other half within this time window, and ϕ would be zero. After, say, 100 ms, however, there is enough time for differential effects to be manifested, and ϕ should grow.

The second problem: What determines the quality of consciousness?

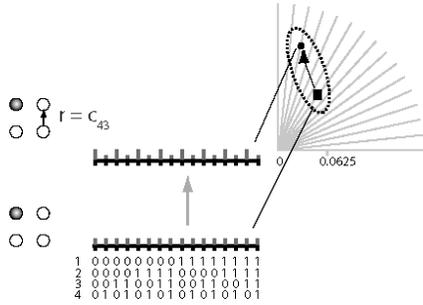

Even if we were reasonably sure that a system is conscious, it is not immediately obvious what kind of consciousness it would have. For instance, our own consciousness comes in specific and seemingly irreducible qualities, exemplified by different modalities (vision, audition, pain, etc.), submodalities (visual color, motion, etc), and sub-submodalities (red, blue, etc.). What determines that colors look the way they do, and different from the way music sounds, or pain feels? Once again, neurological and neurophysiological evidence indicates that different qualities of consciousness must be contributed by different cortical areas. Thus damage to certain parts of the cerebral cortex impairs our ability to perceive visual motion, whereas damage to other parts selectively eliminates our ability to perceive colors (or to imagine, remember, and dream about them (van Zandvoort, Nijboer, & de Haan, 2007). There is obviously something about the organization or functioning of these cortical areas that makes them contribute specific qualities to conscious experience. Unless we accept that the kind of consciousness a system has is arbitrary, then, there must be some necessary and sufficient conditions that determine exactly what kind of experiences it can have. This is the second problem of consciousness.

THE SPECIFICITY OF CONSCIOUSNESS The intuitions that may help in addressing the second problem of consciousness build directly upon the approach taken to tackle the first

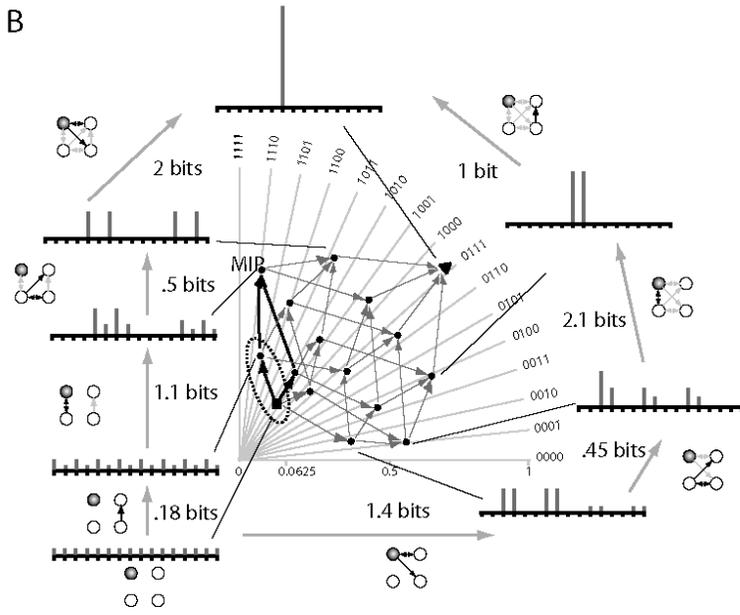

A

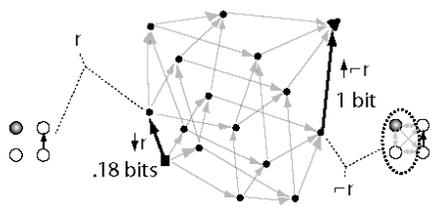

Qualia space (16-dimensional) parametrizes repertoires of the system

B

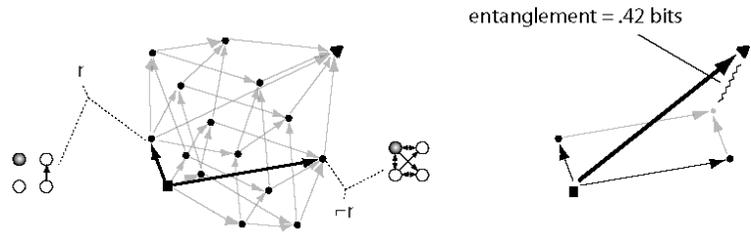

C

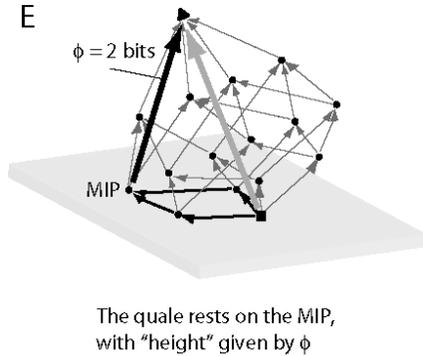

The same connection generates different q-arrows; informational relationships depend on context

D

Entanglement measures how the composite (thick) q-arrow differs from a simple combination (product) of component q-arrows

E

F

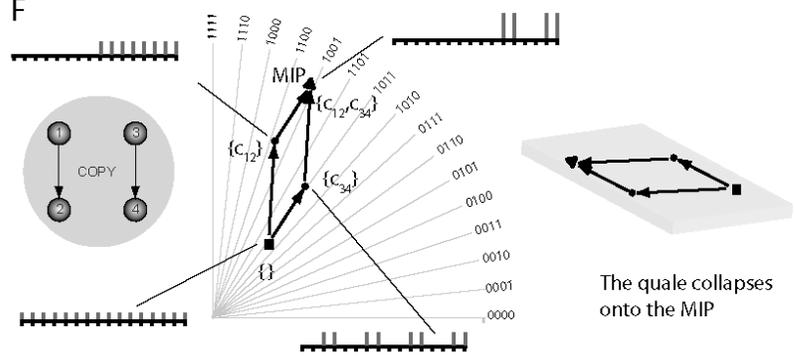

FIGURE 84.5 Qualia. (A): The system in the inset is the same as in figure 84.2A'. Qualia (Q) space for a system of 4 units is 16 dimensional (one axis per possible state; since axes are displayed flattened onto the page, and points and arrows cannot be properly drawn in two dimensions, their position and direction are for illustration purposes only). In state $x_1 = 1000$, the complex generates a quale or shape in Q -space, as follows. The maximum entropy distribution (the “bottom” of the quale, indicated by a black square) is a point assigning equal probability ($p = 1/16 = 0.0625$) to all 16 system states, close to the origin of the 16-dimensional space. Engaging a single connection r between elements 4 and 3 (c_{43}) specifies that, since element n_3 has not fired, the probability of element n_4 having fired the previous time step is reduced to $p = 0.25$ compared to its maximum ignorance value ($p = 0.5$), while the probability of n_4 not having fired is increased to $p = 0.75$. The a posteriori probability distribution of the 16 system states is modified accordingly. Thus the connection r “sharpens” the maximum entropy distribution into an a posteriori distribution, which is another point in Q -space. The q -arrow linking the two distributions geometrically realizes the *informational relationship* specified by the connection. The length (divergence) of the q -arrow expresses *how much* the connection specifies the distribution (the effective information it generates or relative entropy between the two distributions); the direction in Q -space expresses *the particular way* in which the connection specifies the distribution. (B) Engaging more connections further sharpens the a posteriori repertoire, specifying new points in Q -space and the corresponding q -arrows. The figure shows 16 out of the 399 points in the quale, generated by combinations of the four sets of connections. The insets around the quale are representative of the repertoires generated by two q -edges formed by q -arrows that engage the four sets of connections in two different orders (the two representative q -edges start at bottom left, one goes clockwise, the other counterclockwise; black connections represent those whose contribution is being evaluated; gray connections those whose contribution has already been considered and which provides the context on top of which the q -arrow generated by a black connection begins). Repertoires corresponding to certain points of the quale are shown alongside, as in previous figures. Effective information values (in bits) of the q -arrows in the two q -edges are shown

alongside. Together, the q -edges enclose a shape, the quale, which completely specifies the quality of the experience. (C) The same connection considered in two contexts (black arrows). At the bottom of the quale (null context, corresponding to the maximum entropy distribution when no connections are engaged), the connection r generates a q -arrow (called down-set of r , or $\downarrow r$) corresponding to 0.18 bits of information pointing up-left in Q -space. Near the top of the quale (full context, corresponding to the a posteriori distribution specified by all other connections except for r , indicated as $\neg r$), r generates a q -arrow (called up-set of nonred, or $\uparrow \neg r$) corresponding to 1 bit of information pointing up-right in Q -space. (D) Entanglement. (Left) The q -arrow generated by the connection r and the q -arrow generated by the complementary connections $\neg r$ at the bottom of the quale (null context). (Right) The product of the two q -arrows (corresponding to independence between the informational relationships specified by the two sets of connections) would be a point corresponding to the vertex of the dotted parallelogram opposite to the bottom. However, “ r ” and “ $\neg r$ ” jointly specify the a posteriori distribution corresponding to the top of the quale (black triangle). The distance between the probability distribution in Q -space specified jointly by two sets of connections and their product distribution (squiggly arrow) is the entanglement between the two corresponding q -arrows (how much the composite q -arrow specifies above and beyond its component q -arrows). (E) The q -edges converging on the minimum information partition of the system (MIP) form the natural base on which the complex rests, depicted as a “tent.” The informational relationships *among* the parts are built on top of the informational relationships generated independently *within* the minimal parts. From this perspective the ϕ q -arrow (in black) is simply the tent pole holding the quale up above its base; the length (divergence) of the pole expresses the breathing room in the system. (F) The quale (not) generated by the double couple considered as a single system. Note that in this case the quale reduces to the MIP: the “tent” collapses onto its base, so there is no breathing room for informational relationships within the system. As shown in figure 84.2A, the system reduces to two independent parts, so it does not exist as a single entity. The quale generated by each part considered in isolation does exist, corresponding to an identical q -arrow for each couple.

problem. As we have seen, according to the IIT, the *quantity* of consciousness generated by a complex is determined by the amount of integrated information its mechanisms and state generate as a whole, above and beyond its parts. By extension, the IIT claims that the *quality* of consciousness generated by the complex is determined by the set of all the informational relationships generated by its mechanisms and state. That is, *how* integrated information is generated within a complex determines not only the amount of consciousness it has, but also what kind of consciousness.

Consider again the photodiode thought experiment. As we discussed before, when the photodiode reacts to light, it can only tell that things are one way rather than another way. On the other hand, when we see “light,” we discriminate against many more states of affairs, and thus generate much more information. In fact, we argued that “light” means what it means and becomes conscious “light” *by virtue of* being discriminated not just against dark, but also against

any color, any shape, any combination of colors and shapes, any frame of every possible movie, any sound, smell, thought, and so on.

What needs to be emphasized at this point is that discriminating “light” against all these alternatives implies not just picking one thing out of “everything else” (an undifferentiated bunch), but distinguishing at once, in a specific way, between each and every alternative. Consider a very simple example: a binary counter capable of discriminating among the four numbers: 00, 01, 10, 11. When the counter says binary “3,” it is not just discriminating 11 from everything else as an undifferentiated bunch, otherwise it would not be a counter, but a 11 detector. To be a counter, the system must be able to tell 11 apart from 00, as well as from 10, as well as from 01 in different, specific ways. It does so, of course, by making choices through its mechanisms. For example, is this the first or the second digit? Is it a 0 or a 1? Each mechanism adds its specific contribution to the

discrimination they perform together. Similarly, when we see light, mechanisms in our brain are not just specifying “light” with respect to a bunch of undifferentiated alternatives. Rather, these mechanisms are specifying that light is what it is by virtue of being different, in this and that specific way, from every other alternative, from dark to any color to any shape, movie frame, sound or smell, and so on.

In short, generating a large amount of integrated information entails having a highly structured set of mechanisms that allow us to make many nested discriminations (choices) as a single entity. According to the IIT, these mechanisms working together generate integrated information by specifying a set of informational relationships that univocally determine the quality of experience.

QUALIA SPACE: GIVING SHAPE TO EXPERIENCE To see how this intuition can be given a mathematical formulation, let us consider again a complex X of n binary elements in a particular state x_1 . Let us now suppose that each possible state of the system constitutes an axis or dimension of a *qualia space* (Q -space) having 2^n dimensions. Each axis is labeled with the probability p for that state, going from 0 to 1, so that a repertoire—that is, a probability distribution on the possible states of the complex—corresponds to a point in Q -space (figure 84.5).

Let us now examine how the connections among the elements of the complex specify probability distributions, that is, how a set of causal interactions specifies a set of informational relationships. First, consider the complex with all connections among its elements disengaged, thus discounting any causal interactions (figure 84.5A). In the absence of a mechanism, the state x_1 provides no information about the system’s previous state: from the perspective of a system without causal interactions, all previous states are equally likely, corresponding to the maximum entropy or uniform distribution (the a priori repertoire). In Q -space, this probability distribution is a point projecting onto all axes at $p = 1/2^n$ (probabilities must sum to 1).

Next, consider engaging a single connection (figure 84.5A; the other connections are treated as extrinsic noise and averaged over). As with the photodiode, the mechanism implemented by that connection and the state the system is in rule out states that could not have caused x_1 and increases the a posteriori probability of states that could have caused x_1 , yielding an a posteriori repertoire. In Q -space, the a posteriori repertoire specified by this connection corresponds to a point projecting onto higher p values on some axes and onto lower p values (or zero) on other axes. Thus the connection generates some information by shaping the uniform distribution into a more specific distribution, and thereby generates information (reduces uncertainty). More generally, we can say that the connection specifies an *informational relationship*, that is, a relationship between two probability

distributions. This informational relationship can be represented as an arrow in Q -space (*q-arrow*) that goes from the point corresponding to the maximum entropy distribution ($p = 1/2^n$) to the point corresponding to the a posteriori repertoire specified by that connection. The length (divergence) of the q -arrow expresses *how much* the connection specifies the distribution (the effective information it generates, i.e., the relative entropy between the two distributions); the direction in Q -space expresses *the particular way* in which the connection specifies the distribution, that is, a change in position in Q -space. Similarly, if one considers all other connections taken in isolation, each will specify another q -arrow of a certain length, pointing in a different direction.

Next, consider all possible combinations of connections (figure 84.5B). For instance, consider adding the contribution of the second connection to that of the first. Together, the first and second connections specify another a posteriori repertoire—another point in Q -space—and thereby generate more information than either connection alone as they shape the uniform distribution into a more specific distribution. To the tip of the q -arrow specified by the first connection, one can now add a q -arrow bent in the direction contributed by the second connection, forming an “edge” of two q -arrows in Q -space (the same final point is reached by adding the q -arrow due to the first connection on top of the q -arrow specified by the second one). Each combination of connection therefore specifies a *q-edge* made of concatenated q -arrows (component q -arrows). In general, the more connections one considers together, the more the a posteriori repertoire will take shape and differ from the uniform (a priori) distribution.

Finally, consider the joint contribution of all connections of the complex (figure 84.5B). As was discussed previously, all connections together specify the a posteriori repertoire of the whole. This is the point where all q -edges converge. Together, these q -edges in Q -space delimit a *quale*, that is, a *shape* in Q -space, a kind of 2^n -dimensional solid (technically, in more than 3 dimensions, the “body” of a polytope). The bottom of the quale is the maximum entropy distribution, its edges are q -edges made of concatenated q -arrows, and its top is the a posteriori repertoire of the complex as a whole. The shape of this solid (polytope) specifies all informational relationships that are generated within the complex by the interactions among its elements—also known as the *effective information matrix* (Tononi, 2004). Note that the same complex of elements, endowed with the same mechanism, will typically generate a different quale or shape in Q -space depending on the particular state it enters.

It is worth considering briefly two relevant properties of informational relationships or q -arrows. First, informational relationships are context-dependent (figure 84.5C) in the following sense. A *context* can be any point in Q -space corresponding to the a posteriori repertoire generated by a

particular subset of connections. It can be shown that the q -arrow generated by considering the effects of an additional connection (how it further changes the a posteriori repertoire) can change in both magnitude and direction depending on the context in which it is considered. In figure 84.5C, when considered in isolation (null context), the connection r between elements 4 and 3 generates a short q -arrow (0.18 bits) pointing in a certain direction. When considered in the full context provided by all other connections (not- r or $\neg r$), the same connection r generates a longer q -arrow (1 bit) pointing in a different direction.

Another important property of q -arrows is *entanglement* (Balduzzi & Tononi, submitted). Two Q -arrows are entangled if their underlying mechanisms, considered jointly, generate information above and beyond the information they generate separately (note the analogy with ϕ). Thus entanglement characterizes informational relationships (q -arrows) that are more than the sum of their component relationships (component q -arrows, figure 84.5D). Geometrically, entanglement “warps” the shape of the quale away from a simple hypercube (where q -arrows are orthogonal to each other). Entanglement has several relevant consequences (discussed in Balduzzi & Tononi, submitted), one of which being that it can identify *modes*. Modes are sets of q -arrows that are more densely entangled than surrounding q -arrows and can be considered as clusters of informational relationships constituting distinctive “subshapes” in Q -space.

SOME CONSEQUENCES OF VIEWING QUALIA AS SHAPES What is the relevance of these constructs to understanding the quality of consciousness? It is not easy to become familiar with a complicated multidimensional space nearly impossible to draw, so it may be useful to resort to some metaphors (for a more detailed mathematical treatment, see Balduzzi & Tononi, submitted). Perhaps the most important notion emerging from this approach is that *an experience (a quale in the broad sense) is a shape in Q -space*. What gives each experience its particular shape are the informational relationships in Q -space (q -arrows between repertoires) generated by causal interactions among the elements of a complex. Only the informational relationships within a complex (those that give the quale its shape) contribute to experience. Conversely, the informational relationships that exist outside the main complex—for example, those involving sensory afferents—do not make it into the quale, and therefore do not contribute either to the quantity or to the quality of consciousness.

By the same token, different experiences are, literally, different shapes in Q -space. For example, when the same system is in a different state (firing pattern), it will typically generate a different shape or quale (even for the same value of ϕ). Moreover, experiences are similar if their shape is similar, and different to the extent that their shapes are

different. Therefore, phenomenological similarities and differences can in principle be quantified as similarities and differences between shapes.

Note that a quale can only be specified by a mechanism and a particular state. On the one hand, it does not make sense to ask about the quale generated by a mechanism in isolation or by a state (firing pattern) in isolation. On the other hand, it does make sense to ask what kind of shapes or qualia the same system (mechanism) can generate when it is in different states. The set of all shapes generated by the same system in different states provides a geometrical depiction of all its possible experiences.

Another consequence is that two systems in the same state can generate two different experiences (i.e., two different shapes). As an extreme example, if a system were to copy one by one the state of the neurons in a human brain but had no internal connections of its own, it would generate no consciousness and no quale (Balduzzi & Tononi, 2008; Tononi, 2004).

Note also that informational relationships, and thus the shape of the quale, are specified both by the elements that are firing and by those that are not. This situation is natural considering that an element that does not fire will typically rule out some previous states of affairs (those that would have made it fire), and thereby it will contribute to specifying the a posteriori repertoire. Indeed, many silent elements can rule out, in combination, a vast number of previous states and thus be highly informative. From a neurophysiological point of view, such a corollary may lead to counterintuitive predictions. For example, take elements (neurons) within the main complex that happen to be silent when one is having a particular experience. If one were to temporarily disable them (e.g., make them *incapable* of firing), the prediction is that, though the system state (firing pattern) remains exactly the same, the quantity and quality of experience would change (Balduzzi & Tononi, 2008; Tononi, 2004).

It also follows that two systems with different architectures can generate the same experience (i.e., the same shape). For example, consider again the photodiode, whose mechanism determines that if the current in the sensor exceeds a threshold, the detector turns on. This simple causal interaction is all there is, and when the photodiode turns on, it merely specifies an a posteriori repertoire where states (00,01,10,11) have, respectively, probability (0,0, $\frac{1}{2}$, $\frac{1}{2}$). This corresponds in Q -space to a single q -arrow, one bit long, going from the a priori, maximum entropy repertoire ($\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4}$) to (0,0, $\frac{1}{2}$, $\frac{1}{2}$). Now imagine the light sensor is substituted by a temperature sensor with the same threshold and dynamic range—we have a thermistor rather than a photodiode. While the physical device has changed, according to the IIT the experience, minimal as it is, has to be the same, since the informational relationship that is generated by the two devices is identical. Similarly, an AND gate when silent and

an OR gate when firing also generate the same shape in Q -space, and therefore must generate the same minimal experience (it can be shown that the two shapes are isomorphic, that is, have the same symmetries, Balduzzi and Tononi, submitted). In other words, different “physical” systems (possibly in different states) generate the same experience if the shape of the informational relationships they specify is the same. However, more complex networks of causal interactions are likely to create highly idiosyncratic shapes, so systems of high ϕ are unlikely to generate exactly identical experiences.

It is important to see what ϕ corresponds to in this representation (figure 84.5E). The minimum information partition (MIP) is just another point in Q -space: the one specified by the connections *within* the minimal parts only, leaving out the contribution of the connections *among* the parts. This point is the a posteriori repertoire corresponding to the product of the a posteriori repertoires of the parts taken independently. Then ϕ corresponds to an arrow linking this point to the top of the solid. In this view, the q -edges leading to the minimum information bipartition provide the natural “base” upon which the solid rests—the informational relationships generated *within* the parts upon which are built the informational relationships *among* the parts. The ϕ -arrow can then be thought of as the height of the solid—or rather, to employ another metaphor, as the highest pole holding up a tent. For example, if ϕ is zero (say a system decomposes into two independent complexes as in figure 84.5F), the tent corresponding to the system is flat—it has no shape—since the a posteriori repertoire of the system collapses onto its base (MIP). This configuration is precisely what it means when $\phi = 0$. Conversely, the higher the ϕ value of a complex, the higher the tent or solid, the more “breathing room” there is for the various informational relationships within the complex (the edges of the solid or the seams of the tent) to express themselves.

In summary, and not very rigorously, the generation of an experience can be thought of as the erection of a tent with a very complex structure: the edges are the tension lines generated by each connection in turn (the respective q -arrow or informational relationship). The tent literally takes shape when the connections are engaged and specify a posteriori repertoires. And when the system enters a different state, a different tent is erected.

TRANSLATING PHENOMENOLOGY INTO GEOMETRY The notions just sketched provide an initial framework for translating the seemingly ineffable qualitative properties of phenomenology into the language of mathematics, specifically, the language of informational relationships (q -arrows) in Q -space. Ideally, when sufficiently developed, such language should permit the geometric characterization of phenomenological properties generated by the human

brain. In principle, it should also allow us to characterize the phenomenology of other systems. After all, in this framework the experience of a bat echolocating in a cave is just another shape in Q -space, and, at least in principle, shapes can be compared objectively.

At present, because of the combinatorial problems posed by deriving the shape of the quale produced by systems of just a few elements and because of the additional difficulties posed by representing such high-dimensional objects, the best one can hope for is to show that the language of Q -space can capture, in principle, some of the basic distinctions that can be made in our own phenomenology, as well as some key neuropsychological observations (Balduzzi and Tononi, submitted). A short list includes the following:

1. Experience is divided into modalities, like the classic senses of sight, hearing, touch, smell, and taste (and several others), as well as submodalities, like visual color and visual shape. What do these broad distinctions correspond to in Q -space? According to the IIT, modalities are sets of densely entangled q -arrows (*modes*) that form distinct *subshapes* in the quale; submodalities are subsets of even more densely entangled q -arrows (submodes) within a larger mode, thus forming distinct sub-subshapes. As a two-dimensional analog, imagine a given multimodal experience as the shape of the three-continent complex constituted by Europe, Asia, and Africa. The three continents are distinct subshapes, yet they are all part of the same landmass, just as modalities are parts of the same consciousness. Moreover, within each continent there are peninsulas (sub-subshapes), like Italy in Europe, just as there are submodalities within modalities.

2. Some experiences appear to be “elementary,” in that they cannot be further decomposed. A typical example is what philosophers call a “quale” in the narrow sense, say, a pure color like red, or a pain, or an itch: it is difficult, if not impossible, to identify any further phenomenological structure within the experience of red. According to the IIT, such elementary experiences correspond to submodes that do not contain any more densely entangled sub-submodes (*elementary modes*).

3. Some experiences are homogeneous and others are composite: for example, a full-field experience of pure darkness, compared to that of a busy street. In Q -space, homogeneous experiences translate to a single homogeneous shape, and composite ones into a composite shape with many distinguishable subshapes (modes and submodes).

4. Some experiences are hierarchically organized. Take seeing a face: we see at once that as a whole it is somebody’s face, but we also see that it has parts such as hair, eyes, nose, and mouth, and that those are made in turn of specifically oriented segments. The subjective experience is constructed from informational relationships (q -arrows) that are entangled (not reducible to a product of independent components)

across hierarchical levels. For example, informational relationships constituting “face” would be more densely tangled than unnatural combinations such as “eyelash + half of lip.” The subshape of the quale corresponding to the experience of seeing a face is then an overlapping hierarchy of tangled q -arrows, embodying relationships within and across levels.

5. We recognize intuitively that the way we perceive taste, smell, and maybe color is organized phenomenologically in a “categorical” manner, quite different from, say, the “topographical” manner in which we perceive space in vision, audition, or touch. According to the IIT, these hard-to-articulate phenomenological differences correspond to different basic subshapes in Q -space, such as 2^n -dimensional *gridlike* structures and *pyramidlike* structures, which emerge naturally from the underlying neuroanatomy.

6. Some experiences are more alike than others. Blue is certainly different from red (and irreducible to red), but clearly it seems even more different from middle C on the oboe. In the IIT framework, in Q -space colors correspond to different subshapes of the same kind (say pyramids pointing in different directions) and sounds to very different subshapes (say tetrahedra). In principle, such subjective similarities and differences can be investigated by employing objective measures of *similarity between shapes* (e.g., considering the number and kinds of symmetries involved in specifying shapes that are generated in Q -space by different neuroanatomical circuits).

7. Experiences can be refined through learning and changes in connectivity. Say, for example, one learns to distinguish wine from water, then reds from whites, then different varietals. Presumably, underlying this phenomenological refinement is a neurobiological refinement: neurons that initially were connected indiscriminately to the same afferents become more specialized and split into subgroups with partially segregated afferents. This process has a straightforward equivalent in Q -space: the single q -arrow generated initially by those afferents *splits* into two or more q -arrows pointing in different directions, and the overall subshape of the quale is correspondingly refined.

8. Qualia in the narrow sense (experiential primitives) exist “at the top of experience” and not at its bottom. Consider the experience of seeing a pure color, such as red. The evidence suggests that the “neural correlate” (Crick & Koch, 2003) of color, including red, is probably a set of neurons and connections in the fusiform gyrus, maybe in area V8. (Ideally, neurons in this area are activated whenever a subject sees red and not otherwise, if stimulated trigger the experience of red, and if lesioned abolish the capacity to see red.) Certain achromatopsic subjects with dysfunctions in this general area seem to lack the feeling of what it is like to see color, its “coloredness,” including the “redness” of red. They cannot experience, imagine, remember, and even dream of color, though they may talk about it, just as we

could talk about echolocation, from a third-person perspective (van Zandvoort et al., 2007). Contrast such subjects, who are otherwise perfectly conscious, with vegetative patients, who are for all intents and purposes unconscious. Some of these patients may show behavioral and neurophysiological evidence for residual function in an isolated brain area (Posner & Plum, 2007; Schiff, chapter 78, this volume). Yet it seems highly unlikely that a vegetative patient with residual activity exclusively in V8 should enjoy the vivid perceptions of color just as we do, while being otherwise unconscious.

The IIT provides a straightforward account for this difference. To see how, consider again figure 84.5C: call “ r ” the connections targeting the “red” neurons in V8 that confer them their selectivity, and non- r ($\neg r$) all the other connections within the main corticothalamic complex. Adding r in isolation at the bottom of Q -space (null context), yields a small q -arrow (called the *down-set of red* or $\downarrow r$) that points in a direction representing how r by itself shapes the maximum entropy distribution into an a posteriori repertoire. Schematically, this situation resembles that of a vegetative patient with V8 and its afferents intact but the rest of the corticothalamic system destroyed. The shape of the experience or quale reduces to this q -arrow, so its quantity is minimal (ϕ for this q -arrow is obviously low) and its quality minimally specified: as we have seen with the photodiode, r by itself cannot specify whether the experience is a color rather than something else, such as a shape, whether it is visual or not, sensory or not, and so on.

By contrast, subtract r from the set of all connection, so one is left with $\neg r$. This “lesion” collapses the q -arrow, called the *up-set of nonred* ($\uparrow \neg r$), which starts from the full context provided by all other connections $\neg r$ and reaches the top of the quale (more precisely, the lesion collapses all q -arrows generated by r starting from any *context*). This q -arrow will typically be much longer and point in a different direction than the q -arrow generated by r at the bottom of the quale. This result occurs because, the fuller the context, the more r can shape the a posteriori repertoire. Schematically, removing r from the top resembles the situation of an achromatopsic patient with a selective lesion of V8: the bulk of the experience or quale remains intact (ϕ remains high), but a noticeable feature of its shape collapses (the up-set of nonred). According to the IIT, the feature of the shape of the quale specified by “the up-set of nonred” captures the very quality or “redness” of red.

It is worth remarking that the last example also shows why specific qualities of consciousness, such as *the “redness” of red, while generated by a mechanism, cannot be reduced to a mechanism*. If an achromatopsic subject without the r connections lacks precisely the “redness” of red, whereas a vegetative patient with just the r connections is essentially unconscious, then

the redness of red cannot map directly to the mechanism implemented by the r connections. However, the redness of red can map nicely onto the informational relationships specified by r , as these change dramatically between the null context (vegetative patient) and the full context (achromatopsic subject).

Conclusion and outstanding issues

To recapitulate, the IIT claims that the quantity of consciousness is given by the integrated information (ϕ) generated by a complex of elements, and its quality by the shape in Q -space specified by all the informational relationships they generate. As we have tried to indicate, this theoretical framework can account, at least in principle, for several basic neurobiological and neuropsychological observations. Moreover, the same theoretical framework can be extended to begin translating phenomenology into the language of mathematics. At present, the very notion of a theoretical approach to consciousness may appear far-fetched, yet the nature of the problems posed by a science of consciousness seems to require a combination of experiments and theories: one could say that theories without experiments are lame, but experiments without theories are blind.

The IIT converges with other neurobiological frameworks (e.g., Crick & Koch, 2003; Dehaene, Changeux, Naccache, Sackur, & Sergent, 2006; Edelman, 1989) and cognitive theories (Baars, 1988) on several key facts: that our own consciousness is generated by distributed corticothalamic networks, that interactions among multiple cortical regions are important, and that there are many “unconscious” neural systems (or rather minimally conscious ones). Importantly, however, the IIT tries to account, in a coherent manner, for several key but puzzling facts about consciousness and the brain, such as the association of consciousness with the corticothalamic but not the cerebellar system or the fading of consciousness during certain stages of sleep or epilepsy despite continuing neural activity (as sketched in figure 84.4).

The IIT also predicts that consciousness depends exclusively on the ability of a system to generate integrated information. Whether or not the system is interacting with the environment on the sensory and motor side, it deploys language, capacity for reflection, attention, episodic memory, and a sense of space, of the body, and of the self. These are obviously important functions of complex brains and are crucial in shaping its connectivity. Nevertheless, contrary to some common intuitions but consistent with the overall neurological evidence, none of these functions seems absolutely necessary for the generation of consciousness “here and now” (Tononi & Laureys, in press).

Finally, the IIT says that the presence and extent of consciousness can be determined, in principle, also in cases in

which we have no verbal report, such as infants or animals, or in neurological conditions such as minimally conscious states, akinetic mutism, psychomotor seizures, and sleep-walking. In practice, of course, measuring ϕ accurately in such systems will not be easy, but approximations and informed estimates are certainly conceivable. The theory also implies that consciousness is not an all-or-none property, but is graded: specifically, it increases in proportion to a system’s repertoire of discriminable states. In fact, any physical system with some capacity for integrated information would have some degree of experience, irrespective of the constituents of which it is made and independent of its ability to report. In particular, this statement implies that suitably wired computers or robots can be conscious (Koch & Tononi, 2008). Whether these and other predictions turn out to be compatible with future clinical and experimental evidence, a coherent theoretical framework should at least help to systematize a number of neuropsychological and neurobiological results that might otherwise seem disparate.

To conclude, it is worth pointing out some outstanding issues that will need to be addressed in further developments of the theory. One of these is finding a principled way to determine the proper spatial and temporal scale to measure informational relationships and integrated information. What are the elements upon which probability distributions of states are to be evaluated? For example, are they synapses, neurons, or minicolumns? Similarly, what is the “clock” to use to identify system states? Does it run in milliseconds or hundreds of milliseconds? A working hypothesis is that the relevant spatial and temporal scales are those that jointly maximize ϕ (Tononi, 2004)—different systems will generate maximal amounts of integrated information at a particular spatiotemporal scale that is determined by their mechanism.

Another important issue has to do with the relationship between complexes and the outside world. The mechanisms of a complex generate integrated information and informational relationships from within. As shown by dreams, an adult brain does not need the outside world to generate experience. However, the mechanisms inside the complex are what they are, and so is the quality of the experience they generate, by virtue of a long evolutionary history, individual development, and learning. In fact, it appears that as a system incorporates statistical regularities from its environment and learns, its capacity for integrated information may grow (Tononi, Sporns, & Edelman, 1996). It will thus be important to see how the informational relationships (q -arrows) inside a complex reflect and react to informational relationships existing in the world. These and related issues, together with the intrinsic difficulty of characterizing Q -space for even the simplest of systems, will provide a challenging test bed for the IIT.

85 Mapping Cognitive Neuroscience: Two-Dimensional Perspectives on Twenty Years of Cognitive Neuroscience Research

JOHN T. BRUER

Michael Gazzaniga and George A. Miller coined the name *cognitive neuroscience* in 1976, over martinis at the Rockefeller University Faculty Club. They chose the name to designate a new research program at the interface of systems neuroscience, computational neuroscience, and cognitive psychology. The goal of the research program would be to address the biological foundations of human cognition (Gazzaniga, 1984). In 1987, the James S. McDonnell Foundation, later joined by the Pew Trusts, made a commitment to grow and institutionalize this new field. One of the first initiatives McDonnell funded was the Summer Institute in Cognitive Neuroscience. Steve Kosslyn organized the first institute at Harvard University in 1988. Gazzaniga assumed the directorship of the Summer Institute the following year and has guided the institute since that time.

Gazzaniga initiated the practice of devoting every fifth Summer Institute to producing a volume that summarized the state of cognitive neuroscience at the time, presenting chapters that highlighted both progress made in the previous four years and outstanding research questions for the future. This volume, coming 20 years after the first Summer Institute, is the fourth such volume (Gazzaniga, 1995, 2000, 2004). These Summer Institute in Cognitive Neuroscience volumes (hereafter referred to as CN volumes) serve as significant resources for researchers and students in the field. Their impact comes as no surprise. Section editors and contributors were carefully picked from among the leading authorities in the field to present critical reviews of all areas of research, from cellular neuroscience to cognitive psychology, that were deemed relevant to the cognitive neuroscience enterprise.

As compilations of state of the science review articles, the CN volumes can be viewed not as snapshots, but rather as

photo albums of the development of cognitive neuroscience. This perspective piece will capitalize on this feature of the volumes to initiate a historical look at this still relatively young field. Such a perspective is useful for established researchers and new students to assess progress the field has made, as well as to recall the origins of problems and questions in the field. Cognitive neuroscience also provides an interesting example for scholars of science to examine how an initially multidisciplinary research program coalesces into a new research field.

In this perspective piece, I attempt to initiate this historical discussion using articles published by contributors to the CN volumes as the starting point. As a first step, I will examine how publication patterns in cognitive neuroscience changed and how research topics changed between 1988 and 2007. Using bibliometric methods and data visualization techniques developed by information scientists, I will generate journal citation and topic word maps of a small portion of the cognitive neuroscience literature. Although the resulting maps are interesting and illustrative, keep in mind that they are first steps and generated from the published work of a relatively small and possibly unrepresentative sample of cognitive neuroscientists. Compared to larger studies of disciplines and maps of the entire scientific literature, the maps in this chapter can be characterized as “toy maps,” in the same sense that early connectionist models were dubbed “toy networks.” Like the early toy networks, these toy maps illustrate trends, questions, and possibilities that might be addressed in more extensive bibliometric and historical studies.

The author, publication, and topic word data set

Bibliometric studies are based on published documents and relationships that hold among them. Studies can be done at various levels of analysis (individual papers, authors, journals, institutions, nations, or scientific disciplines) and using various

JOHN T. BRUER James S. McDonnell Foundation, St. Louis, Missouri

relationships, among them: citation, cocitation, and co-authorship. This study will begin by compiling two author sets. The first author set consists of the 150 authors who contributed chapters to CN 1995. The second author set consists of the 107 authors who have contributed to the current volume, CN 2008. These two author sets have 20 authors in common. For the 1995 contributors, I collected from the *Web of Science*[®] the bibliographic records for all articles these authors published in 1995. I will call this the *1995 data set*. To obtain a longer historical perspective, I also collected bibliographic records for all articles these authors published in 1988, the earliest year available on the *Web of Science*. I will call this the *1988 data set*. For the contributors to the current volume, I collected bibliographic records for all articles they published in 2007, the most recent complete year available on the *Web of Science* when the search was executed. This is the *2007 data set*. The journals in which the authors published in each of the three data sets, plus data on journal cocitations, provide the basis for three journal citation maps (1988, 1995, and 2007). With these maps, one can visualize how publication patterns changed and see the citation flow among journals publishing cognitive neuroscientific research. Using programs developed by Loet Leydesdorff (Leydesdorff, 2004; Leydesdorff & Hellsten, 2005), I gathered title word co-occurrence data for articles in the three data sets to create topic word maps. With these maps, one can visualize how research topics in cognitive neuroscience and their interrelationships might have changed between 1988 and 2007. The data for the author sets are summarized in table 85.1.

The journal citation maps

A journal citation occurs when an article in journal A cites a previously published article in journal B. In citation maps, this relationship is depicted as $A \rightarrow B$, which is read, "A cites B." Citations flow from journal A to journal B. If the journals cite each other, this is represented as $A \leftrightarrow B$. Journal citation maps have a long history in bibliometric studies of science. On a large scale, using hundreds or thousands of journals, they can be used to visualize interrelationships among major scientific disciplines. (For example, see www.eigenfactor.org.) On a smaller scale, they can be used to show how subdisciplines merge into new research fields. (Leydesdorff, 1994; McCain, 1998).

On the small scale employed in this study, one might hope to see how cognitive neuroscience emerged from its progenitor disciplines (systems neuroscience, cognitive psychology, neuropsychology) by noting changes in cocitation patterns among the progenitor discipline journals and possibly through the appearance of new cognitive neuroscience journals. These maps also allow us to visualize the citation flow among journals and to assess how results and ideas flowed among them. For an interdisciplinary field that is emerging from a multidisciplinary foundation, such as cognitive neuroscience, one might be able to see, for example, how ideas and results from neuroscience fed into psychology, from psychology into neuroscience, or both.

In order to ensure clear and readily interpretable maps, the journal citation maps presented here include only journals that published five or more articles in each of the data sets. There are around 30 journals in this category for each data set, and these journals contain on average 62% of the articles in each set (see table 85.1). These journals and the number of articles they published in each data set appear in table 85.2. These journals fall into four general categories: neuroscience (N), psychology (P), general (G), and clinical medicine (C).

The Science and Social Science Citation Indexes publish annual compilations of journal citation counts for major scientific journals, the *Journal Citation Reports* (JCR). For the 1988 journals, the citation data came from 1987 JCR, the year closest to 1988 for which I had access to hard copy volumes of the reports. For the 1995 and 2007 journals, data came from the on-line version of the JCR available through *Web of Science*: for 1995, the 1998 reports (the earliest year available on-line), and for 2007, the 2006 reports (the latest complete year at time of data collection).

For each of the data sets, the citation data is entered into an asymmetric matrix in which entries are the number of times row-journal A cites column-journal B. The matrix is asymmetrical because if journal A cites journal B n times, it is not generally the case that journal B cites journal A n times. Journal self-citations are omitted, so the matrix diagonal is empty. Asymmetric matrices are isomorphic to directed graphs, where in this case journals are nodes in the graph and directed edges represent the citation relation. It is these graph structures that information scientists call *maps*.

TABLE 85.1
Summary of 1988, 1995, and 2007 data sets

Year	Authors	Articles	Title Words	Journals	Journals with ≥ 5 Articles	Percentage of Articles in Journals with ≥ 5 Articles
1988	150	433	1531	144	26	57
1995	150	567	1870	159	33	64
2007	107	558	1713	146	27	66

Journals vary widely in the number of papers published in a year and thus vary in the citation opportunities they afford and in the number of citations they make. To normalize the citation data, the relative frequency with which journal A cites journal B (the number of times journal A cites journal B divided by the total number of citations journal A made in that year) is used as a measure of similarity or relevance between journals. The asymmetric relative frequency matrices are input to *Pajek*, a network analysis and visualization program (de Nooy, Mrvar, & Batagelj, 2005) that yields the directed graphs, or journal citation maps. To remove citation noise and clutter, a relative frequency threshold of greater than 0.03 is used. Edges that represent relative frequencies of 0.03 and less are removed from the maps. Nodes are placed in the map by using the Kamada-Kawai algorithm, which represents the network as a system of springs with relaxed lengths proportional

to the edge length and iteratively repositions nodes to minimize overall energy of the spring system. The node size is scaled to the journal's "importance," which will be explained below. Isolated journals in the maps, that is, journals that do not cite or are not cited above the threshold by other journals, are shown in the top left of each map. Figure 85.1 presents the journal citation map for the 1988 data set.

Before analyzing entire maps, it is useful to focus first on portions of the maps, on subgraphs within the larger directed graphs. Is it possible to identify subsets of journals that mutually influence one another? Are there subsets of journals in which there is a citation flow from one journal in the subset to every other journal in the subset? If so, in a directed graph, these subsets of journals would form strong components of the graph. A strong component is the largest subset of nodes in the graph for which there is a directed path

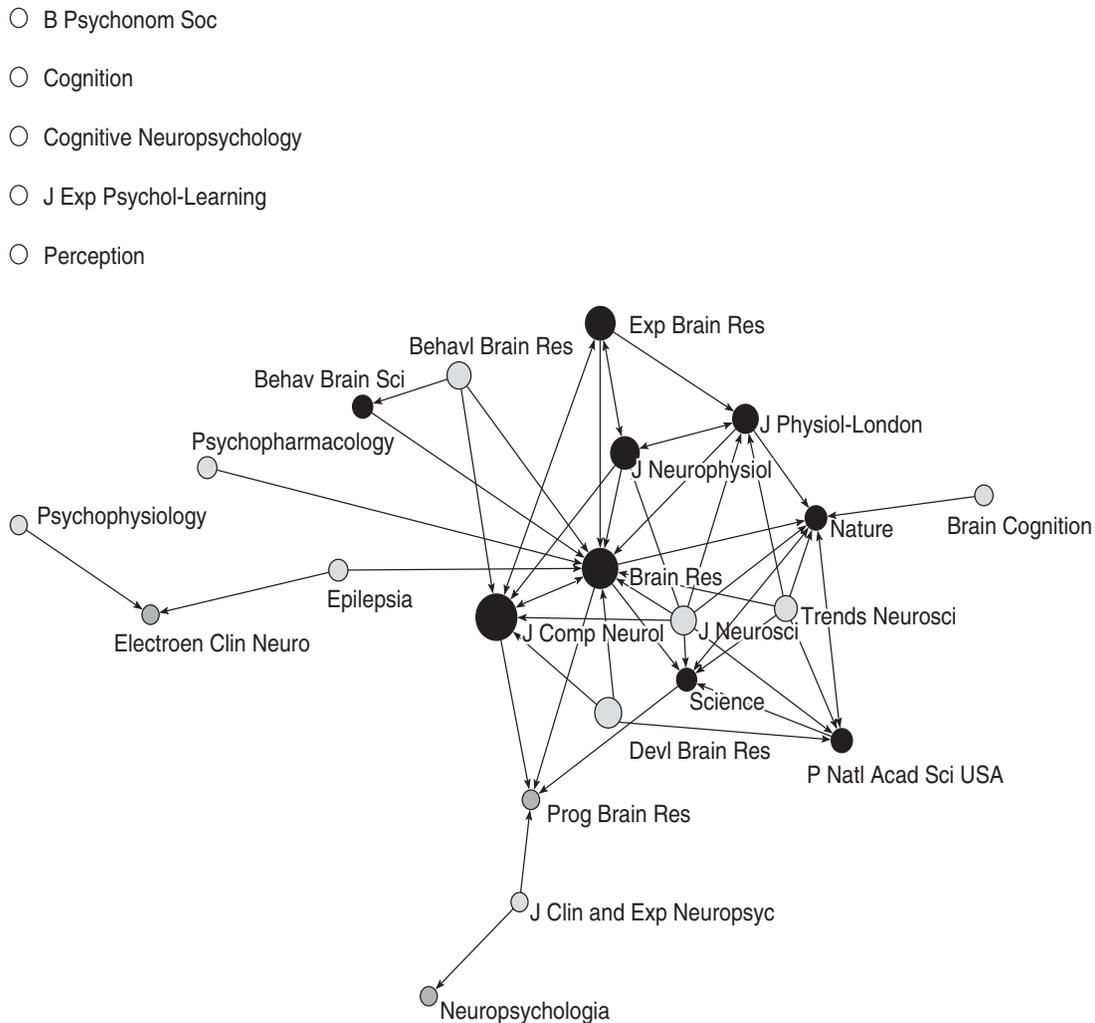

FIGURE 85.1 The 1988 journal citation map. Hub-authority journals are black nodes, authority journals are dark gray nodes, and hub journals are light gray nodes. Nodes are proportional to hub scores, authority scores, and hub + authority score for the black nodes.

(a path that follows the direction of the arrows) from any node in the subset to any other node in the subset. A strong component in the journal citation map is then the largest subset of journals for which there is a directed citation flow from each journal in the component to any other journal in the component. One can thus identify the strong components

as cohesive sets of journals that mutually seek ideas, methods, and results from one another. The strong components in the journal citation maps represent cohesive subdisciplines of cognitive neuroscience. Figure 85.2 shows the strong components of the journal citation maps for 1998 (figure 85.2A), 1995 (figure 85.2B), and 2007 (figure 85.2C).

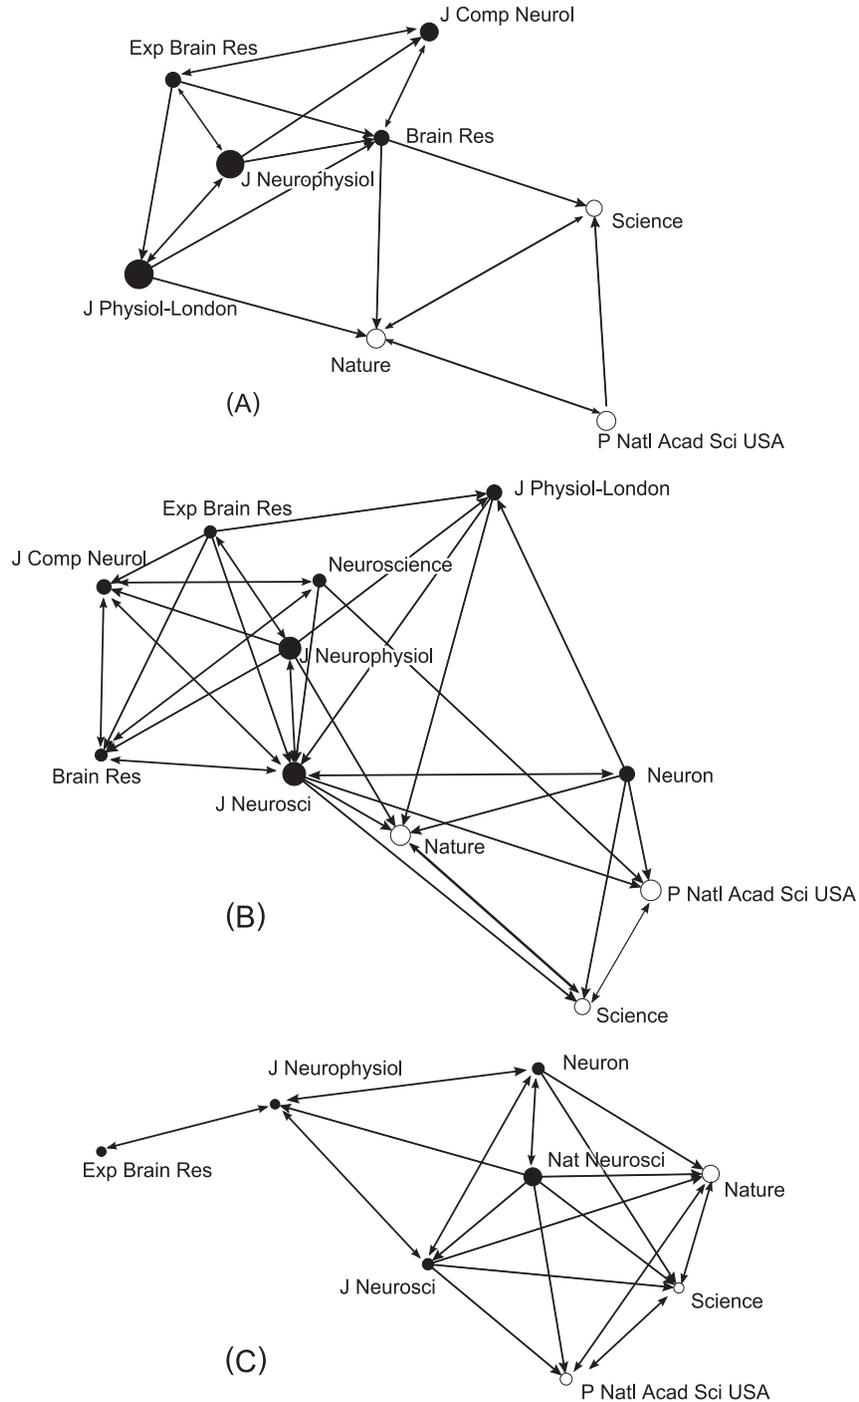

FIGURE 85.2 The neuroscience (black nodes) and general science (white nodes) strong components of the (A) 1988, (B) 1995, and (C) 2007 journal citation maps. Citations flow from neuroscience to general science strong component.

Each of the three maps contains the same two strong components. The larger component in each map, the neuroscience component (the black nodes in figure 85.2), contains journals that are categorized in table 85.2 as neuroscience journals. The number of journals in the neuroscience component varies from five (1988, 2007) to eight (1995). The *Journal of Neurophysiology* and *Experimental Brain Research* appear in the neuroscience strong component for all three data sets. The second, and smaller component, is a general science component (the white nodes in figure 85.2) which remains constant in the three maps and contains the prestigious, multidisciplinary journals *Nature*, *Proceedings of the National Academy of the U.S.A. (PNAS)*, and *Science*. The percentage of articles in the article sets published by journals in the neuroscience component is 12% in 1988, 18% in 1995, and 21% in 2007. The percentage of articles published in the prestigious general science journals is between 8% and 9% each year. These two strong components, containing at most 5% of the journals for each data set, publish around 30% of the articles written by volume contributors in each of the years. No psychology or clinical journals appear in any of the strong components.

We can interpret the neuroscience component as representing a highly cohesive, mutually influential set of journals that captures one subdiscipline of cognitive neuroscience over the last 20 years. The existence of the general science component indicates that contributors to cognitive neuroscience are publishing articles in this highly selective group of journals and that the contributors to CN 1995 and 2007, by publishing in these journals, are part of the scientific mainstream.

Note also that the citation flow between the two strong components is the same for the three data sets. Journals in the neuroscience component cite journals in the general science component, and the converse never occurs. Articles in the general science component serve as sources for ideas, results, and methods in neuroscience. This is no surprise. The elite journals in the general science component are highly selective and publish across all areas of science. One would expect that neuroscience articles that meet publication criteria for the elite journals would be cited by core neuroscience journals, such as the *Journal of Neurophysiology* and the *Journal of Neuroscience*. Conversely, one would not expect disciplinary journals, such as the neuroscience journals, to be cited with high relative frequency in general science journals, which publish articles across the scientific spectrum.

Let us now turn to interpreting entire journal citation maps, as shown in figures 85.1, 85.3, and 85.4. First, one can discern the strong components, discussed above, at the center of each of the three maps. In the maps, there are also journals (five in 1998, four in 1995, and two in 2007) that are not connected to any other journals above the 0.03 threshold. In the 1988 map, all five isolated journals are

psychology journals; in 1995, there is a two-journal component containing two of the major psychology journals. In 2007, there is a three-journal component that consists of two neuroscience journals and a clinical journal.

The large single components contain primarily neuroscience and general science journals. In 1988, three psychology journals appear on the periphery of the large component: *Behavioural and Brain Science*, *Journal of Clinical and Experimental Neuropsychology*, and *Psychophysiology*. In 1995, none of the five psychology journals listed in table 85.2 appear in the large component. In 2007, the three psychology journals—*Brain and Language*, *Perception*, and *Psychophysiology Brain and Language*—appear on the edge of the dominant neuroscience–general science component.

How might one identify “important” journals in these maps? Graph theorists and social network analysts have developed numerous methods for determining centrality, or prestige, of nodes in a network (Wasserman & Faust, 1994). Here, following a suggestion by Börner, Chen, and Boyack (2003), I will identify important journals in the maps by determining each journal’s hub and authority scores. (Kleinberg, 1999) In analyses of links between pages on the World Wide Web, Kleinberg observed that some pages were pointed to by many hyperlinks and that these pages tended to contain primary or authoritative information on a topic. He called such pages *authorities*. There were other pages that sometimes contained little primary content but pointed to numerous pages that did. He called such pages *hubs*. Kleinberg developed a method to compute authority and hub scores for nodes in a directed graph. This method formalizes the intuition that a good authority is pointed to by other good hubs and a good hub points to many good authorities.

In the context of a journal citation map, journals with high authority scores are journals that are highly cited by other highly citing journals. Journals with high authority scores, then, would tend to serve as sources for ideas, methods, and results for the journals that cite them. A journal with a high hub score cites many other authorities and can be viewed as serving a synthesizing function by bringing together ideas, methods, and results from numerous authority journals.

Pajek includes a function that computes authority and hub scores for directed graphs, such as the journal citation maps. It also partitions the maps into four disjointed sets of nodes. It is these partitions that are shown in the maps in figures 85.1, 85.3, and 85.4. Some journals are neither authorities nor hubs (white nodes in the maps); some are both authorities and hubs (black nodes); some are authorities only (dark gray); and some are hubs only (light gray). Nodes representing the journals are scaled according to their authority and/or hub scores, the white nodes representing a zero score on both measures. The *Pajek* routine requires that one specify

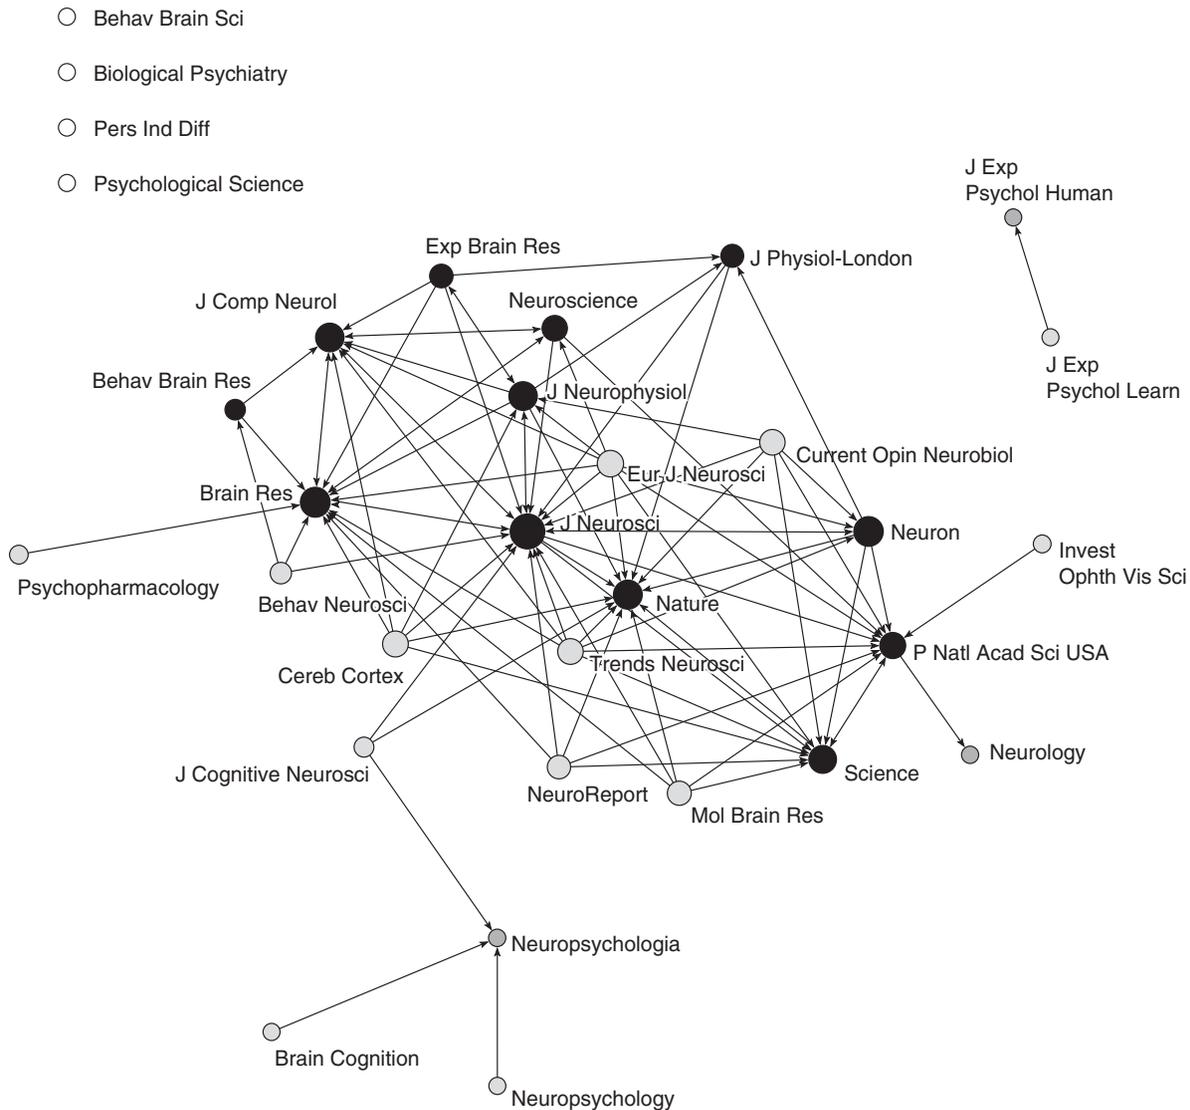

FIGURE 85.3 The 1995 journal citation map. Hub-authority journals are black nodes, authority journals are dark gray nodes, and hub journals are light gray nodes. Nodes are proportional to hub scores for light gray nodes, authority scores for dark gray nodes, and hub + authority score for the black nodes.

the number of authorities and hubs to be identified. I assumed that every cited journal is a potential authority and that every citing journal is a potential hub. Thus for 1988, the routine was requested to find 12 authorities and 18 hubs; for 1995, 15 authorities and 24 hubs; and for 2007, 14 authorities and 21 hubs.

The authority-hub journals with hub-plus-authority scores greater than 0.2 are shown in table 85.3. All the journals in table 85.3 are either neuroscience journals or general journals; that is, all journals that are in the two strong components are also both authorities and hubs. There are hub-authority journals that are not in one of the strong components, but their hub-plus-authority scores are quite low: *Behavioural and Brain Science* (score 0.10, a psychology journal) in the 1988 map, *Behavioral and Brain Research* (score,

0.11) in 1995, and *Brain Research* (score, 0.10) and *Neuropsychologia* (0.01) in 2007.

There are relatively few pure authority journals in the maps. The three pure authority journals in the 1988 map and the two in the 1995 are all neuroscience or clinical journals. In 2007, there are three pure authority journals: *Perception* and *Psychophysiology* are psychology journals, and *NeuroImage* is a neuroscience journal devoted to brain imaging studies and methods, which, as we will see in the topic maps, has become the mainstay of cognitive neuroscientific research. All these journals, with one exception, might be called degenerate pure authorities. They have authority scores less than 0.01; some have scores that are barely over zero. The exception is *NeuroImage* in the 2007 map, which has an authority score of 0.05.

- Sleep
- Schizophrenia Bull

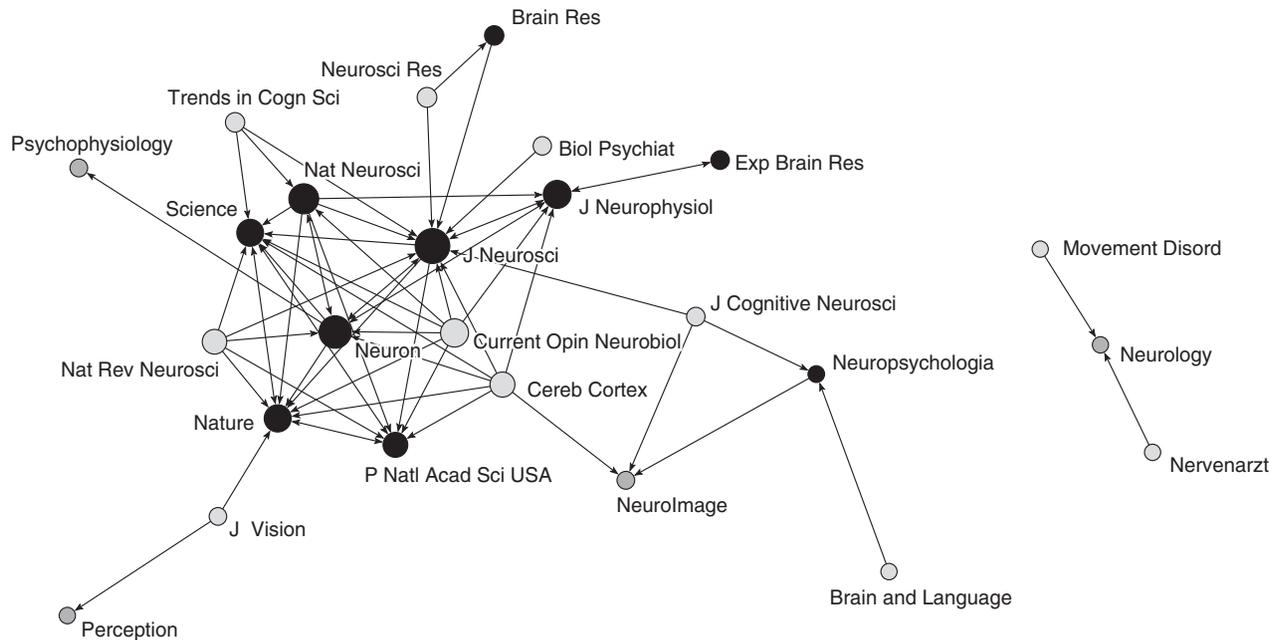

FIGURE 85.4 The 2007 journal citation map. Hub-authority journals are black nodes, authority journals are dark gray nodes, and hub journals are light gray nodes. Nodes are proportional to hub scores, authority scores, and hub + authority score for the nodes.

TABLE 85.3
Hub-authority journals with scores equaling the sum of their hub score and authority score

1988	1995	2007
<i>Journal of Comparative Neurology</i> 1.19	<i>Journal of Neuroscience</i> 0.80	<i>Journal of Neuroscience</i> 0.89
<i>Brain Research</i> 0.82	<i>Brain Research</i> 0.52	<i>Neuron</i> 0.74
<i>Experimental Brain Research</i> 0.50	<i>Neuron</i> 0.50	<i>Nature Neuroscience</i> 0.60
<i>Journal of Neurophysiology</i> 0.45	<i>Nature</i> 0.47	<i>Journal of Neurophysiology</i> 0.48
<i>Journal of Physiology—London</i> 0.31	<i>Journal of Neurophysiology</i> 0.46	<i>Nature</i> 0.44
	<i>Journal of Comparative Neurology</i> 0.45	<i>Science</i> 0.43
	<i>Science</i> 0.42	<i>PNAS</i> 0.33
	<i>PNAS</i> 0.34	
	<i>Neuroscience</i> 0.31	
	<i>Experimental Brain Research</i> 0.23	
	<i>Journal of Physiology—London</i> 0.20	

The most common role for a journal in these citation maps is that of a pure hub. There are 9 pure hubs in the 1988 map, 13 in the 1995 map, and 11 in the 2007 map. Table 85.4 shows the pure hub journals with hub scores greater than 0.2. All are neuroscience journals and acquire their high hub score by dint of citing authoritative journals in both the neuroscience and general science strong components.

What is the relationship between psychology and neuroscience that is indicated by the publication patterns of the 1995 and 2008 CN contributors? If one looks at the number of psychology journals that publish more than five articles in our article sets, their number declines from eight psychology journals in 1988 to five psychology journals in 1995 to three psychology journals in 2007. The percentage of articles in each data set published in psychology

TABLE 85.4
Pure hub journals with hub scores greater than 0.2

1988		1995		2007	
<i>Developmental Brain Research</i>	0.37	<i>European Journal of Neuroscience</i>	0.39	<i>Current Opinion in Neurobiology</i>	0.50
<i>Journal of Neuroscience</i>	0.31	<i>Cerebral Cortex</i>	0.30	<i>Cerebral Cortex</i>	0.34
<i>Behavioural Brain Research</i>	0.25	<i>Molecular Brain Research</i>	0.28	<i>Nature Reviews Neuroscience</i>	0.32
<i>Trends in Neurosciences</i>	0.20	<i>NeuroReport</i>	0.28		
		<i>Psychopharmacology</i>	0.28		
		<i>Trends in Neurosciences</i>	0.28		
		<i>Current Opinion in Neurobiology</i>	0.27		

journals likewise decreases from 25.0% in 1988 to 10.3% in 1995 to 7.3% in 2007. On the basis of the overall exclusion of psychology journals from the main components of the journal citation maps and using authority and hub scores as measures of journal importance, one can conclude that the cognitive neuroscience literature, at least as published by contributors to the 1988 and 2008 CN volumes, is dominated by neuroscience and general science journals. There is no significant citation flow from neuroscience to psychology or conversely, at a relative frequency threshold of 0.03. If one goes below this threshold and includes all instances of a psychology journal citing a nonpsychology journal or conversely, for the 1995 and 2007 journal sets, in which complete data were available, there are 57 instances of a psychology journal citing a nonpsychology journal versus 20 instances of a nonpsychology journal citing a psychology journal. So for these authors and years, whatever citation flow there is appears to occur at a very low level and tends to be from psychology to neuroscience; that is, there is a greater tendency for psychology journals to look to neuroscience journals for ideas, results, and methods than conversely.

I mentioned in the introduction that in the late 1980s, computational neuroscience was also considered to be a contributing discipline to the development of cognitive neuroscience. In the 1558 articles in the three combined data sets, only four articles were published in dedicated computational neuroscience journals: two in *Computational Neuroscience* and two in *Neural Networks*. If computational neuroscience was a primary contributor to cognitive neuroscience, one can only assume that it is underrepresented among the authors and articles considered here. On the basis of these publication patterns, one can conclude cognitive neuroscience appears to be a variety of neuroscience and therefore that the field is appropriately named.

The journal citation maps also reveal something about the emergence of cognitive neuroscience as a field, apart from its relationship to progenitor disciplines. An important step in the development of any new field is a journal dedicated to work in the field. The *Journal of Cognitive Neuroscience* began

publication in 1989 and appears in both the 1995 and 2007 journal citation maps. It published 2.5% of the entire 1995 article set (the eighth-ranked journal in number of articles published) and 2.5% of the 2007 article set (the tenth-ranked journal). In both maps, the *Journal of Cognitive Neuroscience* is a pure hub with moderate hub scores: 0.13 in 1995 and 0.07 in 2007. In this capacity, it appears to serve an interesting integrative function. In 1995, it appears to synthesize work from the *Journal of Neuroscience*, *Nature*, and *Neuropsychologia*. *Neuropsychologia*, according to its website, “publishes papers that explicitly address functional aspects of the brain.” (www.elsevier.com) and describes itself as a journal in the behavioral and cognitive neurosciences. Functional aspects of the human brain as studied in neuropsychology rely heavily on cognitive psychological models of human behavior. As one can see in the 1995 map, *Neuropsychologia* also cites *Neuropsychologia*. Thus in 1995, we can view the *Journal of Cognitive Neuroscience* as a journal integrating work in neuroscience, as found in the strong components of the citation maps, with neuropsychology and, through this connection to neuropsychology, to some extent with work in cognitive psychology.

In 2007, the *Journal of Cognitive Neuroscience* plays a similar integrating role. It once again synthesizes work from neuroscience and neuropsychology, as shown by its links to the *Journal of Neuroscience* and *Neuropsychologia*. However, it now also integrates ideas, methods, and results published in *NeuroImage*. *NeuroImage* began publication in 1993 and did not appear in the 1995 map. In 2007, however, it published 5.22% of the articles in that year’s data set, second only to the *Journal of Neuroscience* (8.63% of the articles). Given that *Neuropsychologia* is the fifth-ranked journal in 2007, the *Journal of Cognitive Neuroscience* is a hub that cites and integrates work published in three of the most productive journals in the 2007 set.

Note also that *NeuroImage* is an authority journal with an authority score of 0.05. This journal is described as a journal that publishes imaging and modeling studies of structure-function relations in the brain (www.elsevier.com). The emerging prominence of this journal is indicative of the

central role that brain imaging technologies play in contemporary cognitive neuroscience. We will see more evidence of the centrality of imaging and recording studies in the next section on topic maps in cognitive neuroscience.

Topic maps

The stop-listed title words from articles contained in the three article sets can be used to generate topic maps of cognitive neuroscience for 1988, 1995, and 2007. (Freeware for compiling word co-occurrence matrices is referenced in Leytesdorff, 2004.) For each year, the analysis is limited to topic words that occur 11 or more times in the article titles for that year. There were 38 such words for the 1988 articles, 66 words for the 1995 articles, and 59 words for the 2007 articles. Co-occurrence matrices are symmetric, so the graphs, and therefore the maps, are undirected. In the matrix, each row is a vector of values giving the number of times the row title word occurs with the column title word. To normalize the data and to compute distances between topic words in the map, the cosine measure is used. This is the normalized inner product of the two vectors, which yields the cosine of the angle between the two vectors. The

cosine measure varies from 0 (no similarity between the two topic-word vectors) to 1 (identity between the two topic word vectors). The maps below are drawn using a threshold of cosine of 0.2 or greater. Topic words are placed within the map using the Kamada-Kawai algorithm as explained above. In these maps, each node is scaled to the logarithm of the number of occurrences of the title word in the article set for that year. The smallest nodes in each map represent 11 occurrences. The largest node occurs in the 2007 map, for *cortex*, which occurs 76 times in article titles that year.

At a threshold of cosine ≥ 0.2 , there are isolated nodes in the maps, words that despite their relatively high occurrence do not have vectors, or co-occurrence profiles, sufficiently similar to any other topic words to be linked to it in the map. In the 1988 map, there are 14 such isolated words; in the 1995 map, there are 21 such words; and in the 2007 map, there are 13 such words. These nodes have been removed from the maps.¹

The three maps are shown in figure 85.5, 85.6, and 85.7. Before one looks for cohesive subsets of words, it is instructive to look at the overall structure of the maps. In each year, the most frequent topic words are *visual* and *cortex*, indicating the prominence of research on the visual system in neuroscience

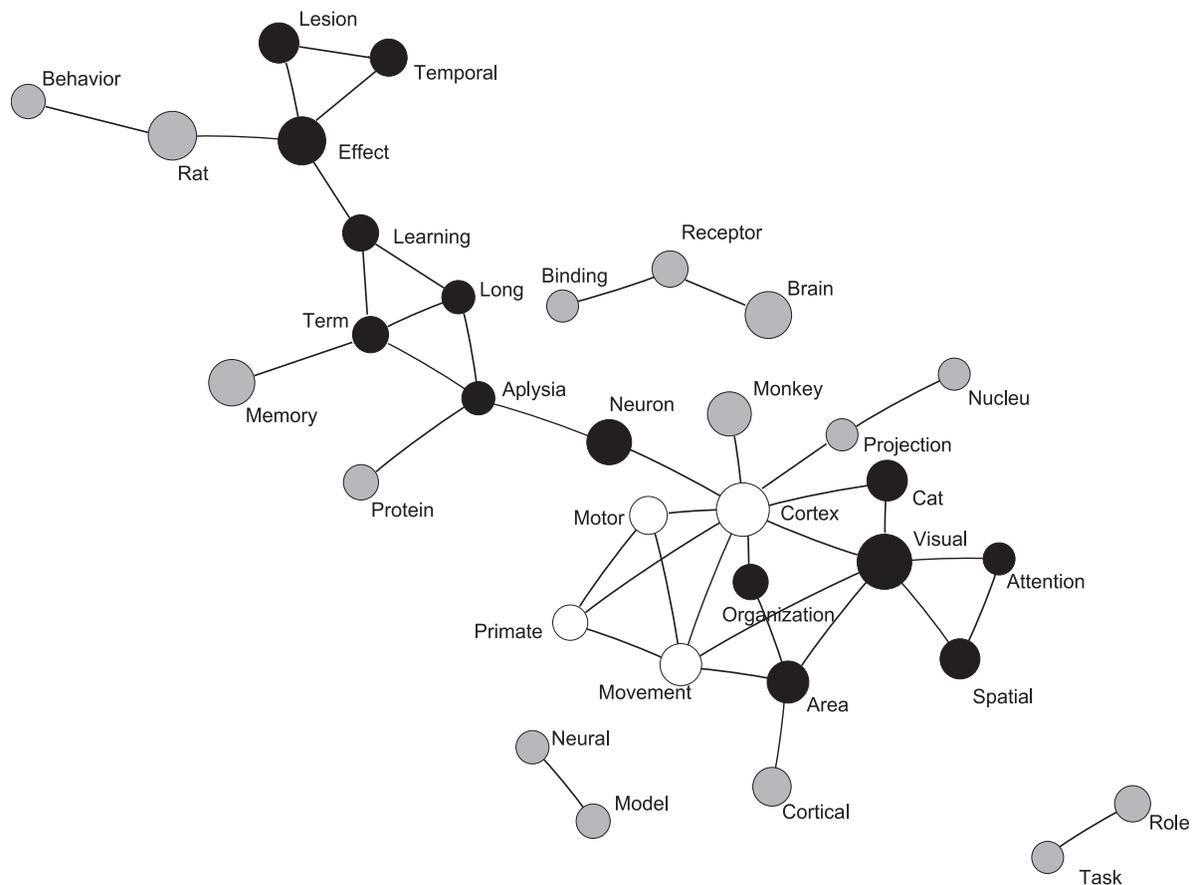

FIGURE 85.5 The 1988 cognitive neuroscience topic map. Black nodes are in the 2-core, and gray nodes are in the 1-core. Node size is proportional to the log of word occurrences.

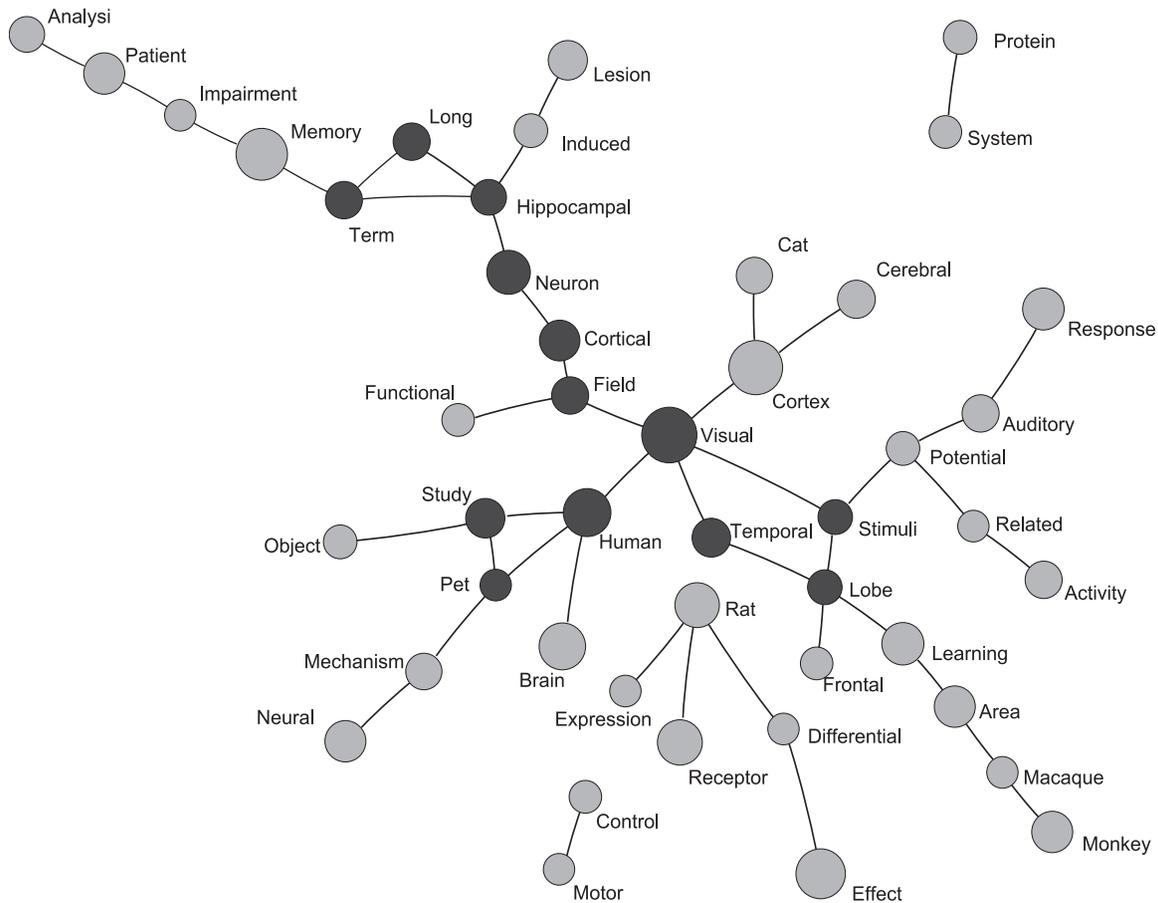

FIGURE 85.6 The 1995 cognitive neuroscience topic map. Black nodes are in the 2-core, and gray nodes are in the 1-core. Node size is proportional to the log of word occurrences.

and cognitive neuroscience. One can also see that the maps make intuitive sense, in that topic words in the same proximity correspond with research topics in cognitive neuroscience; for example, *visual-spatial-attention* in 1988, *hippocampal-long-term-memory* in 1995, and *transcranial-magnetic-stimulation* in 2007. The maps indicate the emergence of new methods, as with TMS, and new research areas, as shown in the *memory-emotion-amygdala* branch of the 2007 map.

One interesting change in the maps is in the topic words that refer to methods and experimental organisms. In the 1988 map, the only two words that refer to methods are *lesion* and *model*. In 1996, *lesion* is accompanied by *PET-study* and *response-potential*, the last two topic words referring to evoked response potential studies. By 2007, seven topic words, six of which refer to brain imaging and recording technologies, dominate the map. As for experimental organisms, in the 1988 map, five topic words referring to experimental organisms appear (*aphysia*, *cat*, *monkey*, *primate*, *rat*), none of which refer to humans. In 1995, four topic words designate non-human organisms (*rat*, *cat*, *macaque*, *monkey*), but *human* and *patient* appear. In the 2007 map, only *human* and *patient* occur as referring to experimental organisms or, more accu-

rately, to study participants. Over the 20-year period, method words in the maps increase, but the variety of experimental organisms dwindles to one: humans.

For each of the three years, the map contains one large connected component and several smaller disconnected components. In 1988, there are three disconnected components. The *model-neural* component might be interpreted as representing neural networks or connectionist models. *Binding-receptor-brain* might represent neurochemistry. *Task-role* is too vague to interpret. There are also three disconnected subnetworks in the 1995 map. The largest of these, *rat-expression-receptor-differential-effect*, might again represent neurochemistry or genetics. There are six disconnected subnetworks in the 2007 map that seem to refer to perception, neural correlates, cognitive control, motor control, object representations, and modeling.

Now let us look at the structure of the large connected components in each map. Cohesive subsets of topic words in these maps should delineate cohesive research topics that are prominent in cognitive neuroscience. One way to identify cohesive subsets of nodes in an undirected graph is to identify its k -cores. One can think of k -cores in the

other topic words, *imaging* and *related* with five. The 2-core is again separated into two noncontiguous parts, one representing the topic of transcranial magnetic stimulation (TMS) and one containing only the topic word *schizophrenia*, which in turn connects to 1-core words referring to memory, emotion, and other words descriptive of research on learning and affect. The two most common and highly connected topic words in previous maps, *visual* and *cortex*, are now part of the 1-core, with connections to only two and four other topic words, respectively. If we imagine the 3-core removed from the map, we are left with four independent branches of the map. One of the four branches is again a methods branch relating to TMS. The three remaining branches are research subject branches that contain words connoting affective processing, studies on sleep, visual attention and studies on prefrontal cortex.

Over the 20-year period, the topic maps change from being dominated by research areas with little mention of method to being dominated by topic words that refer to methods of brain imaging and recording. Overall, the number of method words appearing in the maps increases, and the number of experimental organisms decreases to include only human studies. Research topic words, such as *visual* and *cortex*, move from the peak of the maps to the base and decrease in their connectivity with other topic words. Brain imaging and recording come to occupy the highest ground in the maps and increase in their connectivity. This change in the topic maps is consistent with a change that we noted in the journal citation maps: *Neuroimage* emerged in the 2007 map as the second-ranked journal in number of publications and as a pure authority for three other journals in the map. Cognitive neuroscience appears to have changed from a collection of diverse research subjects to a field dominated, if not defined, by imaging technologies.

The change in the experimental organism from a variety of nonhuman animals to solely human also reflects a significant change in cognitive neuroscience research. The intent of most cognitive neuroscientists from the outset has been to understand human cognition, relying on animal models where needed and when they are the appropriate or only alternative. As Gazzaniga and Miller described the new field, its intent was to describe the biological foundations of human cognition. At the outset, in the early to mid-1980s, the methods for studying human cognition (with the exception of electroencephalography) were confined to behavioral studies using unimpaired (cognitive psychology) or impaired (neuropsychology) participant groups. Animal models provided the means for conducting invasive studies. Brain imaging technologies, particularly the development of PET and later fMRI and TMS, coupled with paradigms from cognitive psychology, allowed cognitive neuroscientists to map cognitive functions onto neural structures in normal human participants. It became possible to study, at one level

at least, the biological foundations of human cognition in humans. From this perspective, the journal citation and topic maps reflect the development of the field over two decades into the discipline that Gazzaniga and Miller envisioned over martinis.

Conclusion

The CN volumes that I used in this study seem to reflect nicely the emergence of cognitive neuroscience over the past two decades. Although the samples used here are small, there is much more of scientific and historical interest that could be gleaned just from the contributions to these—now four—volumes. It would be presumptuous to state any strong conclusions based on the data and methods used here. So rather than offering conclusions, I will formulate two conjectures, which the data imply that others might test and debate. First, a positive conjecture: Noninvasive imaging and recording technologies have allowed cognitive neuroscience to develop into a science of the biological foundations of human cognition.

Second, a cautionary conjecture: Cognitive neuroscience not only has become coextensive with imaging studies, but also has become a variety of neuroscience, with psychology very much in the background. Might the full exploitation of advances in imaging technology require the constant infusion of better understandings of behavior, tasks, and task demands, along with better cognitive models?

In 1988, Michael Posner, Steve Petersen, Peter Fox, and Marcus Raichle (1988) articulated what I call the working hypothesis of cognitive neuroscience: “The human brain localizes mental operations of the kind posited by cognitive theories.” (p. 1627) Imaging technology made this a viable and highly successful working hypothesis. This is consonant with my positive conjecture. In 1994, Posner and Raichle also stated, “The challenge for the future is to understand at a deeper level the actual mental operations assigned to the various areas of [brain] activation. Before this goal can be achieved, the experimental strategies used in PET studies must be refined so that more detailed components of the process can be isolated” (1994, p. 98). This statement would seem to suggest the importance of the continuous infusion of cognitive psychological ideas and results into cognitive neuroscience. This is consonant with my cautionary conjecture.

NOTE

1. The isolated topic words that were deleted from the maps and their number of occurrences are as follows: for 1988, amnesia (11), cell (17), cortical (18), development (19), evidence (12), human (23), pattern (17), patient (15), potential (12), processing (16), response (14), studies (14), study (13), and system (20); for 1995, attention (15), cell (22), cognitive (12), development (12), evidence (21), information (13), model (12), motion (13),

multiple (11), primate (12), priming (11), processing (15), regulation (11), representation (20), role (17), selective (13), spatial (26), specific (11), and task (17); for 2007, action (18), adult (11), behavioral (11), brain (40), effect (29), motion (16), movement (11), network (12), neuron (15), role (29), sensory (11), signal (11), and temporal (26).

86 Reflections on the Cognitive Neuroscience of Language

SHEILA E. BLUMSTEIN

ABSTRACT This chapter provides some brief reflections on how the past 20 years of study of the cognitive neuroscience of language have changed the way in which we think about the nature of human language and the functional role of the two hemispheres in processing language. Two theoretical claims about the modularity of language are considered: (1) that language is modular in a narrow sense, that is, its various parts or components are functionally and neurally autonomous, and (2) that language is modular in a broad sense, that is, it is functionally and neurally separate from other cognitive functions. It is argued that the evidence to date challenges both claims of a theory of modularity. The functional properties of language, that is, speech, lexical processing, and syntactic processing, appear not to be focally represented in one area of the brain; rather, each recruits a broadly distributed neural network or processing stream. Moreover, certain areas of the brain that have been associated with language processing appear to be recruited across other cognitive domains, suggesting that while language may be functionally special, it draws on at least some neural mechanisms and computational properties shared across other cognitive domains. Finally, although it is generally assumed that the left hemisphere is dominant for language, functional neuroimaging studies often show activation in right hemisphere areas that are homologous to areas in the left hemisphere. These findings raise new questions about the potential role of the right hemisphere in language processing.

When we use language, it appears to be a unified whole in which all aspects—sounds, words, meaning, sentences, conversations—are integrated as a single piece. However, as we have known from the early historical record and the seminal work of Paul Broca and Carl Wernicke, language representation in the brain comprises a vast network in which damage to different areas of the brain have different linguistic consequences. Until about 20 years ago, the aphasias (speech and language impairments in adults as a consequence of organic brain pathology) served as the primary method of study and provided the foundation of our knowledge about brain-language relationships. Since then, a broader palette of methodologies has become available to study the cognitive neuroscience of language, such as positron emission tomography (PET), functional magnetic resonance imaging (fMRI), magnetoencephalography (MEG), transcranial magnetic

stimulation (TMS), and event-related potentials (ERP). These methods in conjunction with the lesion method have enriched and revolutionized the study of the neural basis of language and have provided both new insights and new challenges.

The goal of this chapter is to provide some brief reflections on how the past 20 years of study of the cognitive neuroscience of language have changed the way we think about the nature of human language itself and the functional role of the two hemispheres in processing language. In particular, we will focus on two theoretical claims about the modularity of language: that language is modular in a narrow sense, that is, its various parts or components are functionally and neurally autonomous, and that language is modular in a broad sense, that is, it is functionally and neurally separate from other cognitive functions. We will then briefly consider recent evidence that raises questions about the role of the right hemisphere in language processing.

The modularity of language: Components of the grammar

Owing to the rich history of study in linguistics and psycholinguistics, there is a general consensus about the general properties of language and the nature of language structure. The “pieces” that make up language have been operationally defined in terms of separate components including the sound structure of language (phonetics and phonology), lexical structure, morphological structure, and syntactic structure. Each of these components has separate functions and operates over different knowledge types (e.g., sounds, meanings). As a consequence, current models of language processing for speaking and understanding assume that language is a functionally modular system, that is, that each component is a separate module with a particular function (Pinker, 1994; Levelt, 1989).

Whether this means that for any given component of the grammar, there is a neural area dedicated to its processing is less clear. Past research from the aphasias has largely taken a modular approach, focusing on each component of the grammar separately and attempting to characterize deficits of patients in terms of impairments to a particular component of the grammar (Caplan, 1992, 1994; Grodzinsky,

SHEILA BLUMSTEIN Department of Cognitive and Linguistic Sciences, Brown University, Providence, Rhode Island

Shapiro, & Swinney, 2000; Shelton & Caramazza, 1999). However, even the lesion data suggest that this story is not correct. For example, Broca's aphasics with damage including the inferior frontal gyrus (IFG) display deficits that cut across components of the grammar (cf. Grodzinsky & Amunts, 2006): They have phonetic and phonological impairments that affect particularly speech production but also speech perception (Blumstein, 2000); they have deficits in syntactic or sentence processing (Martin, Vuong, & Crowther, 2007; Grodzinsky, 1990), and they show impairments in lexical and semantic processing (Cappa & Perani, 2006; Milberg, Blumstein, Giovanello, & Misiurski, 2003). Wernicke's aphasics with damage including posterior portions of the superior temporal gyrus (STG) have auditory comprehension deficits that affect sound structure, lexical structure, and also syntactic structure (Blumstein, 2000; Yee, Blumstein, & Sedivy, 2008; Bates, Friederici, & Wulfeck, 1987; Dronkers, Wilkins, Van Valin, Redfern, & Jaeger, 2004; Piñango & Zurif, 2001). Additionally, these patients display impairments in spoken language production that cut across these components of the grammar (Blumstein, 2000; Yee et al., 2008; Baum, Blumstein, Naeser, & Palumbo, 1990; Goodglass, 1993; Faroqi-Shah & Thompson, 2003).

Because the lesions of aphasic patients tend to be very large, it is possible that multiple neural "modules" are indeed affected and contribute to the broad spectrum of language impairments of the patients. It is also possible that even within a particular neural area, there are functional subdivisions. Evidence from the neuroimaging literature can speak to these issues, allowing for a closer examination of the neural areas that are activated during various language tasks than that typically possible from lesion studies. There are some neuroimaging data that suggest functional subdivisions of the IFG across linguistic domains with Brodmann's area (BA) 45 involved in semantic processing and BA44 involved in phonological processing (Buckner, Raichle, & Petersen, 1995; Burton, 2001, 2009; Fiez, 1997; Poldrack et al., 1999), indicating that there might indeed be multiple "neural" modules relating to different functional properties of language. Nonetheless, there is currently much debate in the literature about whether different parts of the IFG reflect functional subdivisions of language or cut across these functional subdivisions and reflect different processes involved in cognitive control (Badre & Wagner, 2007; see also the section below entitled "The Modularity of Language: Language and Other Cognitive Functions"). Future studies will need to be done to determine how and in what ways different areas of the IFG contribute to language processing.

Whatever the role these different parts of the IFG may take, there is no question that many of the same areas (STG, middle temporal gyrus, supramarginal gyrus, and IFG) are involved in putatively different language functions. That is, these areas appear to be recruited in speech process-

ing (Scott & Wise, 2004), lexical processing (Paulesu, Frith, & Frackowiak, 1993; Prabhakaran, Blumstein, Myers, & Hutchison, 2006), and syntactic processing (Just, Carpenter, Keller, Eddy, & Thulborn, 1996; Kaan & Swaab, 2002). Thus the evidence to date does not support a strict modular view of language in which there is a "fixed neural architecture" (Fodor, 1983, p. 98) for each component of the grammar.

If this is the case, the challenge then is to determine the functional role of these different areas. Of course, it is possible that each component of the grammar has a dedicated neural architecture, but current neuroimaging methods cannot provide a sufficiently fine-grained picture of the neural structures associated with particular language functions. After all, activation of any particular voxel reflects responses of a large population of neurons that might themselves have distinctive and functionally distinct response properties. However, another possibility is that different neural areas have different computational properties, and the functional subdivisions do not cut across different information sources corresponding to the components of the grammar but rather reflect the nature of the computations that are done across these different information sources (cf. Hasson, Yang, Vallines, Heeger, & Rubin, 2008; Poeppel, 2001; for further discussion, see the section below entitled "The Modularity of Language: Language and Other Cognitive Functions").

It is also clear from the neuroimaging literature that the functional properties of language, that is, speech, lexical, and syntactic processing, are not focally represented in one area of the brain; rather, each recruits a broadly distributed neural network or processing stream. An example from speech processing provides a window into the complexity of the neural systems underlying the processing of this one aspect or component of language.

The functional architecture of the speech perception system suggests a series of transformations of the acoustic input into a phonological representation. The neural instantiation of this system also appears to involve a hierarchical organization of the phonetic-processing stream in which information is transformed, conveyed, and ultimately acted upon with early auditory processing of the speech signal occurring in temporal areas and later stages of processing involving temporoparietal and frontotemporal systems. In particular, this phonetic processing stream includes temporal areas, including the STG, superior temporal sulcus (STS), and middle temporal gyrus (MTG); parietal areas, including the angular gyrus (AG) and supramarginal gyrus (SMG); and frontal areas, including the IFG (for detailed discussion, see Scott & Wise, 2004; Hickok & Poeppel, 2000, 2004). Nonetheless, the particular areas recruited vary as a function of the cognitive or task demands required (Poeppel, 1996). Mapping the acoustic-phonetic input to phonetic categories

recruits a different system from mapping this input to meaning or mapping that input to lexical form, and it recruits a different neural system for mapping acoustic-phonetic input to articulatory output. For example, one phonetic processing stream, the “what” stream, appears to be specialized for the recognition of auditory “objects” and recruits Heschl’s gyri and the superior temporal lobes at early stages of processing, the left middle and anterior STG and STS of the left dominant hemisphere for the perception of speech sounds, and the left IFG for phonetic decisions (Scott & Wise, 2004; Hickok & Poeppel, 2004; Burton, Small, & Blumstein, 2000). The perception of phonetic category structure recruits the posterior STG, the SMG, and the IFG (Blumstein, Myers, & Rissman, 2005; Myers, 2007). The mapping of sound structure onto words involves a processing stream that involves temporal lobe structures, including the STG and the posterior portions of the STS and the MTG, as well as parietal lobe structures, including the AG and SMG (Paulesu et al., 1993; Prabhakaran et al., 2006). The mapping of auditory representations to articulatory representations recruits a processing stream that involves the STG, an auditory-motor interface area (the inferior parietal lobe including the posterior STG and the planum temporale) (Buchsbaum, Hickok, & Humphries, 2001; Hickok, Buchsbaum, Humphries, & Muftuler, 2003), and premotor cortex including the IFG and the SMA (Hickok & Poeppel, 2004).

These results suggest that the phonetic/phonological component of language and speech processing is not a modular system, involving solely dedicated neural machinery, but rather is a distributed neural system that requires the integration of multiple functional systems. Although phonetic processing itself might be functionally modular, it appears not to be neurally modular.

The modularity of language: language and other cognitive functions

There is ample evidence to show that there is neural specialization for different cognitive processes and that for most right-handers, language appears to be localized in the left hemisphere. Within the left hemisphere, language areas are located in areas surrounding the sylvian fissure, including Broca’s area (the pars opercularis (BA44) and triangularis (BA45), Wernicke’s area (the posterior superior and middle temporal gyrus), the angular gyrus (BA39), and the supra-marginal gyrus (BA40). Lesions in any of these areas will cause an aphasia, and the locus of the lesion will result in a particular profile of language abilities and disabilities called a *symptom complex* (Goodglass, 1993).

It has also been shown that the neural systems underlying language can be dissociated from other cognitive functions and abilities. For example, patients with damage to different parts of the medial temporal lobe have memory deficits for

recent events (anterograde amnesia) or for recalling the past (retrograde amnesia). Yet they show normal knowledge of language structure. Likewise, Alzheimer’s disease patients who have neural degeneration in areas of the temporal and parietal lobes as well as parts of the frontal cortex and cingulate gyrus display severe cognitive and memory deficits. Their knowledge of language structure (at least at early stages of the disease) appears to be relatively intact. The dissociation between language and these functions goes in both directions. Individuals with aphasia show relatively normal cognitive abilities: They can reason, can solve problems (if they do not require language to do so), and have no demonstrable memory deficits; they remember both the past and the present. Thus it appears that language is a functional and neural module.

Nonetheless, recent neuroimaging research has suggested that certain areas of the brain that have been associated with language processing may be recruited as well in other cognitive domains. In this case, the neural area appears to be recruited to perform a particular type of computation or process that is domain general in the sense that it cuts across a number of cognitive domains. Such examples challenge the view that language is a “module” with neural areas specialized only for the processing of components of language or language more generally and suggest that language processing is built upon a set of computational principles shared by other higher cognitive functions.

There are two examples that suggest shared resources in a domain-general manner. Both involve prefrontal areas, including Broca’s area (BA44 and BA45) and BA47. It has been suggested that the left inferior frontal gyrus (Broca’s area) is recruited in the selection of a representation from among competing representations with the extent of activation modulated by the degree of competition among these representations (Thompson-Schill, 2005; Novick, Trueswell, & Thompson-Schill, 2005; Badre & Wagner, 2007; Miller & Cohen, 2001; Snyder, Feigenson, & Thompson-Schill, 2007; Bilenko, Grindrod, Myers, & Blumstein, 2008).

Competition among competing representations occurs in different levels of language processing. Increased IFG activation has been shown under conditions of competition at the phonological level, for example, selecting a phonetic category such as [t] from acoustically similar phonetic categories such as [d] or [p] (Blumstein et al., 2005; Myers, 2007); at the lexical level, for example, selecting a word such as *can* from the set of words that are similar in their sound shape, such as *pan, con, cab* (Prabhakaran et al., 2006; Righi, Blumstein, Mertus, & Worden, 2009); at the syntactic level, for example, selecting the appropriate interpretation of an ambiguous sentence such as *put the pear on the paper in the crate* (Novick et al., 2005; Trueswell, Tanenhaus, & Garnsey, 1994); and at the semantic level, for example, selecting the appropriate meaning of an ambiguous word such as *bank*

(*river/money*) (Bilenko et al. 2008; Mason & Just, 2007). As Thompson-Schill (2005) discusses, increased activation of the IFG also occurs in other cognitive domains under conditions of increased competition including memory, for example, reducing interference in a working memory task (Thompson-Schill et al., 2002), and in visual tasks requiring the maintenance of fixation on a target when another target is in the display (Guitton, Buchtell, & Douglas, 1985). Thus the functional role of the IFG appears to serve as a general cognitive control mechanism that is domain general recruited for both linguistic and nonlinguistic processing.

The prefrontal cortex appears to also play a role in computing categorical representations for both linguistic and nonlinguistic stimuli. The ability to map different sensory stimuli onto a common category plays a critical role in many cognitive domains: We recognize the same face across multiple views, and we perceive the same phonetic category spoken by different speakers. Freedman, Reisenhuber, Poggio, and Miller (2001, 2003) have shown invariant responses in lateral prefrontal cortex to exemplars from a learned visual category (either cats or dogs) in single-cell recordings of monkeys. Similarly, invariant responses in the IFG have been shown for humans who were presented with acoustically different stimuli drawn from the same phonetic category, that is, different exemplars of [t] (Myers, Blumstein, Walsh, & Eliassen, 2009). Thus it appears that the same neural mechanism is recruited in the categorization of both linguistic and nonlinguistic stimuli and that the recruitment of these areas is dictated by the computational requirements underlying categorization rather than the functional domain in which categorization occurs. Taken together, these results suggest that while language may be functionally “special,” it draws on at least some neural mechanisms and computational properties that are shared across other cognitive domains. It remains to be seen whether there are other aspects of language that share neural resources across other cognitive domains.

The role of the right hemisphere in language processing

As was discussed earlier, the lesion data support the view that the left hemisphere is dominant for language for most individuals, particularly for right-handers. Patients with right hemisphere lesions are typically not aphasic, and they do not show deficits that can be attributed to linguistic impairments per se. They do, however, show impairments in critical aspects of language communication. In particular, they seem not to be aware of what other speakers know or should know in the communicative process (the theory of mind); they fail to be sensitive to the metaphorical use of language and interpret sentences such as “He has a heavy heart” literally; and they have difficulty in making inferences in sentences (Brownell, Gardner, Prather, & Martino, 1995).

Yet, although the neuroimaging literature shows right hemisphere activation in these paralinguistic and discourse tasks, it also often shows bilateral activation in language-processing tasks. In particular, although typically weaker, right hemisphere activation has often been shown in areas homologous to those activated in the left hemisphere in studies exploring phonetic/phonological, lexical, semantic, and syntactic processing (Burton et al., 2000; Bilenko et al., 2008; Rissman, Eliassen, & Blumstein, 2003; Kaan & Swaab, 2002; Mason & Just, 2007). The question then is what role, if any, does the right hemisphere play in linguistic processing. Does it play a functional role? If so, how is its processing integrated with that of the left hemisphere? Is it dominated and hence inhibited by the left hemisphere under normal circumstances, becoming “active” only after left hemisphere injury?

These questions are only starting to be explored. Studies of the neural activation patterns of patients after a stroke and at different stages of language recovery have provided some interesting but conflicting data (for reviews, see Cappa, 2000; Pizzamiglio, Galati, & Committeri, 2001). In some cases, it appears that there is increased activation in the homologous right hemisphere during the recovery process. Other data show increased activation of the right hemisphere in early stages of recovery but activation in perilesional areas for the patients who show the greatest degree of recovery. In fact, increased activation of the right hemisphere is often seen in older subjects in cognitive tasks, raising the question of whether right hemisphere areas reflect a compensatory mechanism or pathological recruitment in the context of language or cognitive capacities during the aging process (Wingfield & Grossman, 2006; Persson et al., 2006; Cabeza, Anderson, Locantore, & McIntosh, 2002).

Agenda for the future

The cognitive neuroscience revolution has enriched our knowledge of the neural systems that underlie language. At the same time, it has raised new questions and challenges that could help to provide a roadmap for future research. First and foremost, localizing areas of the brain that are activated in language processing fails to provide an “explanation” of the functional role those areas play. And it is apparent that no aspect of language activates a single focal neural area. Rather, language and cognitive processing more generally recruit a network of areas. Understanding the functional role of specific neural areas and the neural system in general will occur only when the functional connectivity of these areas is mapped out and when the temporal course of the information flow to and from these areas is delineated. Such research requires the integration of methods that allow for good spatial resolution (e.g., fMRI) with those that allow for good temporal resolution (i.e., MEG, ERPs).

It is generally assumed that activation reflects active involvement of an area in a particular function. This appears not always to be the case. Several studies have shown that a lesion to an area that shows activation in a particular language task does not necessarily result in pathological performance (Price, Mummery, Moore, Frackowiak, & Friston, 1999). Thus the fact that an area is activated in functional neuroimaging does not mean that the area is *necessary* for accomplishing that particular language function. Coupling lesion studies with neuroimaging experiments with normals provides a means of addressing this issue directly. The functional role of an area may be “tested” by examining whether a lesion in an area that is activated in a neuroimaging study results in a functional deficit. Alternatively a lesioned area giving rise to a particular deficit should show activation in normal individuals using neuroimaging methods, assuming that comparable language stimuli and experimental tasks are used.

Finally, it is not at all clear whether a component of the grammar can ever be studied and identified independent of a particular task. After all, the function of language is to communicate and the use of language whether for speaking or understanding is a goal-directed behavior. Does it make sense, then, to talk about sound structure, lexical structure, semantic structure, or syntactic structure independent of its use? That is, accessing sound structure to identify a sound segment is different from accessing sound structure to compare to another sound or mapping a sound on to lexical form (cf. Poeppel, 1996). Yet each of these tasks recruits the “linguistic component” as well as a set of other cognitive and executive resources needed to accomplish the specific goal. In the end, it would seem that understanding the neural basis of language requires the study of language in action. If this is the case, then it is less clear that there will ever be a true dissociation between a linguistic component per se and the processes and mechanisms underlying its use.

87 Why the Imagery Debate Won't Go Away

STEPHEN M. KOSSLYN, WILLIAM L. THOMPSON, AND GIORGIO GANIS

ABSTRACT In this chapter, we summarize the theoretical and empirical history of the imagery debate. We argue that the debate about the nature of mental imagery has lasted so long in part because it taps into much more general issues, which bear on the nature of theories of cognitive functions. The imagery debate has focused on whether depictive representations are used in cognition, but the depictive and antidepictive camps have often failed to engage each other, in part because they have asked questions at different levels of analysis. Depictive theories have focused on the nature of internal representation and processing, which has resulted in their embracing computational and neuroscientific evidence to explain data from experiments and to produce empirical predictions. In contrast, antidepictive theories have tended to focus on competence, developing abstract explanatory principles couched in the language of formal logic, with little attention to processing per se. Rather than being in direct conflict, the two sorts of theories often can complement each other.

The so-called imagery debate began in 1973, with publication of Zenon Pylyshyn's paper "What the Mind's Eye Tells the Mind's Brain: A Critique of Mental Imagery." Pylyshyn argued that just as the heat emitted by a light bulb plays no functional role in the process of reading, the pictorial aspects of mental imagery play no role in information processing. Kosslyn and Pomerantz (1977) replied to this article, and the debate was off and running. The imagery debate is not about whether people report experiencing picture-like mental images (they do), nor is it about whether visual information is stored and used in memory and reasoning (yes, it is); moreover, the debate is not about whether mental imagery shares mechanisms with perception (yes, it does). Rather than addressing whether visual *content* can be stored in memory and used in reasoning, the debate is about the *format* of the representation—the nature of the code itself. Whereas some of us argue that visual mental images are called *images* because they in fact share structural properties with actual pictures (in particular, space in a representation is used to depict the layout of surfaces in actual space), others argue that only a single kind of representation is used in all of

cognition and that this representation uses language-like symbols and is best understood in the context of the characteristics of formal logic. This is the "propositional" view of mental imagery.

Uncounted salvos and exchanges followed, and long after most colleagues have lost interest, the debate still smolders. Why won't the imagery debate go away, and why should anybody care whether it does or doesn't? In this brief chapter, we expand on our earlier views (Kosslyn, Thompson & Ganis, 2006) and explain how the lessons of the imagery debate apply more broadly to cognitive psychology, cognitive science, and cognitive neuroscience as a whole.

What is a theory of cognition?

The imagery debate has persisted in part because the two camps have sought different types of theories, which have different purposes. The issues that have been revealed apply broadly.

COMPETENCE VERSUS PROCESSING When considering theories of cognitive processing in general and imagery in particular, we must emphasize a crucial distinction between two classes of theories. On the one hand, *theories of competence* specify principles that describe a system; the system itself does not actually follow the rules specified by these principles any more than a seal solves differential equations when it hunches its neck to catch a ball on its nose or the planets follow the laws of motion when they wheel around the sun. On the other hand, *theories of processing* specify mechanisms that underlie performance; in so doing, they indicate how information (including specifications of rules) is represented and processed (including by processes that actually follow rules) in a system in real time (cf. Chomsky, 1965).

Not only are the two types of theories designed to answer different types of questions, but the answers themselves are qualitatively distinct. Depictive theorists, who propose that visual mental images rely on depictive, picture-like representations, have sought to explain the details of empirical findings by appeal to mechanisms, which requires them to specify the nature of representations and the processes that operate on these representations. In contrast, antidepictive

STEPHEN M. KOSSLYN and WILLIAM L. THOMPSON Harvard University, Cambridge, Massachusetts

GIORGIO GANIS Massachusetts General Hospital, Charlestown, Massachusetts

theorists, who posit that a single language of thought underlies all forms of cognition, have more recently tried to explain previous findings with simple, general principles. For example, antidepictive theorists seem satisfied that they have explained a finding by appealing to “tacit knowledge” of how perception works; according to this view, such knowledge is unconscious and can guide behavior in laboratory experiments. For instance, tacit knowledge is taken to explain the increase in time to scan farther distances over an object in an image. According to this view, during imagery, people unconsciously simulate what they believe would happen in perception, which leads them to wait a little longer to respond when they should have traversed greater distances while scanning.

The initial phases of the debate pitted depictive and propositional theories against each other, which was appropriate, since both began as theories of processing. However, with the advent of tacit knowledge accounts (Pylyshyn, 1981), the debate shifted. The alternative to depictive theories was no longer another mechanistic theory, but—as far as we can tell—a theory of competence (e.g., of the sort that Pylyshyn [2002] believes has been successful in characterizing language). That is, the theory aims to describe what people know (largely unconsciously) and ways in which that knowledge can be used, without characterizing the mechanisms that give rise to performance.

The two sorts of theories can, of course, go hand in hand. A theory of competence can provide guidelines that must be met by theories of processing. The two kinds of theories are not exclusive, which might be one reason why the imagery debate has proven so slippery: The theorists are talking past each other.

FORMAL SYSTEMS Another reason that the imagery debate has persisted lies in the different conceptions of how a theory should be stated. The nondepictive camp has asserted that theories must be stated by using formalisms such as logic or mathematics. But is this necessarily so? Darwin’s answer would be clear, and the success of his theory of evolution by natural selection serves as a model for the utility of nonformal theories.

Pylyshyn and his colleagues urge us to consider the most general constraints or boundary conditions that have to be met by a system of imagistic reasoning. For example, Fodor and Pylyshyn (1988) have proposed such constraints as productivity, compositionality, and systematicity. In addition, Pylyshyn (1978) has proposed some formal constraints on theories of imagery; for example, they must represent token individuals and visual rather than abstract properties, and they must not encode properties of sets, such as cardinality, or represent negative statements. Although plausible, these very abstract ideas do not go very far in explaining the data, such as increases in time as objects in images are rotated by

greater amounts (Shepard & Cooper, 1982). In other words, these formal constraints are not very illuminating from the point of view of a theory of processing.

COMPUTATIONAL MODELS Seen from another perspective, the debate has also continued because the depictive camp has sought to develop models that do not make close contact with the sorts of theories developed by most antidepictive theorists. Specifically, the depictive theorists have relied on theoretical constructs borrowed from computer science, arguing that computer simulation models provide one way to begin to specify crisply concepts that are exceedingly slippery and difficult to nail down using natural language alone. Models, by their nature, are not fully specified (Hesse, 1963).

In contrast to this approach, Pylyshyn (2002, 2003) not only argues that the depictive theory is incorrect, but also goes so far as to suggest that the issue of the format of image representations is actually irrelevant. According to this view, pursuing knowledge about the format of images tells us nothing truly interesting about imagery. If Pylyshyn is (implicitly) focusing on a formal theory of competence, we can make sense of this claim. In this case, he would seek an abstract characterization of what people know, not how information is represented and processed when one actually performs specific tasks.

If one seeks a mechanistic theory, then it is difficult to understand the claim that characterizing the format of the representation is irrelevant. Rather, such a goal focuses us on a fundamental question about the nature of information processing: Is there a single “language of thought”? The answer to this question has wide-ranging implications for studies of many faculties. On the one hand, if it turns out that there really is only a single type of internal representation, this fact would place very strong constraints on theories of all forms of cognition. On the other hand, if it turns out that there are different types of representations, this opens the door to theories of specialized mechanisms for specialized tasks. To address the question of the format of representations in imagery, one needs to specify a theory of processing mechanisms.

MOTIVATING A THEORY Pylyshyn (again taking him as the prototypical antidepictive theorist) considers it a major drawback if a theory is “speculative,” and he simply dismisses such theories out of hand; his view seems to be that a theory must be considered as “speculative” if any of its details are not motivated by proven facts. In contrast, we (taking ourselves as typical depictive theorists) maintain that there is a sense in which *any* theory is “speculative” in this way. We know of no case in science in which an “adequate theory” (from Pylyshyn’s point of view) was in place before properties of the subject matter were well characterized. In

fact, it often goes the other way around: Theories are constructed by an act of bootstrapping, general principles being abstracted out of individual discoveries, which in turn were guided by earlier theories (e.g., see Fodor, 2003). It is not possible to motivate every detail of a theory in advance; part of what makes a theory a “theory” (as opposed to a description of fact) is that it is a stab into the unknown.

Much of the motivation for the formal constraints imposed by antidepictive theorists appears to be based on introspection and logical considerations. Therefore it is not surprising that some of these claims are debatable. For example, Barsalou (1999) challenges the idea that images must represent only token individuals; instead, he offers detailed arguments that perceptual representations can perform all the functions often assumed to require symbolic or amodal representations. Again, the camps appear to be barking up different trees.

WHAT THEORIES ARE FOR Another point of fracture focuses on what work we want theories to do. Depictive theorists stress the importance of generating and testing new predictions, whereas antidepictive theorists are usually content to try to explain previous findings. Depictive theorists have stressed that their theories have led to an avalanche of new empirical discoveries (e.g., Kosslyn, 1980, 1994; Kosslyn, Ganis & Thompson, 2001; Kosslyn & Thompson, 2003; Kosslyn et al., 2006; Thompson & Kosslyn, 2000), whereas it is not clear that antidepictive theories have led to many new discoveries. The antidepictive camp downplays the role of depictive theories in the empirical enterprise for the reasons noted above, claiming that these theories are not really theories at all.

No wonder the imagery debate has ground on for so long!

Relevance of the brain

We were moved to write this chapter now because the debate has resurged in recent years. This uptick in discussion is a direct result of a change in research strategy. Specifically, the depictive camp has come to focus on neural evidence. Anderson (1978) showed that certain classes of behavioral evidence could be easily accounted for by either depictive or nondepictive explanations. To resolve this fundamental ambiguity, he proposed that additional sources of evidence, such as neural data, should be taken into account. However, the currently popular antidepictive approach rejects the very idea that facts about the brain can be used to discover the format of an internal representation.

THE ROLE OF NEUROANATOMY As an example of the lack of utility of using facts about neuroanatomy to constrain theorizing about cognitive function, Pylyshyn points out that

knowing about the projections from the retina to the brain has led to fruitless debates about why we don't see the world upside down. In sharp contrast, the depictive camp emphasizes that studying the wiring of the visual system has led to enormous progress in our understanding of how vision works (e.g., Desimone & Ungerleider, 1989; Felleman & Van Essen, 1991; Hubel, 1988). For instance, the fact that object-properties processing and spatial-properties processing are accomplished by separate neural systems allows us to understand why we sometimes erroneously conflate shape and location information. Similarly, by observing the relative amount of cortex devoted to the foveal versus peripheral areas of the retina, we gain insight into the nature of visual acuity. Moreover, Anderson (1978) used structure/process tradeoffs to show how depictive theories of behavioral findings could be converted to antidepictive theories. Such tradeoffs require being able to specify the nature of processing to fit the properties of representations. But once we know certain facts about the brain, such tradeoffs can no longer be made—we can no longer alter properties of representations and processes willy-nilly to perform such tradeoffs.

Why do the two camps have opposite evaluations of the potential utility of neuroscientific data? One reason might be that no hint of a mapping to neural mechanisms has been found for theories that posit only tacit knowledge or only propositional representations. This is not surprising, given the abstract level of analysis that the antidepictive theories have typically taken.

TYPES OF DATA In addition, the two camps have different assumptions about what sorts of data bear on the issues. According to some antidepictive theorists (e.g., Dennett, 2002; Pylyshyn, 2002), *only* behavioral evidence can reveal the nature of information processing. This view sharply contrasts with that of the depictive theorists, who note that researchers can learn an enormous amount about the types and course of information processing by tracking the spatial and temporal properties of activity in the brain itself, (e.g., Ganis, Thompson, & Kosslyn, 2004; Ganis & Schendan, 2008). From the perspective of depictive theories, the approach advocated by the opposing camp throws away valuable tools and evidence that can help us to understand the system that underlies all information processing. According to this view, it is as if during the early stages of research on the building blocks of life, researchers had decided to throw away X-ray crystallography data by assuming that it had nothing to do with understanding “life.” (But without this tool, they would not have discovered DNA!)

THE VALUE OF STUDYING INTERNAL EVENTS Some antidepictive theorists—perhaps as an outgrowth of their distrust of introspection—have discounted the value of studying internal events that do not lead to overt, observable behavior.

Again in contrast, the view that most depictive theorists espouse is that by studying the brain, we can discover the nature of processing that never leads to an overt response. This divergence in viewpoints bears on issues much broader than the nature of mental imagery. To take a simple example, it has long been known that after extinction of a classically conditioned stimulus-response pair, animals later can be conditioned again more easily than they were at the outset. But why is this so? Is it because there is still some residual learning that was not affected by extinction and therefore not all neural connections need to be reestablished? Is it because extinction replaces the conditioned response with a new one and relearning consists of removing the new response? As it happens, LeDoux and colleagues (reviewed in LeDoux, 1996) have shown that extinction of classically conditioned responses relies on the frontal lobe's suppressing reflexive connections (mediated by the amygdala). That is, extinction does not obliterate or overwrite the conditioned memory; it simply keeps it in check, but that memory is always there, lurking in the background. Observing behavior alone would never tell us this because, by all overt appearances, the behavior has been eliminated and then can be relearned more easily—but without access to the neuroscientific data, we might never have learned why.

A SPECIAL ROLE FOR NEUROLOGICAL DATA? Another point of divergence is that some in the antidepictive camp assert that biological or neuroscience-based data do not have a special role in evaluating theories of information processing. This claim is ironic, given that Pylyshyn's (1981) shift to focusing on the alternative interpretations of key imagery findings motivated us to turn to the brain. Specifically, Pylyshyn claimed that the results of classic imagery experiments, such as mental rotation or mental scanning (for review, see Kosslyn et al., 2006), do not directly reflect the nature of internal mechanisms. Rather, as was noted earlier, Pylyshyn speculates that such results are produced on the basis of participants' tacit knowledge about the corresponding perceptual phenomena—and that knowledge leads the participants (unconsciously) to try to mimic what they think they would have done in the corresponding perceptual situation.

In this context, neuroanatomical and neurophysiological facts do play a special role. To the extent to which we shift from measuring overt behavior to measuring neural events, we take tacit knowledge out of the picture. For example, the brain has many visual areas that are topographically organized; the structure of activation across the retina is physically laid out (albeit with various distortions) across the surface of the cerebral cortex. Many studies (but not all; see Kosslyn & Thompson, 2003) have now shown not only that these areas are activated when one visualizes an object with high resolution, but also that spatial

properties of the object (such as its orientation) are directly reflected by the pattern of activation. These representations are not language-like and are not abstract descriptions; they are literally depictions: Activation in specific locations of space on cortex specifies objects in space in the real world. No amount of tacit knowledge can explain them away.

In addition, facts about the brain introduce constraints that prevent theories from being arbitrarily modified to fit data. For example, any theory of visual processing must respect the fact that these areas are topographically organized. Similarly, many additional facts about the brain constrain theories of information processing, such as the fact that object properties and spatial properties are processed by largely separate neural systems, that color and motion are processed by partially distinct systems, that different systems subserve different sorts of working memory, and so on and so forth. Such constraints affect all theories.

Some general lessons from the imagery debate

Why should anybody care about the imagery debate? Because the debate strikes to the heart of issues regarding what the study of the mind should be. Can we characterize the nature of internal representations and is it even worth trying to do so? Should we try to characterize mental function at a very abstract level or at an information processing level? Or should we do both? Should theories be stated formally, or can they do useful work when cast as partially specified models?

The imagery debate and the ways in which the arguments on either side have failed fully to engage each other have brought into sharp relief three general lessons. First, we need to be clear on the goals of theorizing. What do we want to use theories to do? In cognitive neuroscience, we are trying to characterize a system, and in so doing, we need to characterize the individual components and how they interact. This effort requires analysis at multiple levels. Not only must we understand what individual neurons are doing and how neurons affect each other, but we also need to understand how large ensembles of neurons come into play and interact, and we need to understand what these events are accomplishing. As Marr (1982) stressed, we need to specify what is being computed as well as how the computation is taking place. In much of contemporary cognitive neuroscience, we have set aside the “what” part and have focused solely on the “how.”

Second, ultimately, we will need to engage in formal theorizing. Cognitive science, with its emphasis on computational models, might not have had a sufficient influence on the empirical work in contemporary cognitive neuroscience. But these sorts of models are likely to be useful primarily during a transitional phase, before truly rigorous theorizing underlies research in cognitive neuroscience. However, in

the early years of the 21st century, it is not clear what will be the most appropriate formalisms for characterizing the brain; it is possible that the most useful formal vocabulary, capable of capturing the complex dynamics of the brain, has not even been invented yet. In the meantime, although it is reasonable to use formalisms that are available, we must avoid being dogmatic about them. We must avoid the “man-with-hammer” phenomenon: To the man who has only a hammer, the whole world looks like a nail. To the person with a particular formalism, every phenomenon may look like fair game—but it might not be.

Third, we need to be clear about the best ways to evaluate our theories. Many metrics are possible, as the imagery debate has illustrated. Surely, clarity and elegance are to be valued, but so is predictive power.

In short, cognitive neuroscience must fully embrace the idea that neural activity should be characterized as computation, and one aspect of understanding a computational system is understanding the sorts of representations that can be used. Moreover, characterizing the format of the representations used in cognition is one part of this challenge. When we visualize shapes with high resolution, either a depictive representation is employed or it is not. If cognitive neuroscience is a science, we should be able to resolve this issue.

88 Looking Toward the Future: Perspectives on Examining the Architecture and Function of the Human Brain as a Complex System

MICHAEL S. GAZZANIGA, KARL W. DORON, AND CHADD M. FUNK

ABSTRACT With the arrival of increasingly sophisticated methodologies, cognitive neuroscience has quickly matured into a remarkably prolific field. However, amid such progress, it is possible to lose sight of the overarching purpose of the field, which is to promote an understanding of how the brain creates the marvels of the mind. We argue that viewing the brain as a complex system is a useful way of regaining this perspective. Here, we consider fundamental characteristics of brain organization and function in hopes of finding analogous complex systems that might yield novel insight into how cognitive function and subject experience emerge from activity in distributed regions of the brain.

The aim of cognitive neuroscience is to advance our understanding of the organization and function of the human brain and, ultimately, to solve the mystery of how the human brain creates the human mind. Moving toward these ends occasionally requires dismissing obsolete theoretical constructs and taking new perspectives in order to devise the theories that will succeed them. This chapter is an effort to do both. We first consider the modular organization of the brain; we then address why it renders some descriptions of brain function—namely, those that appeal to a homunculus-like entity—inadequate. Though slowly fading, the notion that a homunculus is embedded somewhere inside the depths of the brain persists, subtly masked by terms such as *executive function* or *cognitive control*. This reliance upon a central executive or neural hub that receives feedforward input and distributes attention, induces actions, and carries the cognitive

burden is likely a remnant of outdated views of the brain that assume that perception, cognition, and action are discrete functions of the human brain that always occur in a prescribed hierarchical sequence.

Accumulating evidence has revealed that the brain is organized into modules that operate in parallel rather than in any simple progression, leaving no single neural apex to act as an executive. Cognitive neuroscience must move forward without a central hierarchy, even though there are significant challenges inherent in forging a new path. We would like to add our voice to those of the people who view the human brain as a complex system. We wish to promote the application of this type of theoretical inquiry within the field of cognitive neuroscience and further demonstrate that, by doing so, we may dispose of the fabled homunculus. Viewing the brain as a complex system provides a worthwhile perspective from which to understand how the interconnected modular architecture of the brain generates the many emergent properties studied by cognitive neuroscience.

In what follows, we describe several complex systems and draw parallels and contrasts between these systems and human brain activity at the global level, ultimately revealing the brain as a complex and dynamic system. In this view, emergent properties of the organizational and functional structure of the brain are the result of the interaction of neuronal assemblies, thus eliminating the need for a central controller.

The modular hypothesis as successor to traditional views

One of the most radical truths to emerge from decades of split-brain research is that the human brain is not an

MICHAEL S. GAZZANIGA SAGE Center for the Study of Mind and Department of Psychology, University of California, Santa Barbara, California

KARL W. DORON and CHADD M. FUNK Department of Psychology, University of California, Santa Barbara, California

all-purpose computing device but instead is organized in modular fashion, consisting of specialized circuits that have been sculpted by evolution to efficiently perform specific functions (Gazzaniga, 1989; Baynes, Eliassen, Lutsep, & Gazzaniga, 1998). This observation has been complemented by studies of patients with various other neurological disorders (Cooney & Gazzaniga, 2003) and by an ever-growing body of functional brain imaging literature. This architecture accounts for the unexpectedly enormous amount of distributed nonconscious processing that goes on from moment to moment, since parallel activity across modules can facilitate vast amounts of simultaneous activity (Volpe, Ledoux, & Gazzaniga, 1979). Functional modules typically consist of hierarchical processing, involve long-distance interactions between distributed neural regions, and also interact with or share neural real estate with numerous other modules. However, the attribute of this organization that is most relevant for the discussion that follows is the lack of an inter-modular hierarchy. If correct, and accumulating evidence is quickly reducing remaining doubts, this theory challenges certain prominent undercurrents in psychology and cognitive science that have guided research and theory for nearly a half-century.

Cognitive science, a major precursor to cognitive neuroscience, has come a long way since triumphing over the behaviorist movement in the middle of the 20th century (Miller, 2003). In the 1950s, after decades focused entirely on measurable behaviors rather than the cognitive events that triggered them, the idea that the brain did something more than act as a mere organ for learning responses to input from the world took hold, never again to relinquish its grip. This revolution enabled extensive investigation of the function of the brain and eventually gave birth to modern cognitive neuroscience. Though progress has led to constant revision of specific theories and models of various brain functions, certain fundamental principles have endured. Central among these is the idea that cognition is purposefully wedged between sensation and action and that sharp boundaries isolate the components of this tripartite conception. However, implicit in this model is a hierarchy in which all the information derived from perception is processed and eventually passed on to some decision-making area at the apex that selects a motor response. This theoretical neural pinnacle, which has inevitably remained elusive, is tantamount to the fabled homunculus, which receives information from all areas of the brain and pulls the strings necessary to cause actions.

The modular hypothesis challenges the orderly sequence of perception, cognition, and action and, in doing so, destroys the chamber occupied by the homunculus. As we acquire a deeper understanding of the function of the brain, it is becoming clear that many functions defy simple classification as perception, cognition, or action. Indeed, the view of the motor system surfacing in this volume is one in which its

components play an important role in many functions that have traditionally been thought of as cognitive, such as theory of mind (chapter 43 in this volume) and intention formation (chapter 83 in this volume). Also, a separate line of research indicates that regions necessary for control of eye movements also play a role in attention (Wardak, Ibos, Duhamel, & Olivier, 2006).

Meanwhile, areas associated with perception may also be involved in processes that have traditionally been deemed cognitive. For instance, cortical regions that support perception may also provide the basis for object recognition (chapter 32 in this volume). Also, bottom-up forms of attention, based on salience, indicate that enhanced processing could be promoted by intramodular activity (chapter 13 in this volume). These are just a few of the many examples of phenomena that violate conventional categorization. Some might debate the above statements, but that is precisely the point. We believe that time would be better spent on accepting and further exploring the diverse nature of brain function as a consequence of parallel processing in which modules influence activity in other modules in myriad ways, leading to subjective experience and behavioral output, than on arguing about how to classify hybrid functions.

Furthermore, it is quite clear that the organization of the brain cannot accommodate a homunculus or any similar entity. This should not come as a surprise to philosophers and psychologists alike, who have already banished the homunculus from the brain on other grounds, such as the principle of infinite regression (surely the homunculus needs a homunculus; see Niesser, 1967). However, cognitive neuroscientists often still cling to a subtle extension of this doctrine that operates under the guise of “executive function” or the “top” in “top-down.” There are a number of reasons why this might be the case. It is, for instance, tempting to think that the well-established limited capacities of attentional processing imply a central executive capable of only serial cognitive function (Holtzman & Gazzaniga, 1982; Dux, Ivanoff, Asplund, & Marois, 2006). But a bottleneck does not mandate a final common cognitive pathway for every type of upper-level neural processing. The far more likely explanation of limited cognitive resources is that certain tasks require the same modules that have limited capacity. This explains how other tasks, which might require separate resources, could be performed in the absence of attention. For instance, subjects can make discriminations about whether or not an animal appeared in pictures shown peripheral to a demanding central task (Li, VanRullen, Koch, & Perona, 2002).

The persistence of the homunculus likely reflects the common forceful intuition of being a unified agent with a strong sense of self. The mystery of this persuasive intuition certainly must be addressed (Crick & Koch, 2000, 2003), but the solution will not depend on the existence of a traditional

homunculus. Nowhere is this more evident than in chapters scattered throughout this volume. For instance, research on networks for self-regulation of emotional responses (chapter 66 in this volume) and cognitive retrieval of episodic memory (chapter 48 in this volume) indicates that even the seemingly unitary notion of cognitive control or executive function is implemented by distributed neural regions with distinct functions. Others have provided evidence for distinct networks involved in task control that act on different timescales and by different mechanisms (Dosenbach et al., 2007). Each of these lines of research further attenuates the potential repertoire of the homunculus, revealing that cognitive neuroscience no longer has any need for this theoretical crutch.

Moving toward a comprehensive theory of brain function

As the field replaces these notions with a modular architecture in which modules act in parallel to perform varied functions without guidance of an all-powerful central executive, it is imperative that these observations are fit within an explanatory framework that facilitates further research and comprehension. This is the new challenge faced by the field of cognitive neuroscience, and it requires a somewhat different approach from the one that has brought us this far. The conclusions discussed above are largely the result of careful scrutiny of specific modules or components of modules in order to elucidate their anatomical basis and function, an undeniably worthwhile and fruitful approach that attempts to connect neural cause with functional effect. However, the ultimate goal of cognitive neuroscience is to understand how the many modules of the brain interact in a way that explains complex human experience and behavior. The conscious experience generated by the human brain is both integrated and coherent, and our many capabilities related to perception, cognition, and action rarely act in noticeable isolation. Clearly, then, integration is essential and has rightfully been at the center of recent quantitative theoretical approaches to brain function (Tononi, Sporns, & Edelman, 1994; Seth, Izhikevich, Recke, & Edelman, 2006).

Yet while modularity and integration are fundamental components of the organization of the human brain, various other essential properties of the brain have shaped its organization by implementing significant constraints. Chief among these is the evolutionary context. The human brain comprises a collection of specialized circuits that were selected for over time on the basis of environmental pressures and the social landscape, and they endow us with an unparalleled array of abilities and underlie our unique capacities. It is impossible to fully understand the intricate organization of the brain without addressing the forces that fashioned it. Furthermore, complex interactions between the splendid product of evolution—the human genome—and

the environment that each individual encounters uniquely sculpt these circuits during development and throughout life. Patterns of activity in these circuits manifest as cognitive function and conscious experience, but fully understanding this activity requires characterizing the properties of neurons and their innumerable molecular constituents. Neuronal activity also has a metabolic cost; in fact, neurons have exceedingly high metabolic requirements (Raichle & Mintun, 2006) and consume energy, in the form of glucose, at an unsustainable rate during the waking hours of the day (Tononi & Cirelli, 2003).

Thus the biological brain is made of delicate organic tissue that, at the molecular and cellular levels, requires overwhelmingly precise homeostatic regulation (Marder & Prinz, 2002) and that, at the neural circuit and systems levels, produces an expansive range of adaptive human behavior and experience. A unified theory of brain function must parlay these separate principles and constraints into a comprehensive understanding of how the brain accomplishes this impressive feat. So far, the field has not approached anything converging on such an ideal, though different combinations of the above facts have received consideration (Sporns, Tononi, & Edelman, 2000b).

As we alluded to above, in the early going, we did not have the proper tools or intuitions to sustain such a comprehensive effort, so the foundation of the field was built by reducing grand mysteries to tractable puzzles, mainly by associating specific structures with observed functions. We believe that the time is right to step back and examine the larger framework within which the terrifically diverse discoveries of cognitive neuroscience fit. Sometimes the biggest hurdle in tackling seemingly insuperable problems is articulating what a solution might resemble. We attempt such a feat here in hopes of generating discussion, for it is often in the act of critique and revision that the deepest of insights are born.

We suggest that a critical step in a comprehensive understanding of the human brain is acknowledging that it is a complex system and thus exposing it to novel analysis from a somewhat different perspective. Though formal definitions of complex systems vary, there is a consensus that complex systems are composed of many independent elements that interact and, in doing so, generate emergent properties that are greater than the mere sum of the individual components. Complex systems are self-organizing and often are capable of adaptation, interacting with and changing on the basis of the environment (Amaral & Ottino, 2004). There is room for great variance in both the characteristics and number of building blocks of the system and the nature of their interactions, which may be dynamic or static, local or global. The claim that the brain is a complex system should not be controversial and has, in fact, been asserted by others (e.g. Sporns, Tononi, & Edelman, 2000a, 2006b; Jirsa & McIntosh, 2007). Given this characterization, it might be

informative to examine theoretical approaches to other complex systems. These discussions could provide important clues related to how to think about neural function. We turn now to a few complex systems that have received recent compelling theoretical treatment.

Other complex systems

By definition, all complex systems are composed of interconnected subunits, so at first glance, it might appear to be trivial to draw parallels between the brain and these systems. However, it is prudent, and quite useful, to dig a bit deeper and to examine specific complex systems that have architectural or functional properties similar to those of the human brain. For example, a Boeing 747 is a complex system made up of many interconnected parts, but to a large extent, it is unable to flexibly adapt to environmental demands and therefore might not provide much insight into the function of the brain (Amaral & Ottino, 2004). We examine complex systems that share attributes with the organization and function of the human brain beyond the obvious features dictated by the general criteria of complex systems, beginning with other examples of complex systems in nature.

A common feature of natural complex systems that is also observed in the brain is the dramatic effect that minor alterations in initial conditions can exert on global systems. Edward Lorenz (1963), a pioneer of meteorology and chaos theory, showed that large-scale dynamics in weather were highly sensitive to differences in initial conditions. This became known as the butterfly effect. Imagine, for example, that you were to place a leaf in a stream of rocky and turbulent water. Where you place the leaf, the angle at which you place it, and perhaps dozens of other incalculable variables will determine whether the leaf is carried downstream or ends up on one or other of the riverbanks. Thus small changes in initial conditions determine the final outcomes, which often cannot be predicted. One aspect of brain function is that large changes at the network level can be instituted by very small changes in initial conditions, such as individual spike rate behavior or the activity at the columnar level. While we know that the elemental processing unit of the brain is the neuron, groups of which self-organize into neuronal assemblies without any assistance from a central controller, we do not know how the organizational and functional structure of these assemblies produce observed emergent properties. Several studies and methods highlight the dynamic and complex nature of large-scale neural networks.

One recent study by Izhikevich and Edelman (2008) used diffusion tensor imaging (DTI) data to provide large-scale anatomical constraints on a model of brain function that reproduced spiking behavior of individual neurons that were capable of learning and organizing into functional assemblies. Interestingly, although the model's cortical microcir-

cuitry was uniform, different frequency bands emerged at distinct areas of cortex. The differences in white matter connectivity provided by the DTI data likely accounted for the self-organizing behavior of the model. Additionally, they found that changing the spiking behavior of even a single neuron in the model changed the overall appearance of the large-scale network behavior. While weather systems and brain dynamics are linked at the level of being complex systems, it is clear that brain dynamics comprise subsystems coupled by functionally meaningful information (Jantzen & Kelso, 2007). A clearer understanding of human cognition will come from a greater understanding of how the individual components of the brain exchange information and work together to give rise to large-scale systems. Studying the thalamocortical system is proving to be fruitful in this endeavor (Tononi, 2004).

Other complex systems, such as ad auctions on search engines, share the distributed, decentralized architecture that we argue is a hallmark of brain organization. Consider the challenge faced by designers of a search engine such as Google, who are interested in using search inquiries to guide advertisement placement among search results. The sheer quantity of possible keywords negates the possibility of effectively setting prices for each keyword and ad position. A more viable solution is to use an auction, in which buyers largely set the price; however, traditional auctions feature a centralized auctioneer who ultimately determines the buyer and orchestrates the transaction. Such a structure is impractical—indeed, impossible—to implement when one considers the hugely diverse spectrum of potential advertising keywords and advertisers. Imagine the queue that would build up in such an instance; search engines would be rendered useless. Instead, innumerable simultaneous auctions occur in which Google, advertisers, and consumers engage in a common interaction despite unique interests. The beauty of the design of ad auctions is that the selfish motives of each party are harnessed and ultimately facilitate the most productive interaction possible (Varian, 2007). Advertisers place bids for target keywords, and each time a search occurs, the ad slots are filled on the basis of the highest bidder, who is charged only slightly more than the second highest bidder. An entire economy emerges, completely devoid of a centralized auctioneer.

The structure of ad auctions mirrors in many ways the very platform that is responsible for their existence, namely, the Internet. The Internet also consists of a distributed architecture in which independent processors, called autonomous systems, share processing demands while operating for varying purposes. The interdomain routing system connects these smaller systems, forming a sprawling, self-organizing network that lacks a “trusted center” (Feigenbaum, Papadimitriou, Sami, & Shenker, 2005). Information is sent in the form of packets, which often must traverse many

autonomous systems before reaching the system that is intended to receive them. Carrying this traffic is a burden to autonomous systems, but it is necessary for the function of the Internet, since there is no central system that connects to all autonomous systems and distributes information. Autonomous systems make computations that dictate routing patterns on the basis of information they receive from neighboring systems, leaving open the possibility that systems could lie about the costs they are incurring at any given moment to reduce the volume of packages they are sent. Lying would reduce efficiency of the overall network and thus be detrimental. Understanding how the Internet emerges from this mess of distributed computation and potentially devious and selfish local systems is an enormous challenge.

Complex systems such as ad auctions and the Internet warrant a novel theoretical approach, for they involve both independent, selfish agents (typically understood by the keen analysis of game theory) and complex computation (typically contained within the field of computer science). Moreover, in both cases, the fundamental structure precludes a central authority and requires distributed processing. An emerging theoretical field, distributed algorithmic mechanism design (DAMD) (Feigenbaum, Papadimitriou, & Shenker, 2001; Feigenbaum et al., 2005), represents a marriage of economic and computational concerns within a decentralized, distributed framework. DAMD is a valuable exemplar because it addresses three critical questions one must ask about a distributed complex system:

1. What drives self-organization of a complex system into such an architecture?
2. What are the characteristics of the nodes?
3. What are the nature of and constraints upon the interactions of the nodes?

In regard to the first question, DAMD identifies three major forces that compel a system to be distributed without a trusted center: trust, scalability, and reliability. Agents might not be willing to trust a centralized entity. Furthermore, it might be computationally infeasible for a center to exist, and in many cases, it is exceedingly risky to have a large system rely upon a single central node (Feigenbaum, Schapira, & Shenker, 2007). Addressing the attributes of different nodes, DAMD identifies four varieties: obedient nodes, faulty nodes, strategic (or selfish) nodes, and adversarial nodes (Feigenbaum & Shenker, 2002). Equations or models can be used to provide details or quantitative predictions about each node category. These nodes interact through a network, so a complete description of the system must also characterize these interactions. Complexity in this network is measured by the number of packages sent, the total number of packages sent over a single link, the maximum message size, the local computational burden on

each node, and the storage required at nodes. For the network to function properly, each of these measures must be within a feasible range (Feigenbaum et al., 2007). Thus by determining the theoretical structure of complex systems such as the Internet or ad auctions, DAMD provides a general framework in which specific equations and measurements can be integrated to explain a given complex system.

The tenets of DAMD justify the distributed organization of the human brain promoted in this chapter and may provide a flavor of what a theory of brain function might resemble. First and foremost, the lack of a central trusted center resonates with the concept of a homunculus-less brain. The considerations of scalability and reliability are particularly relevant when we consider the brain, especially in an evolutionary context. A hallmark of the human brain is an increase in intrahemispheric white matter (Rilling & Insel, 1999), which indicates pressure toward specialization of independent processors (Striedter, 2005). As the brain accumulated specializations, the feasibility of a neural region listening in on and orchestrating activity in these diverse processors rapidly decreased. Furthermore, the distributed design is extremely reliable and thus adaptive. Focal neurological damage may incapacitate one or multiple modules, but in most cases, this does not profoundly disrupt conscious experience or the individual's conception of self (Tononi, Sporns, & Edelman, 1999). An extreme example is the split-brain patient, whose left hemisphere reports little disruption to its conscious world following callosal transection.

Though it might be possible to stretch this analogy further, it is important to emphasize that the purpose of this exercise is to derive useful ideas from the study of other complex systems rather than attempting to map neural function on a single existing theory. For instance, neural modules are not likely selfish in an economic sense, and they may be less predictable than obedient nodes, since they are sculpted by both genetic blueprints and interactions with the environment. However, the purpose of this brief tour through Boeings, streams, and the Internet was to expand the scope through which we peer at the brain, in hopes of gaining a better understanding of what a theory of global brain function might resemble. A comprehensive model should set out to do something similar to DAMD, explaining the origins and reasons for the organization of the system, explaining the properties of the nodes, and explaining their interactions. Note that a description of brain function that addresses this problem set will require contributions from evolutionary psychology, cognitive neuroscience, neurobiology, computational neuroscience, and many other fields. This should not be surprising. Assembling the brute force of these varied approaches and integrating their various perspectives in a unified theory that treats the brain as a complex system will surely be an exciting and fruitful venture.

Conclusion and future directions

New methodologies are providing an unprecedented opportunity to study the organization and function of the human brain and are giving rise to exciting results. Human neuroimaging studies have revealed that virtually every perceptual or cognitive task, whether it be object recognition, memory encoding and retrieval, reading, working memory, attentional processing, motor planning or awareness, is the result of activity within large-scale and distributed brain networks (McIntosh, 1999, 2000; Sporns & Tononi, 2007). Neuroimaging methodologies are not without their flaws, however. Recording behavioral measures and correlating them with “activation blobs” from functional imaging data leave enormous gaps in the larger picture. Activation blobs from these studies may be easily confused with spatially localized modules or nodes; however, they are likely to be part of a more distributed functional network. The spatial scale of functional magnetic resonance imaging (fMRI) studies has created an outflow of abbreviations designated, perhaps unintentionally, to be discrete modules, but the neuroimaging field has delivered little indication as to how these areas work together.

It is critical that we do not allow our methodologies to constrain our view of how the brain works. We believe that thinking of the brain as a complex system will help to circumvent perspectives that might otherwise limit our endeavors. To advance our understanding of its interconnected parts, we will need to view brain function as a series of dissociable networks, each communicating upward and downward with subsystems. Considering only the localization of certain functions is equivalent to focusing entirely on the properties of nodes in systems such as the DAMD architecture described above. It is critical that we look beyond functional localization to connectivity and the interaction between the two. Recall that the merit of approaches such as DAMD is the additional emphasis on the interactions between nodes, which ultimately give rise to emergent phenomena.

The importance of connectivity in the brain cannot be overlooked or underestimated. Three separate meanings exist in neuroimaging for the term *connectivity*: anatomical, functional, and effective. The term *anatomical connectivity* refers to the physical or structural connections that link neurons within a given network. Anatomical connections range in scale from local circuits (the minicolumn) to bidirectional white matter pathways, such as those linking frontal and parietal cortices (Schmahmann & Pandya, 2006). Methods such as diffusion-weighted imaging and tractography have allowed us, for the first time, to peer in vivo into the anatomical connections of the human brain (Le Bihan, 2003). Functional connectivity (Friston, Frith, Liddle, & Frackowiak, 1993) is a statistical measure of the correlation or covariance

of activity in spatially distinct brain areas. This distributed activity can be quantified by using multiunit electrode recordings, EEG data, and even fMRI signals. However, measures of functional connectivity make no reference to the causal effect of one area over another. Finally, effective connectivity describes the causal effects one brain area has on another (Büchel & Friston, 2000). Integrating various neuroimaging analyses, to provide a more thorough account of the anatomical basis and functional significance of the interactions between distinct brain areas, will shed light on how the brain produces the enormous range of adaptive human behavior (Sporns, Tononi, & Edelman, 2002).

The need to integrate anatomical, functional, and effective connectivity challenges the field of cognitive neuroscience to think beyond localization of function and more toward a perspective that appreciates complex interactions. It is becoming increasingly clear that the brain operates on a large-scale network level (Sporns, Tononi, & Kotter, 2005; Hagmann et al., 2008). Recent work into what has become known as the brain’s default-state network highlights the importance of approaching the brain as a complex system and emphasizing the interaction of connectivity and function. The default network is a system of highly interconnected brain areas that has consistently demonstrated deactivation when goal-directed behavior is needed (Buckner, Andrews-Hanna, & Schacter, 2008). Thus on the large scale, the brain seems to have at least two anticorrelated networks. One network, consisting of more lateral frontoparietal circuits, seems to be engaged during attention-demanding cognitive tasks. The other, the default network, is located in more medial regions and is involved in non-goal-oriented processes (Fox et al., 2005). Importantly, when the lateral circuits are not recruited by environmental demands, the default network becomes active, perhaps reflecting the functions of the idle mind. This illustrates that the brain possesses some kind of “circuit breaker” that switches and allocates substantial metabolic and neuronal resources in a context-dependent fashion. Efforts to understand how this is accomplished are underway and synthesize theoretical explanations for the origins of this architecture, characterizations of the critical cortical nodes, and a detailed understanding of how the three connectivity concepts noted above produce the emergent functionality (see chapter 73 in this volume).

The investigation of the default network represents a notable example of how thinking of the brain as a complex system produces tangible results. Ultimately, a great number of lower-level variables contribute to such large-scale networks at the level of neurons or neural circuits and their respective connections, and how these lower-level variables enable the emergent properties of the large scale is the question at hand. We can be certain that the sheer complexity of the human brain and the innumerable emergent states that it produces are directly tied to the vast

number of lower-level variables and interactions of which it consists. This is true of other complex systems as well. The Internet would be less impressive if it contained very few independent processors dedicated to only certain kinds of information. Imagine if the modern Internet were only Expedia.com.

No single theory pertaining to the analogous complex systems described above or any other complex system will encompass the findings of cognitive neuroscience, nor will it provide a comprehensive view of how the brain enables the mind. Instead, this burden falls on the shoulders of the researchers at the forefronts of neuroscience. And while the brilliant research, cutting-edge methodologies, and new insights into brain function contained in this volume breed tremendous optimism and excitement, there is still work to be done. Sometimes the thrill of progress dulls awareness of the big problems. As we move forward, it will be paramount not to get lost in details at the expense of a more comprehensive perspective on brain function. Furthermore, we need to acknowledge that the solution we seek should be based not on what was or what we think should be, but on what actually is. This will require communication across many fields, and these many contributions will need to be fit within a single framework that allows us to extract and distill significant ideas. We believe that thinking of the brain as a complex system can redistribute the collective attention of diverse fields in such a way that they will be primed to make inroads into some of the most enduring and tantalizing mysteries in all of science.

The chapters in the volume you are holding reflect an ever-evolving understanding of how the brain—from genes to proteins, from cells to systems, and building blocks in between—generates behavior. Before publication of this book, 22 fellows of the Summer Institute in Cognitive Neuroscience attended a three-week meeting centered on the topics within this text and were challenged by Michael Gazzaniga to write a commentary reflecting current issues in the field. It is not an easy task to integrate a variety of conceptual and methodological approaches and produce an insightful commentary while escaping oversimplification of the issues. Nonetheless, the enterprise proved both exciting and worthwhile, and we hope that it illuminates and unifies some seemingly disparate concepts in a new light. Consistent with the nature of the cognitive neurosciences, we are a heterogeneous, multidisciplinary group. It is from this perspective, by tying together themes that transcend traditional research topics, that we present here our own reflections as we look toward the future of the field.

First, we will discuss recent methodological developments that have allowed for greater integration across multiple levels of analysis. These methods have expanded the range of research questions that can be asked and in some cases have led to new theoretical approaches. In turn, novel theoretical models have generated profound shifts in research foci. Cognitive neuroscientists are now exploring topics that were previously considered impossible or implausible for scientific investigation (e.g., social cognitive neuroscience) and are also revisiting old themes with a new mindset (e.g., the contribution of nature versus nurture). To conclude, we reflect on how this “new” cognitive neuroscience is begin-

ning to influence everyday life, including public policy, education, and healthcare.

Methods

The evolution of cognitive neuroscience has been driven largely by the development of increasingly sophisticated experimental methods. These methods and novel techniques enable us to address hypotheses that were previously unimaginable, such as establishing a causal relationship between patterns of neural activity, cognitive processes, and complex behavior. Methods that are currently under development are allowing us to better estimate the spatiotemporal structure of neural data, move from correlation-based methods to experimental manipulation of brain activity, and gain a deeper understanding of the importance and instructive value of individual differences.

One significant outcome of recent technological advances is the ability to quantitatively measure brain structure (e.g., diffusion tensor imaging and virus tracing technology) and function (e.g., high-resolution functional magnetic resonance imaging (fMRI) and single-unit recordings in humans) at a higher spatial and/or temporal resolution than ever before. The enhanced precision of these measurements is accompanied by increasingly sophisticated data analysis techniques, computational models, and theoretical interpretations. For example, novel multivariate and pattern classification approaches to fMRI data have revealed a spatial structure of hemodynamic activity beyond what is evident from traditional univariate approaches (Carlson, Schrater, & He, 2003; Cox & Savoy, 2003).

One challenge that remains is to bring these methods to bear on the long-standing issue of modular versus distributed processing networks in the brain. An increasing number of

Summer Institute for Cognitive Neuroscience 2008, Lake Tahoe, California. All coauthors contributed equally to this chapter

multivariate analysis techniques enable us to describe brain activity on a network level, including independent and principal component analyses, dynamic causal modeling, and multivoxel pattern analysis. Such methods allow us to test existing theoretical ideas but also reveal new issues that were previously not accessible to scientific measurement. For example, pattern classification techniques have reframed the issue of object processing in the ventral temporal cortex from *where* an object is represented to *how* patterns of brain activity represent information (Norman, Polyn, Detre, Haxby, 2006). We anticipate further methodological advances, as increased resolution reveals new scales of organization of the human brain.

A key objective of any scientific investigation is to uncover causal structure. Continuing advances in functional brain imaging enable neuroscientists to infer functional-anatomical correlates from patterns of blood flow during task performance, but these methods are limited to uncovering correlational links, not causal ones. Historically, the ability to draw conclusions regarding the necessity of a brain structure to perform a particular cognitive operation has been limited to lesion studies in animals and the rare occurrence of focal lesions in humans due to brain insults or surgery. In recent years, new methodological techniques such as transcranial magnetic stimulation (TMS) have enabled the noninvasive manipulation of cortical activity in healthy individuals (chapter 9 in this volume). Additionally, in neurosurgical settings, researchers are increasingly using electrical microstimulation to directly activate a particular population of neurons and study its behavioral outcomes, as well as changes in the neurophysiology locally (around the electrode) and in other parts of the brain that are connected to the stimulated region, (e.g., Kawasaki & Sheinberg, 2008; Houweling & Brecht, 2008). On a different scale, gene knockout manipulations in mice reveal remarkable insights into the genetic basis of cognition and behavior (e.g., Hung et al., 2008; Gunnerson et al., 2007). For example, Hung and colleagues found enhanced performance in spatial learning but impaired long-term retention in Shank1 knockout mice, suggesting an important and complex role for the Shank family of proteins in normal cognitive development. Another approach using neuropharmacological methods has led to exciting new data that point to a link between serotonin levels in the brain and interpersonal trust among human participants (Crockett, Clark, Tabibnia, Lieberman, & Robbins, 2008). As we continue to work toward the refinement of this diverse toolbox of experimental approaches, we are hopeful that they will help to further elucidate the causal links between brain function, structure, and behavior.

An emerging trend in cognitive neuroscience methodology is the study of how individual differences contribute to our understanding of the human brain. Psychologists and

neuroscientists have conventionally relied on aggregating data across a sample of subjects to draw conclusions about how the “average” or prototypical brain might function. In reality, individual differences abound in the dynamic interplay between environment, genes, behavior, anatomy, and topographic patterns of brain activity. These differences offer a vast and scarcely explored source of clues about the nature of the mind and brain. To this end, new methods in correlating environmental and genetic variation with neural data offer exciting new possibilities in understanding how genes and the environment interact to produce a unique brain (see chapters 50 and 64 in this volume). Accounting for interindividual variance not only may give us a more ecologically valid way of looking at cognition, but also may provide important insights into more general, overarching processes that underlie different types of cognition across individuals and perhaps even species. Perplexing as it might seem, understanding universal neural architecture that creates the human condition could rely on first recognizing the complex processes that make each of us unique.

Theory

As reflected in the evolution of the topics addressed in *The Cognitive Neurosciences* volumes that have been published over the past 20 years, there have been major advances in how we conceptualize mind, brain, and body interactions. New methods described above have also led to groundbreaking findings related to genetics and synaptic physiology and to the functions and connectivity underlying complex neural networks. One way to better understand the complexity of the brain has been to further integrate levels of analyses, research perspectives, and conceptual approaches.

For example, genes and experience are no longer considered to be polar opposite factors of influence but are instead viewed as dynamically interacting. The emergent view is that genes serve as scaffolding for the ways in which experience can change brain organization and subsequent behavior. Our innate genetic blueprint determines the development of the human brain continuously throughout the life span at various neural levels (e.g., directing cellular organization, pruning, myelination, molecular structures, cortical maturation, and connectivity), laying the biological foundation for behavioral functionality. For example, various genes have been implicated in anomalous maturation of neural systems and developmental disorders (e.g., FOXP2, among other genes in developmental dyslexia) (Ramus, 2006) and have been linked to the presence of specific psychiatric conditions (e.g., abnormal pruning in schizophrenia and autism) (McGlashan & Hoffman, 2000; Boylan, Blue, & Hohmann, 2007). As our knowledge of gene-environment interactions advances, it becomes ever more evident that while specific genotypes are associated with the phenotypic expression of

certain behaviors, environmental factors are also required for the expression of particular genotypes.

An increasingly sophisticated understanding of these gene-environment interactions is one realm in which the concept of dynamic interplays has borne fruitful insights. One can also observe this dynamic interplay at the level of the brain, which is an ever-changing functional system regulated by adaptive feedback mechanisms. Recent experiments have explored the boundaries of this functional flexibility by looking at primary sensory areas, for which the functional architecture was previously thought to be hard-wired. Specifically, Sur and colleagues have shown that if visual input in the ferret is experimentally rewired during development to auditory cortex, there is an emergence of orientation tuning columns in those auditory areas (Majewska & Sur, 2006), an elegant demonstration that the experiential input to primary sensory areas can dramatically alter functional organization.

However, although the input to a brain area has a powerful ability to remodel cortical structure and function, it must act in concert with the scaffolding laid down by genes. Thus while the rewired auditory cortex shares a similar structure with V1, its orientation map was found not to be as regular and precise, showing that while the brain has the capacity for remarkable plasticity, future research will have to delineate the boundaries of this adaptive function.

At a higher level of cognitive operations, adaptive feedback mechanisms have profound influences on brain-behavior relations. This flexibility is essential to keep up with our ever-changing social environments through the adaptive implementation of appropriate behavioral responses. Accordingly, current research emphasizes the role of top-down control over the selection of information relevant to our behavioral goals. These top-down factors are now believed to modulate cognitive processes at many levels. The influence of top-down control can be illustrated by the activity of sensory neurons, which are modulated by task goals. For example, the neural response of early visual cortices has been shown to be upregulated prior to the onset of attentional cues (Hopfinger, Buonocore, & Mangun, 2000; Giesbrecht, Woldorff, Song, & Mangun, 2003). Top-down modulation has also been shown to prepare sensory areas for upcoming stimuli by filtering out, or suppressing, the processing of unnecessary information and enhancing the processing of relevant features as far downstream as the lateral geniculate nucleus within the visual system (O'Connor, Fukui, Pinsk, & Kastner, 2002). This act of filtering information not only has important implications in the sensory processing of a stimulus, but also can have a strong impact on how we remember a past event. For example, if an emotional event is depicted within a broader spatial context, our attention is focused on the emotional content, leading recognition memory for the background

information to suffer (Kensinger, Piquet, Krendl, & Corkin, 2005).

Top-down and attentional influences have been shown to affect not only systemwide neural activity, but also the precise timing of neural firing patterns within local populations of neurons. For example, increased attention enhances local gamma band synchrony or temporally coincident firing within a population of neurons in the motor system, which, in turn, upregulates the signal output from that region, thereby increasing the speed of behavioral responding (Fries, Womelsdorf, Oostenveld, & Desimone, 2008). These findings demonstrating the flexibility of brain and behavior relationships are a product of integrating different levels of analysis, from genetic expression to neurophysiology to functional organization to manifestations in behavior.

Given the recent trend toward integration of various levels of analysis, there is an emergent move to study neural activity in networks—both local and global—as well as systems across the whole brain. Let's consider an example: Brain regions involved in processing different features of an object (e.g., color, shape, motion trajectories) are reactivated when retrieving visual detail about the object from memory (Martin, 2007). This demonstrates that information about objects is represented via a distributed network in the brain, and various processes related to using such information rely on this distributed network. To fully account for such effects, cognitive processes and their underlying neuronal mechanisms must be analyzed on a global scale. Specifically, traditional neuroimaging studies have focused on the “subtraction paradigm,” in which functional localization is inferred from the brain's response to a particular cognitive task. A shift from localization to understanding large-scale network interactions parallels the emergence of the idea that one can achieve a greater understanding of neural processes by examining dynamic interactions between brain regions. Increasing interest in this network approach is reflected in the growing popularity of integrating multiple neuroimaging techniques in order to understand the structural and spatial (fMRI and diffusion tensor imaging), functional (fMRI, TMS, lesion, and event-related potential (ERP)), and temporal (electroencephalography and ERP) aspects of neural processes.

Another new approach is to study large-scale networks by examining spontaneous, task-independent fluctuations in blood oxygen level dependent (BOLD) signal that can reveal the intrinsic functional architecture of the brain. The first studies by Raichle and colleagues (2001) using positron emission tomography and later fMRI highlighted the fact that spontaneous neuronal activity accounts for the majority of the brain's energy metabolism. In the last several years, the number of studies using the recently developed method of resting-state functional connectivity, which examines temporal correlations between discrete brain regions, has increased

exponentially. While the exact nature and function of so-called resting-state networks and their relationship with anatomical connectivity remain to be elucidated, the field has already progressed to the point at which it is clear that resting-state functional connectivity measures show meaningful correlations with behavioral measures and can be used to understand aberrant cortical connectivity in different clinical populations (Castellanos et al., 2008). Furthermore, this focus on the resting state not only enables analysis of multiple neural networks, but also could have important implications cutting across various fields of cognition. Thus we see the recent emphasis on examination of spontaneous brain activity as an important theoretical advancement with the potential to open new avenues of research in the years to come.

Integration of different levels of analyses has also borne fruit in the fledgling field of social cognitive and affective neuroscience. These efforts have been in part facilitated by the convergence of perspectives (e.g., neuroscience, social psychology, economics) towards understanding higher-order functions of the human mind. As humans, we constantly reflect on ourselves and regulate our behaviors, thoughts, and emotions. Building on work in many areas of neuroscience (e.g., the study of the neural circuitry associated with various emotional experiences), advances have been made in identifying the role of brain areas involved with self-reflection and self-regulation, broadly defined. For example, recent work has started to reveal networks of brain areas that are recruited when we reflect about ourselves in the past, the present, and the future (Arzy, Molnar-Szakacs, & Blanke, 2008; Schacter, Addis, & Buckner, 2007). Another essential aspect of the human mind is our ability to navigate our rich and complex social environment. Indeed, networks of brain areas (i.e., medial prefrontal cortex, superior temporal sulcus, temporoparietal junction, fusiform, intraparietal sulcus, and amygdala) are now believed to be involved in the perception and understanding of others (i.e., their faces, actions, intention, and mental states) (Molnar-Szakacs & Arzy, 2009; Gobbini & Haxby, 2007; Mitchell, 2008). One conceptual breakthrough has been the idea that we use overlapping neural systems in representing our own knowledge, beliefs, intentions, and actions as we use to understand others. This “simulation” account finds empirical support in work by Rizzolatti and colleagues, who have shown that a special class of neurons located in frontal and parietal cortices in the macaque (e.g., “mirror neurons”) respond to both executed and observed actions (Rizzolatti & Craighero 2004). Studies using neuroimaging techniques in humans have revealed a parallel frontoparietal mirror system that has been implicated in a variety of high-level cognitive and socioemotional processes that may rely, at least in part, on a simulation mechanism, including imitation and intention understanding (Iacoboni et al., 2005). These social cognitive and affective

neuroscience approaches are already moving the field in the direction of bringing more ecological validity to the study of cognitive neuroscience, paralleling the social world in which we live.

Integrating the cognitive neurosciences

The common underlying question shared by the many lines of research collected in the chapters of this book can perhaps be summarized as “How does the human brain integrate multiple levels of neural responses—from molecules to neurons, to circuits—to produce adaptive behavior?” Immediately, a second-order question comes to mind: “How do we make sense of all the information that we have acquired about these systems in the past 100 years?” While reading the previous sections on the current theoretical and methodological advances in the field, three key themes seem to stand out with striking relevance: *time*, *context* and *integration*.

Although none of the themes is new per se, they reemerge in current research and shape the landscape of the field in new ways. The necessity for an integrated approach to the space-time dimensions has always been a fundamental framework in the study of cognitive neurosciences. Recently, in addition to the quest for localization of function, an increased emphasis is placed on describing the temporal unfolding of neural activity, such as elucidating neural networks sharing temporal synchrony.

As such, *time* can be seen as a defining element of change, a critical feature to both brain physiology and behavioral output. For example, change in molecular constitution and neural connectivity determines the acquisition of new functional properties during development, perception, learning, memory encoding and retrieval, attention, and every other cognitive activity that one might consider. From an ontogenetic perspective, the temporal unfolding of plasticity critically shapes the growing organism’s cognitive machinery, from cellular mechanisms such as specialized neuronal growth and wiring to later developmental stages associated with higher cognitive functions such as language.

In a phylogenetic perspective, the timescale expands to include the historical record of progress toward understanding the biological bases of cognition. Thus the importance of the study of multiple biological models, with last common ancestors at different evolutionary times, has become increasingly recognized (for coverage of this topic, see Platek, Keenan, & Shackelford, 2006).

The consideration of *context* in current research emerges as an increasingly exciting dimension in cognitive neuroscience. It is now evident that the substrates of cognitive functions cannot be studied in isolation but that insight into their mechanisms and consequent outcomes can be gained only from the full contextual setting in which they develop and operate. From neuronal activity being strongly modulated

by the extracellular surround and glial support to the environmental context influencing the processing of a given stimulus, context plays a critical role in driving and explaining neural activity. One can also consider context more broadly, such as the evolutionary forces that have shaped human and nonhuman primate brains and behavior, driven by ecological and environmental factors. From cellular to systems to social neurosciences, there is no scarcity of examples demonstrating the importance of context.

Finally, the pages of this book consistently remind us of the overwhelming importance of integration. We believe that now is an excellent time for integration at all levels! Critical to the advancement of the field is integration in many forms: of methods, of biological models, and of conceptual perspectives, all reflected in the integration of researchers with very different scientific backgrounds investigating the complexity of the multifaceted discipline of cognitive neuroscience.

Clearly, the advancement of cognitive neuroscience strongly relies on the integration of knowledge across perspectives and domains. The attempt to overcome these limits is already evident in the current use of multiple techniques and interdisciplinary approaches, as well as in the increasing number of multidisciplinary teams and research collaborations. An integrative approach is fundamental to the achievement of our common goal: understanding the multitude of complex neural systems at the core of the causal relationship between our brain and our behavior.

Cognitive neuroscience and society

Over the past two decades, the field of cognitive neuroscience has developed at a frenetic pace. A new wave of research has moved past basic work aimed at understanding brain function toward examining the neural underpinnings of issues that are critically important to humanity. This is admittedly a lofty goal, but cognitive neuroscience has already made important contributions across several spheres of society. In conclusion, we highlight two specific cases in which the study of the brain clarifies and enhances our understanding and social well-being: uncovering the etiology and treatment mechanisms of psychiatric illness and informing behavioral interventions to enhance classroom learning for at-risk young children. While illuminating some societal issues, applied cognitive neuroscience research has complicated others, such as giving rise to legal controversies by fueling debates within the criminal justice system regarding culpability for our actions given certain brain insults. Finally, the surge in applied work has also placed neuroscience research squarely in the public eye. We will conclude with a discussion of the heightened responsibility required of scientists to communicate their findings to the general public in an informative and accurate fashion.

Cognitive neuroscience research is making important contributions in a number of clinical domains, notably in our understanding of the etiology of psychiatric disorders such as depression. For example, brain research has led to the development of animal models that provide a unique window into the cellular and molecular mechanisms of this disorder (Fuchs & Flugge, 2006; McArthur & Borsini, 2006). In humans, neuroimaging techniques in combination with genetic analyses have assisted in characterizing both the structural and functional profiles associated with affective disorders. For instance, the serotonin transporter gene linked polymorphic region (5-HTTLPR) has been identified as a predictor of vulnerability for affective disorders and exaggerated amygdala response to emotional stimuli, as observed by using fMRI techniques (Munafò, Brown, & Hariri, 2008, Hariri et al., 2002). Patterns of fMRI activity can also predict the probability of remission from clinical depression and potentially guide treatment choices. Canli and colleagues (2005) found that greater amygdala activation to emotional faces predicts subsequent symptom reduction in depressed patients, identifying a subgroup of individuals who are predicted to have poorer chances of spontaneous alleviation of depressed symptoms. Furthermore, a number of experiments suggest that repetitive TMS to certain cortical regions might actually exert clinically significant antidepressant effects. Several studies from the laboratory of Alvaro Pascual-Leone (e.g., Stern, Tormos, Press, Pearlman, & Pascual-Leone, 2007) found that repetitive stimulation of the left or right dorsolateral prefrontal cortex was associated with symptom reduction in individuals with recurrent unipolar depression when compared with sham stimulation. These lines of research provide exciting evidence and hope that cognitive neuroscience will inform the prevention, diagnosis, and treatment of severe and disabling conditions of the brain and mind.

Advances in the fields of cognition and neuroscience also shed light on our understanding of brain processes such as learning and memory, which are critical to educational practices. Recent research topics include visual perception benefits accrued from playing complex video games (Green & Bavelier, 2003), focused attention on interventions for both children and parents, reading interventions during the development of language perception, and possible neural correlates of women's underperformance in math (e.g., Stevens and Neville, 2008; Varma, Mc Candliss, & Schwartz, 2008). Well suited to integrating the once disparate disciplines of neuroscience and education, cognitive neuroscience is even elucidating neural algorithms for specific scholastic subject areas. For example, in the domain of mathematics, this approach has begun to identify the brain bases of numerical thinking. Behavioral and neuroimaging results suggest that children and adults share a "number sense," that is, a system for representing approximate numerical magnitude

(Dehaene, Spelke, Pinel, Stanescu, & Tsivkin, 1999; Jordan & Brannon, 2006). It has recently been found that this neural system is compromised in the approximately 5% of children who have developmental dyscalculia, a specific mathematical learning disability (Price, Holloway, Vesterinen, Rasanen, & Ansari, 2007).

Such neuroscientific findings encourage very early interventions to target deficits, even before children enter elementary grades. One such recent behavioral intervention is to play linear number board games akin to Chutes and Ladders, which was shown to boost numerical magnitude understanding in preschoolers who were at risk for later falling behind in mathematics (Ramani & Siegler, 2008). This approach is one example of how cognitive neuroscience is helping in the field of education by translating neuroscientific findings into cognitive interventions that can effectively be implemented at an early age.

Another interesting implication of cognitive neuroscience is its intersection with the law (Gazzaniga, 2005). In a famous court case in 1982, John Hinckley, Jr., who had attempted to assassinate President Ronald Reagan, submitted CT scans indicating cortical atrophy in an attempt to gain a verdict of not guilty due to insanity. In a controversial decision, Hinckley's defense ultimately succeeded (*U.S. v. Hinckley* 1982). Since this historical case, evidence based in cognitive neuroscience, albeit remaining highly controversial, has played an increasingly important role in the criminal justice system. For example, fMRI-based lie detection tests have become a part of legal proceedings (Kozel et al., 2005; Gamer, Bauermann, Stoeter, & Vossel, 2007), although empirical evidence for their reliability is still in question. While providing an illuminating example of the integration of cognitive neuroscience and the law, it is important to ensure that such progress does not compromise justice (Poldrack, 2008). Most important, the legal concept of responsibility should not be weakened by an endless flood of legal defenses attempting to reduce culpability on the basis of subtle neural defects (Gazzaniga, 2005).

Another concern centers on the issue of privacy (Tovino, 2007). Neuroimaging methods allow us to extract health-related information based on patterns of neural activity and brain structure. For instance, we currently have the ability to predict cognitive decline (Small et al., 2008) and risk for psychiatric illness (Phillips & Vieta, 2007) on the basis of the detection of biomarkers using neuroimaging. It is likely that the use of fMRI in the private sector will only increase in the coming years. Laws to regulate the use of private health-related information and to protect the privacy of individuals will have to be enacted.

These are only a few of the ethical challenges faced by those whose job it is to update societal institutions and policies with the knowledge gained from cognitive neuroscience. The newly emerging field of neuroethics

should play a vital role in protecting society from the detrimental effects or imprecise applications of neuroscience and must thoroughly address the difficult ethical dilemmas that arise.

To encourage public dialogue and awareness of the philosophical, ethical, and practical implications of neuroscientific research, U.S. president George H. W. Bush declared the 1990s to be the Decade of the Brain. Whether it was this proactive step on the part of the American government or the rapid and prolific development of the field of cognitive neuroscience, public interest in the brain has exploded. In the entire decade between 1980 and 1990, a mere 100 books were published related to cognitive neuroscience; this number increased tenfold during the Decade of the Brain to more than 1000 books. Since the year 2000, this figure has multiplied to over 4000 volumes on cognitive neuroscience in print (as determined by a keyword search of "cognitive neuroscience" on www.amazon.com in June 2008). Many of these books were written for a lay audience and have become mass market paperbacks reaching a public that is fascinated by the brain—and rightfully so. Cognitive neuroscience has the potential to explain the neural processes underlying consciousness, free will, morality, sexuality, emotion—all of those seemingly ineffable qualities that set us humans apart from other animals. As a result, many new research findings have implications that reach far beyond the relatively small cognitive neuroscience research community. The unique position of cognitive neuroscience of being a rather public science cannot be taken lightly, as we have the potential to profoundly alter and reshape the perception of the human condition in the public eye.

The pressure to present complex empirical data and theories so that they are accessible to nonexperts has sometimes led to excessive reductionism in the popular media. Catchy headlines such as "Nose cells may help paralyzed to walk again," "This is your brain on politics," and "'God spot' researchers see the light in MRI study" attempt to generate interest in readers but provide inaccurate "just-so" explanations of brain function. Admittedly, it is difficult to balance the goal of providing straightforward answers to difficult questions with effective communication to a broad audience, even for those of us in the field. Consequently, we as researchers must work together with journalists, writers, and reporters in the media to recognize and embrace our responsibility to help experts, as well as nonexperts, understand and appreciate the pluralism of our data and of the human mind. Cognitive neuroscience is an evolving discipline, and that is what makes it so exciting, but it also means that insights are sometimes fragmentary, methods suffer from shortcomings, and theories are often conflicting. Accurately representing and communicating these complexities will allow the public to see the passion but also the tireless effort of cognitive neuroscientists. We should therefore be eager to invite

society on this exciting journey toward a deeper understanding of how the human brain creates a mind that has the potential to fall ill, to forget, or to lose sense but also to reason, to empathize, to dream, and to love.

INDEX

A

- Abulia, 568, 573
Acetylcholine, 1140
Acetylcholinesterase (AChE), laminar shifts in, 34
Across-stimulus generalization, in auditory training, 357–358
Across-task generalization, in auditory training, 355–357
Actin polymerization, 146–147
Action
 in intention understanding, 635–636
 in learning and learning transfer, 160–161
 object concepts in support of, 1032–1035
Action-based choice, 1081
Action planning
 central nervous system and, 541–543, 547
 hierarchical nature of, 642–644
 motor primitives in, 541–543
Action semantics, 648–650
Actions
 fear, neural basis of, 914–918
 nature of, 906
 in Pavlovian conditioning, 906–909, 914–918
Actual code, 420, 432
Actual decoder, 420, 432
Actual encoder, 420
Ad auctions, 1250–1251
Adaptation
 aftereffects in face recognition, 468
 defined, 436–437
 eye movements and, 517–518
 fMRI, 715
Adaptive control, basal ganglia function and, 375–377
Adolescence
 cognitive development in, 73–82
 cognitive control, 73, 76–77
 current and future directions for research, 81–82
 fluid reasoning, 77–81
 structural brain development, 73–74
 working memory development, 73, 74–76
 stress and, 893
Adoption studies, language impairment, 856
Adulthood, stress and, 893
Affective theory, 1093–1094
Afference, posterior parietal cortex (PPC) and, 600–601
Aggression, violent video games and, 155
Aging process
 aerobic exercise and cognitive processes, 157
 Alzheimer's disease, 147, 270, 1009–1010, 1237
 episodic memory deficits, 753
 relational reasoning and, 1008–1011
 overview, 1095–1097
 in processing emotional information, 928–929, 931, 932
 fMRI activation to specific stimuli, 936–937, 941, 942
 imaging genetics studies, 947–948
 in retrieval of emotional memories, 731–733
 in self-regulation, 957
 in threat detection, 958
 valuation in decision making, 1097
Analogical reasoning, 78, 79, 1008, 1010, 1012–1013
Anger, facial expression and amygdala response, 935
Animal studies. *See* Birds; Cats; Comparative approach; Ferrets; Fish; Frogs; Monkeys; Neural populations in primate cortex; Rodents
Anisomycin, 698
Anisotropy, 1127–1128
Anomia, 260
Anoxia, 1128–1130
Anterior area (AI), empathy and, 975–982
Anterior cingulate cortex (ACC)
 in conditioned fear reactions, 917, 918
 conflict-control model, 252–257
 in decision making, 1023–1027
 in emotion regulation, 963, 964, 965–970
 empathy and, 975–981
 moral judgment and, 988–991, 992, 993–994
 regulation of control, 709
 reward/value signals in limbic system, 228
 in threat detection, 957–958
Anterior inferior parietal area (AIP), mirror neuron system and, 626–633, 634–635
Anterior intraparietal sulcus (aIPS), goal representation and, 644–645, 647
Anterior olfactory nucleus, 326
Anterior rostral MFC, 1026–1027
Anterior temporal lobes (ATL), in semantic cognition, 1061–1064
Anterograde alteration, of synaptic plasticity, 114–116
Anticipation, 962
 anticipatory signals, 219–223
 movement intention and, 599–601
Antidepressive theories, 1243
Antisocial personality disorder (APD), moral judgment and, 988
Aphasia, 148, 259–260, 1033, 1236
 double dissociation in processing, 767–768, 780, 781
 following stroke, 259–260, 810
 morphological deficits in, 779, 780
 phonological processing in, 767–768
 semantic, 1063–1064
 syntactic deficits and, 808–813
Agnosia, 792
Agrammatic aphasia, 808
Agraphia, 799
Akaike information criterion (AIC), 378, 379
Akakievitch, Akakhi, 310
Alexia, 260, 794, 799
Alexithymia, 979
Alhazen, 511, 514
Allelic variation, 89–90
Altered states of consciousness, 1139
Alzheimer's disease, 147, 270, 1009–1010, 1237
American Association of Anatomists, 9
American Sign Language (ASL), 169–170
Amnesia
 in blocking reconsolidation, 694–695
 cue-induced, 693–694
 experimental, 696–697
 future-event simulation and, 752–754
 HM (patient), 656, 659, 675
 learning rewarding nature of sensory states, 592–593
 medial temporal lobe function
 habit learning studies, 679–680
 retrograde amnesia, 684–685
 working memory studies, 678–679
 recovery from, 696–697
 source, 1118
 time-dependent behavioral impairment, 694–695
AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazole propionate) receptors
 in fear reaction, 912
 synaptic plasticity and, 111–113, 118–119
AMPA endocytosis, 101
Amygdala
 context effects and, 935–942
 context conditioning, 939–940
 experimental context, 941–942
 facial expression, 935–939
 fMRI activation to specific stimuli, 936–937, 941–942
 and domain-specific neural circuitry, 1036–1038
 in emotion regulation, 966
 nonconscious processing of emotion, 1186
 social cognition, 1185
 in fear response, 1095–1096
 conditioned fear actions, 914–918
 conditioned fear reactions, 891–896, 911–913, 930
 infant, 891–896
 parallel processing, 913–914
 memory for visual details of emotional stimuli, 726–727
 modulation of hippocampal consolidation, 729–730
 moral judgment and, 988, 989–990
 organization of, 909–911

- Apoptosis (programmed cell death),
 cross-species comparisons of cortical
 development, 16
- Apperceptive agnosia, 792
- Appetitive conditioning research, 914
- Apraxia, 599, 648–649
 conceptual, 649
 ideomotor, 649
- Aquatic cetaceans, in evolutionary biology,
 52
- Arcuate fasciculus (AF), connectivity studies,
 57–58, 261–262, 263
- Areal domain, neocortical development, 7,
 18–19
- Aristotelian philosophy, 49
- Aristotle, 1116
- Arousal
 in learning and learning transfer, 161
 states of consciousness and, 1139–1140
- Artificial grammar learning, 880
- Asperger syndrome, empathy and, 979
- ASPM (abnormal spindlelike microcephaly
 associated), 59
- Assessment. *See names of specific assessment
 instruments*
- Assimilation, in color vision, 387–388
- Association studies
 basal ganglia function and, 576
 nature of, 856
- Associativity
 in conceptual representations, 1032
 in memory formation, 113–114, 119,
 121–122
 in valuation process, 1087
- Asynchrony detection, in relative-learning
 tasks, 359
- Ataxia, 603
- Athletic domain
 aging process and, 157
 complex learning environments, 156–158
 experience-dependent learning, 155, 157
- Atonia, 1139
- Attachment, infant
 fear learning and, 891–896
 maternal separation/deprivation in, 895
 nature of, 889–890
 neonatal handling, 895–896
 neural circuitry and, 890–891
 odor learning in, 889–890
 rearing environment alteration, 895
- Attention. *See also Cognitive (executive)
 control; Selective attention; Visual
 attention*
 attention training for children, 173–175,
 176
 attentional control processes, 185–186,
 251–252
 basal ganglia function and, 573–575
 behavioral phenomena of, 189–200
 attentional bottleneck, 282–283
 consciousness as, 199–200
 control of attention, 198–199
 feature binding, 197–198, 274–276
 focused versus distributed attention,
 199
 limits on attention, 189–191
 in perceptual processing, 926–928
 selection process, 191–193
 timing, 193–197
 consciousness versus, 199–200, 1141–1143
 control of, 186, 198–199
 integrating with conflict detection,
 251–257
 Sylvian fissure, 186, 263–264
 defining, 185, 219
 effect of emotion on allocation of, 726–727
 emotion and, 925–932
 automaticity, 929–931
 behavioral effects on perception,
 926–928
 cultural factors, 931–932
 current behavior goals, 932
 neural circuits underlying attention,
 928–929
 neural processing in perception,
 925–926
 personality factors, 931–932
 event-related potentials (ERPs) in, 170,
 176, 186, 193, 196–197, 199,
 254–255
 feedback in visual, 1165–1175
 focused versus distributed, 199
 Hillyard principle, 170
 limits of, 189–191
 behavioral coherence, 191
 disappearance of, 191
 general resources, 190
 structural interference, 189–190
 method of selection, 192–193
 changes of tuning or selectivity, 193
 facilitation, 192–193
 inhibition, 193
 microcircuitry of, 186
 orientation of spatial, 795–796
 plasticity in development of, 170–173
 priming and, 196, 197, 199
 stages of, 193–197
 attentional blink, 196, 197, 199, 1153,
 1209
 early versus late, 193–197
 explicit processing and, 196, 197
 implicit processing and, 195–197
 psychological refractory period, 194, 195
 reverse hierarchy theory (Hochstein and
 Ahissar), 194
 top-down control signals, 186–187,
 211–212, 213–214, 220
 video games and, 157
- Attention-deficit/hyperactivity disorder
 (ADHD), 82, 147, 176, 865
 basal ganglia function and, 568, 574
- Attention Network Test (ANT), 192
- Attentional blink, 196, 197, 199, 1153, 1209
- Attentional bottleneck, 282–283
- Attentional control signals. *See also Cognitive
 (executive) control*
 conflict and, 252–253
 nature of, 251
- Attentional dyslexia, 797
- Attentional load theory, 206–207
- Attentional processing, in selective attention,
 293–298
 feature-selective modulation of rhythmic
 synchronization, 297–298
 gamma-band synchronization, 293–295
 inter-areal synchronization, 298–299
 preparatory attentional states, 295
 temporal expectancies of target processing,
 296–297
- Attractive bias, 531
- Attractor networks, 121–123
- Auditory cortex
 neuroplasticity in, 147, 167–169
 in perceptual learning, 132–133,
 353–363
 peripheral auditory attention, 170–171
 rewiring vision into auditory pathway,
 95–98, 131, 166–167
 visual deprivation and auditory
 development, 167–169, 321
- Auditory filter, 345
- Auditory masking, 343–351
 energetic, 344–345, 349, 351
 informational, 345–351
 described, 345–348
 simultaneous multitone maskers and,
 345–348
 speech recognition process, 348–351
 perceptual, 348–349
 simultaneous multitone maskers,
 345–348
- Auditory-motor integration networks, verbal
 working memory in, 771
- Auditory pathway, rewiring vision into,
 95–98, 131, 166–167
- Auditory processing, 132–133, 353–363
 characteristics of, 358–362
 across-task generalization, 355–357
 learning on trained condition,
 354–355
 in fear conditioning, 913
 neural processes in
 described, 353–358
 neural underpinnings of perceptual
 learning, 362–363
 object analysis, 367–380
 concept of auditory object, 367–368
 fMRI studies in, 371–379
 manipulation of natural stimuli,
 368–370
 natural stimuli, 368–370
 stimuli based on sequence of objects,
 370–371
 synthetic stimuli for, 370
- Autism, 147, 166
 empathy and, 979
 motor cognition and, 636–638
 phenomenal consciousness in, 1118
- Autism spectrum disorder (ASD), early
 language acquisition, 845–847,
 848
- Autobiographical memory, 684–686, 726,
 731, 753
- Autobiographical Memory Interview (AMI),
 686, 687, 753
- Automaticity, of emotional processing,
 929–932
- Autosomal dominant retinitis pigmentosa
 (adRP), 388–389
- Avians. *See Birds*
- Avoidance conditioning, 116, 907–909

- Awareness. *See also* Consciousness
 declarative memory and, 686–687
 detecting, following brain injury,
 1125–1127
 self-awareness, 954–955
 visual. *See* Visual awareness
 Axel, Richard, 324–325
- B**
- Back-propagation of error, 1050
 Balanced Emotional Empathy Scale (BEES),
 978–979
 Balint's syndrome
 characteristics of, 269, 270–273, 798
 following stroke, 198
 loss of feature-based attention, 271–272
 loss of object-based attention, 270–271

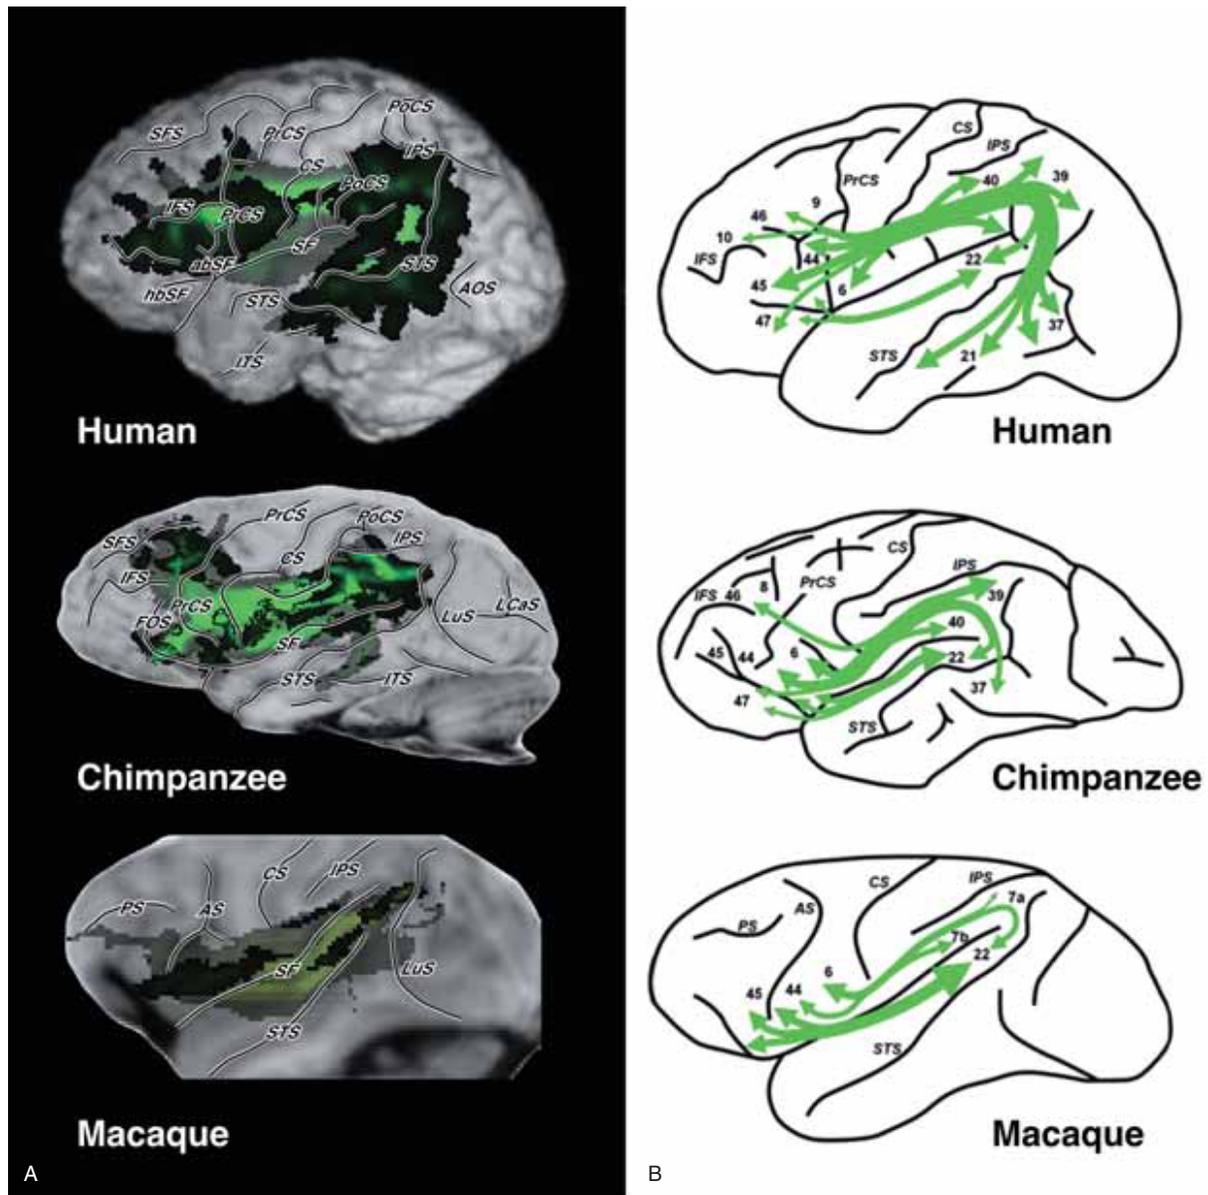

PLATE 1 Evolution of the human arcuate fasciculus (AF), which interconnects frontal and temporal language areas, based on the comparative diffusion-tensor imaging (DTI) results of Rilling and colleagues (2008). (A) Average tractography results from the left hemispheres from 10 humans, three chimpanzees, and two macaque monkeys. (B) Schematic representation of the results shown in A, representing the cortical endpoints of the tracts in terms of Brodmann's areas. Both humans and chimpanzees have a distinct AF, although in humans the AF includes strong connec-

tions with the temporal cortex below the superior temporal sulcus (STS), including area 21, a region where word meaning is represented. Chimpanzees have very few fibers in the AF that extend to the cortex inferior to the STS. Macaques do not have a definite AF: fibers traveling between the posterior inferior frontal cortex and posterior temporal lobe take a more ventral route, passing deep to the insula, and include few if any fibers with endpoints inferior to the STS. (See figure 3.4.)

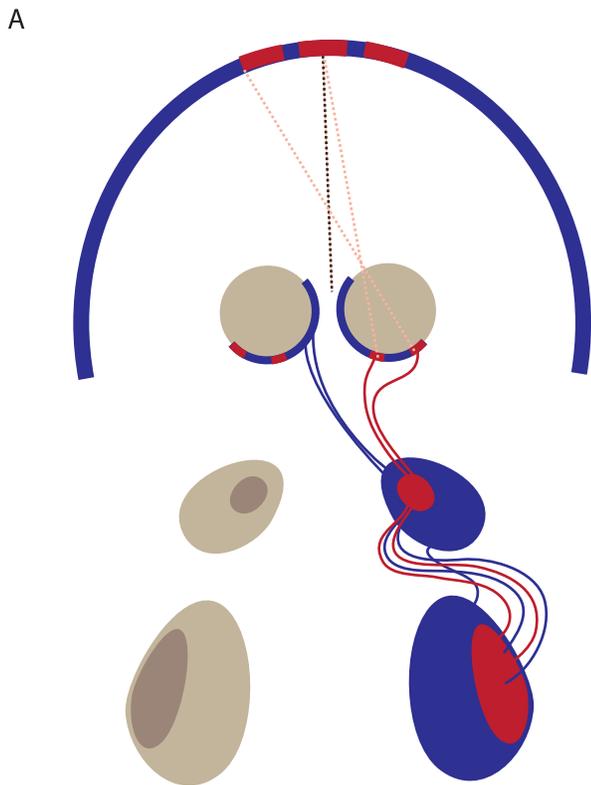

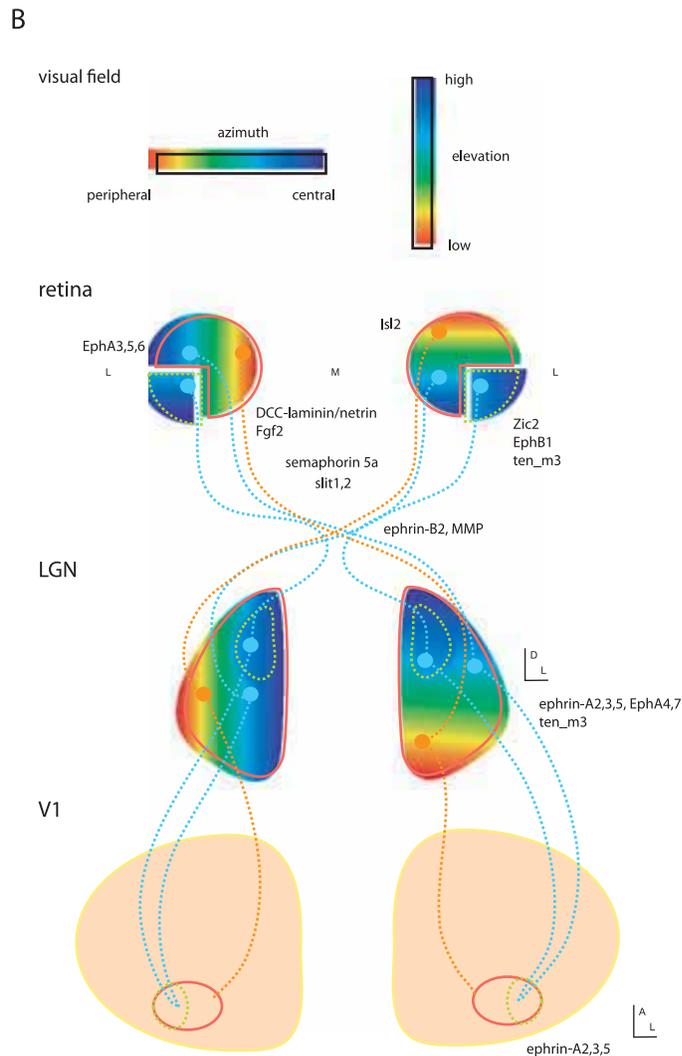

PLATE 2 (A) Representation of the rodent visual pathway. Retinal ganglion cells project to the LGN, which in turn projects to the primary visual cortex (V1). A central region of the visual field is represented by both eyes along the pathway (ipsilateral, red; contralateral, blue). Contralateral and ipsilateral retinal ganglion cell terminals representing this binocular region are segregated in the LGN (red, ipsilateral zone; blue, contralateral zone). Geniculocortical fibers representing this region converge onto a binocular zone located in the lateral half of V1 (red, binocular zone; blue, monocular zone). (B) Schematic representation illustrating retinotopic map organization at each stage of the visual pathway and known guidance cues contributing to patterning. The visual field can be divided into two Cartesian axes, azimuth and elevation. For clarity, the azimuthal map on the left is diagrammed onto the visual pathway of the right hemisphere. The elevation map on the right is diagrammed onto the pathway of the left hemisphere. In reality, both axes of visual space are represented concurrently in both hemispheres. The ganglion cell sheet of the retina is divided into a contralaterally projecting region and an ipsilaterally projecting region. The ipsilateral retina originates from the ventrotemporal quadrant and is characterized in late

embryogenesis by Zic2 and EphB1 expression. Conversely, the contralateral retina is characterized by Isl2 expression. Retinal ganglion cells express DCC and are repulsed out of the optic head by laminin and netrin. Factors, such as semaphoring-5a, keep retinal axons on course in the optic tract, where ipsilateral axons are repulsed by ephrin-B2 while contralateral axons decussate. High temporal to low nasal gradients of EphA receptor and ten_m3 expression in retinal axons likely influence terminal zones onto gradients of ephrin-A in the LGN. Ipsilateral axons terminate in a dorsomedial core of the LGN, segregated from surrounding contralateral axons. Activity-dependent refinement is necessary for proper eye-specific segregation. While ephrin-A gradients shape retinotopic termination zones, ten_m3 specifically influences ipsilateral targeting. Geniculocortical axons innervate V1. Ipsilateral inputs and corresponding contralateral fibers converge in the lateral binocular zone, while contralateral inputs representing regions not detected by the ipsilateral eye terminate in the medial monocular zone. Loss of ephrin-As leads to the disorganization of cortical maps only on the azimuthal axis, suggesting that other, unidentified factors contribute to the mapping of elevation. (See figure 6.1.)

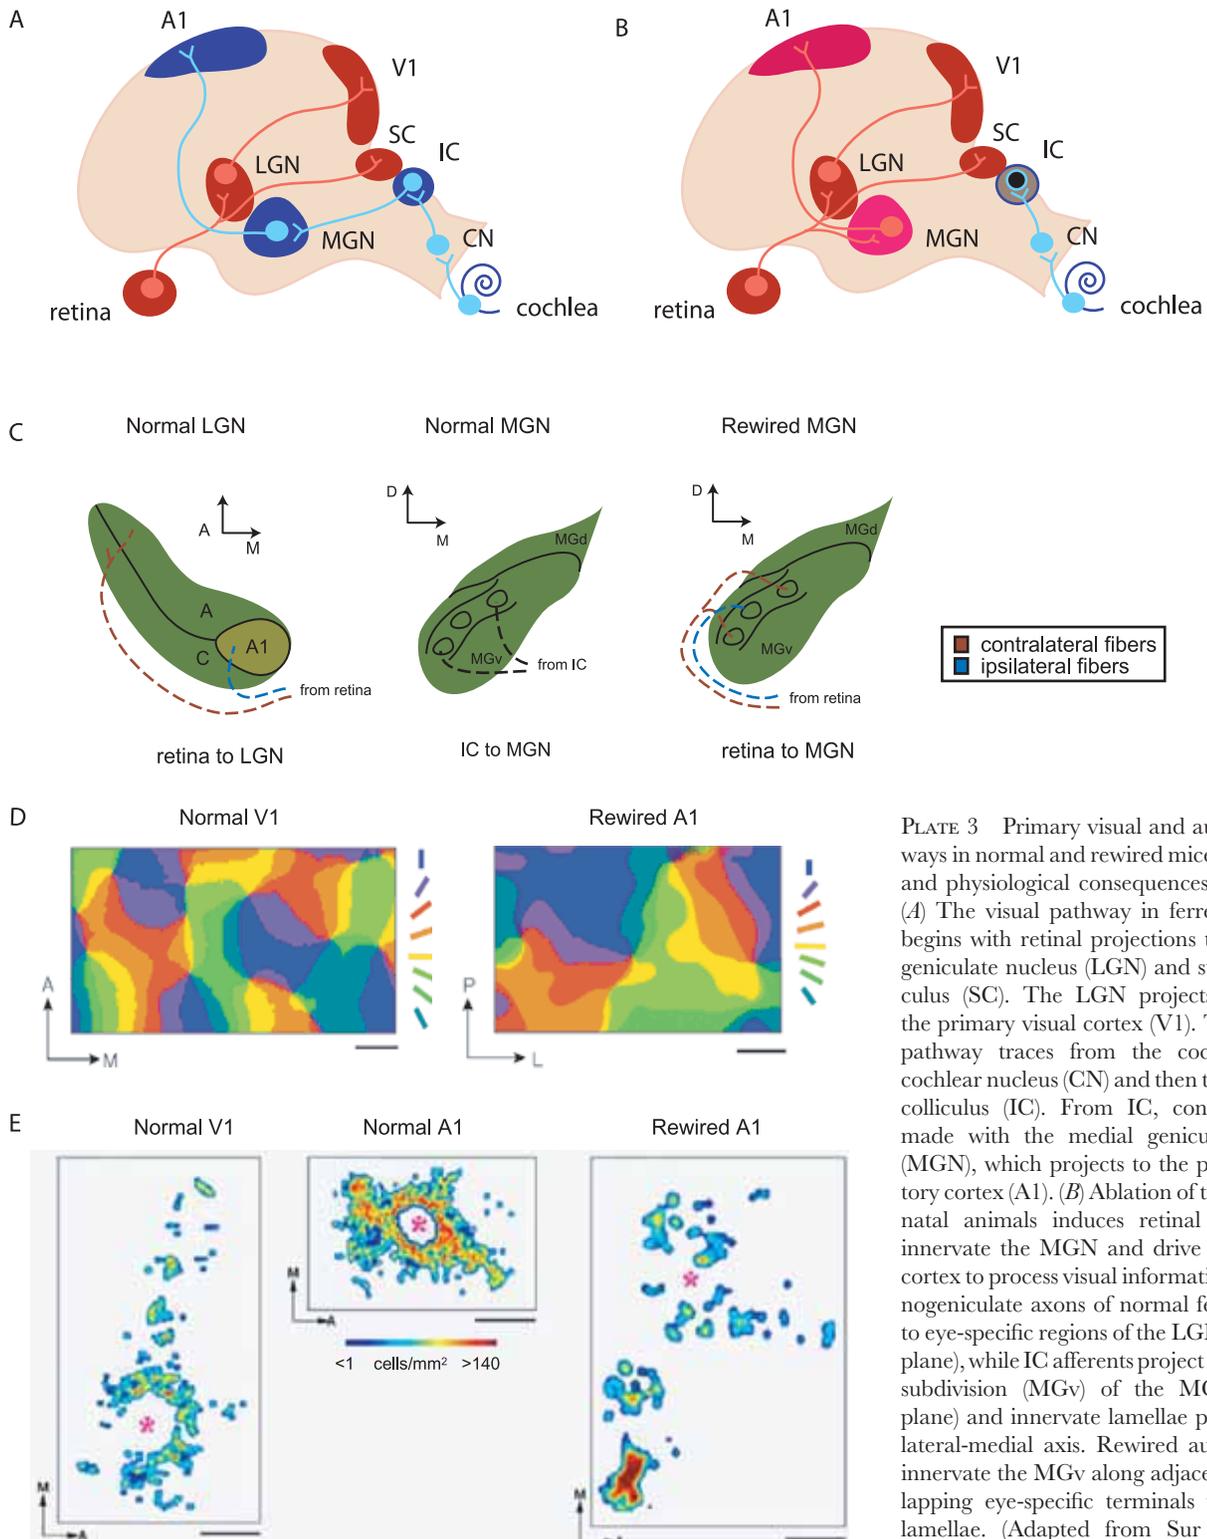

PLATE 3 Primary visual and auditory pathways in normal and rewired mice: anatomical and physiological consequences of rewiring. (A) The visual pathway in ferrets and mice begins with retinal projections to the lateral geniculate nucleus (LGN) and superior colliculus (SC). The LGN projects in turn to the primary visual cortex (V1). The auditory pathway traces from the cochlea to the cochlear nucleus (CN) and then to the inferior colliculus (IC). From IC, connections are made with the medial geniculate nucleus (MGN), which projects to the primary auditory cortex (A1). (B) Ablation of the IC in neonatal animals induces retinal afferents to innervate the MGN and drive the auditory cortex to process visual information. (C) Retinogeniculate axons of normal ferrets project to eye-specific regions of the LGN (horizontal plane), while IC afferents project to the ventral subdivision (MGv) of the MGN (coronal plane) and innervate lamellae parallel to the lateral-medial axis. Rewired auditory fibers innervate the MGv along adjacent, nonoverlapping eye-specific terminals within MGN lamellae. (Adapted from Sur & Leamey, 2001.) (D) Orientation maps are present in

normal V1 and rewired A1 of ferrets using optical imaging of intrinsic signals. The animal is stimulated with gratings of different orientations, while hemodynamic changes in red wavelength light reflectance caused by increases in oxygen consumption are detected from the cortex with a digital camera. The orientation preference map is calculated by computing a vector average of the response signal at each pixel. Color bar: color coding representing different orientations. Scale bar: 0.5 mm. (E) Retrograde tracers reveal the pattern of horizontal connections in superficial layers of normal V1, normal A1, and rewired A1 of ferrets. Distribution of horizontal connections in rewired A1 more closely resembles that of normal V1 than normal A1 and potentially contributes to the refinement of orientation mapping in rewired A1. Scale bars: 500 μ m. (Adapted from Sharma, Angelucci, & Sur, 2000.) (See figure 6.2.)

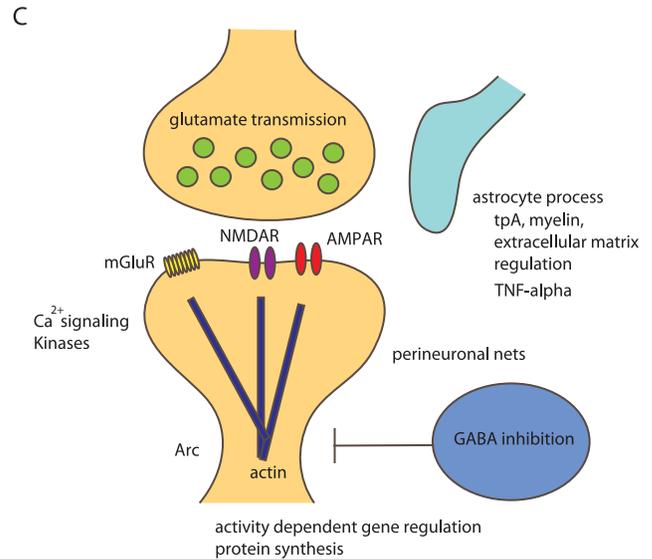

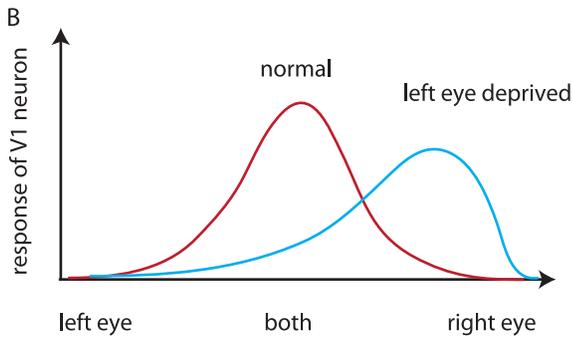

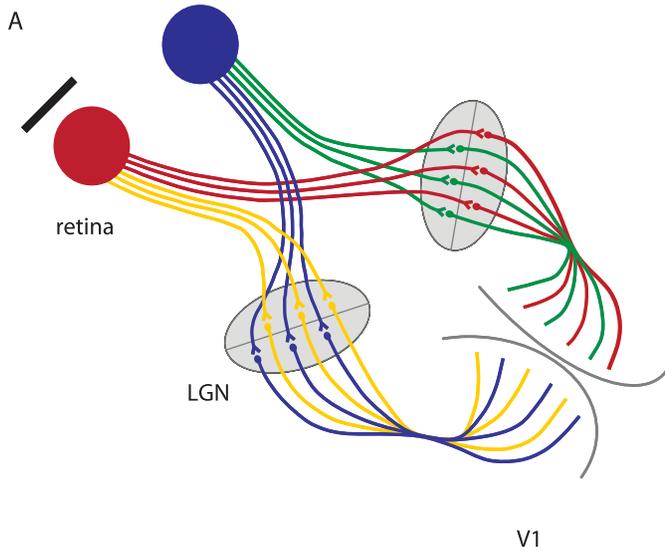

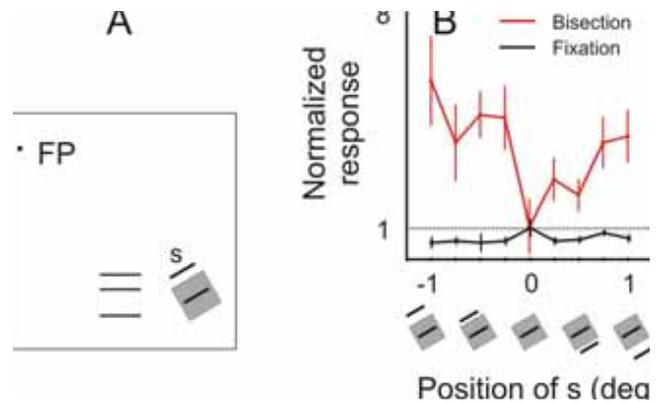

PLATE 4 Ocular dominance anatomy and plasticity in V1. (A) Contralateral and ipsilateral fibers are segregated in the LGN but converge onto binocular cells in V1. (B) When one eye is deprived of input for a brief period during the critical period, or for a longer period during adulthood, binocular cells in V1 become more strongly driven by the nondeprived eye. Ocular dominance plasticity reflects both structural and functional changes of synapses. (C) The cellular and molecular mechanisms of ocular dominance plasticity are an active area of investigation. Processes known to play a critical role include signal transduction pathways downstream of the mGluR and NMDARs, and activity-dependent changes in AMPAR content at synapses, mRNA transcription, and protein translation. GABAergic inhibition is involved in inducing the critical period of ocular dominance plasticity, and extracellular matrix factors and perineuronal nets surrounding inhibitory interneurons have been implicated in constraining plasticity. (See figure 6.3.)

PLATE 5 Perceptual learning modifies contextual influences in V1. (A) The stimulus paradigm. The three horizontal parallel lines indicate the task stimulus. Monkeys were trained to determine whether the middle line was closer to the upper or the lower flanker. After training monkeys on this bisection discrimination task, responses of single V1 neurons to another stimulus, the test stimulus, were recorded when the animal either performed the trained bisection task, or simply maintained its fixation at the fixation point (FP). The test stimulus consisted of two lines, an optimally oriented line fixed in the center of the receptive field (denoted by the gray square), and a second parallel line (indicated by "s") placed at different locations on either side of the RF (see the cartoons at the bottom of B). (B) The normalized responses of a typical V1 cell to the test stimulus as a function of the position of line "s." When the animal was performing the simple fixation task, placing "s" on either side of the RF slightly suppressed neuronal responses relative to the responses at position 0 deg, where the two test lines were superimposed in the RF center. In contrast, when the animal was performing the bisection task, the weak contextual inhibition was changed into strong facilitation. (Adapted from Crist, Li, & Gilbert, 2001.) (See figure 8.3.)

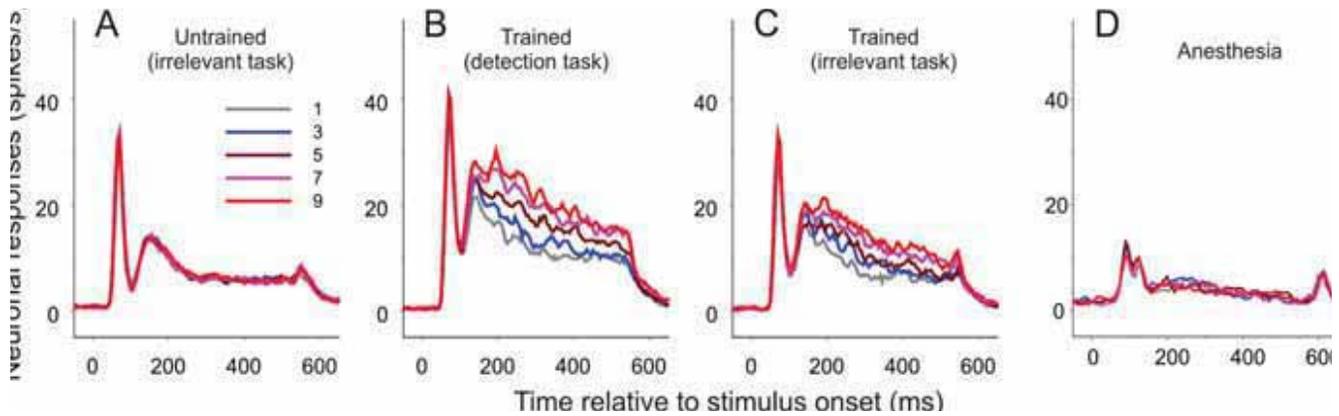

PLATE 6 Learning- and task-dependent changes in V1 associated with training on contour detection. Shown here are averaged population neuronal responses to visual contours consisting of 1, 3, 5, 7, and 9 collinear lines embedded in an array of randomly oriented lines (for example see figure 8.1). Time 0 indicates stimulus onset. (A) Neuronal responses in V1 of untrained monkeys are independent of contour lengths (the six peristimulus time histograms are superimposed), indicating the absence of contour information in

V1 responses. (B) Over the course of training the animals on contour detection, a late response component associated with contour saliency emerges—the longer the contours, the stronger the neuronal responses. (C) In trained animals the contour-related V1 responses are much weakened when the animals perform tasks that are irrelevant to contour detection. (D) Contour-related responses disappear in the trained V1 region under anesthesia. (Adapted from Li, Piech, & Gilbert, 2008.) (See figure 8.4.)

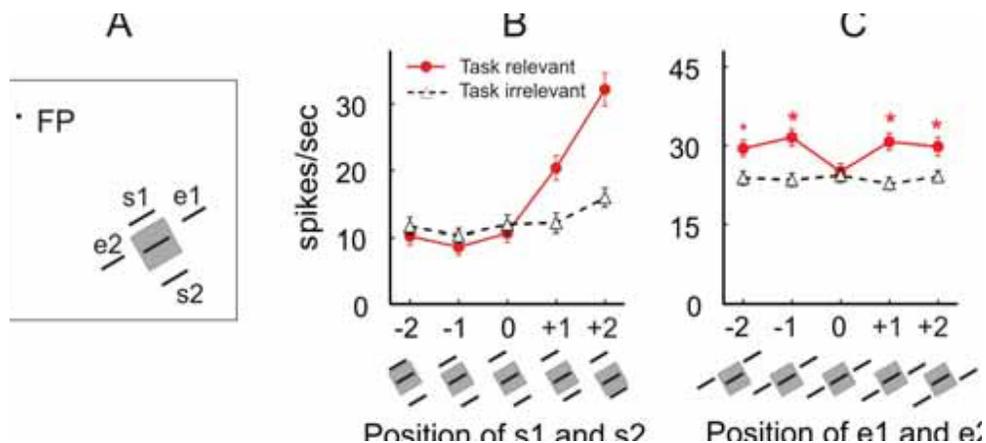

PLATE 7 Task-specific top-down influences on V1 responses. (A) Monkeys were trained to do two different discrimination tasks with identical stimulus patterns at the same visual field location. The stimuli consisted of five simultaneously presented lines: an optimally oriented line fixed in the RF center and flanked by four additional lines surrounding the RF. In different trials, the arrangement of the two side flankers (s1, s2) was randomly assigned from a set of five different configurations (illustrated in the cartoons at the bottom of B, labeled from -2 to +2). Each configuration differs from the others in the separation between the three side-by-side lines (in condition 0 the three lines were equidistant; in the other conditions either s1 or s2 was closer to the central line). In the same trials, the two end-flankers (e1, e2) were also independently assigned a random configuration from a set of predefined arrangements, such that the end flankers were collinear with each other but

misaligned with the central line to either side (the cartoons at the bottom of C). The animal was cued to perform either a bisection task based on the three side-by-side lines or a vernier task based on the three end-to-end lines, using the same set of five-line stimuli. (B) Responses of a V1 cell were examined as a function of the position of the two side flankers s1 and s2 when the animal either performed the bisection task, in which s1 and s2 were task-relevant; or performed the vernier task, in which the same s1 and s2 were task-irrelevant. (C) Responses of a V1 cell were examined as a function of the position of the two end flankers e1 and e2 when the animal either performed the vernier task, in which e1 and e2 were task-relevant; or performed the bisection task, in which the same e1 and e2 were task-irrelevant (Adapted from W. Li, Piech, & Gilbert, 2004.) (See figure 8.5.)

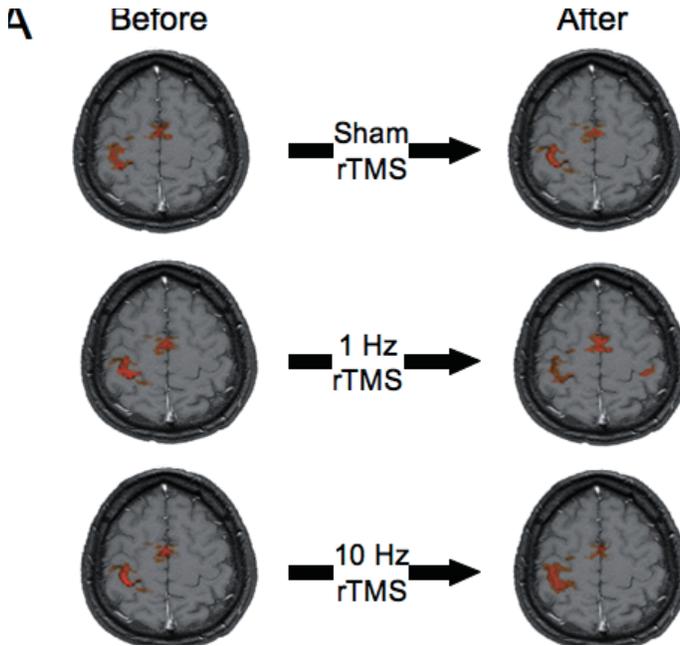

PLATE 8 (A) Brain activation in fMRI while subjects performed the same rhythmic hand movement (under careful kinematic control) before and after repetitive transcranial magnetic stimulation (rTMS) of the contralateral motor cortex. Following sham rTMS (*top row*) there is no change in the significant activation of the motor cortex (M1) contralateral to the moving hand and of the rostral supplementary motor cortex (SMA). After M1 activity is suppressed using 1-Hz rTMS (1,600 stimuli, 90% of motor threshold intensity; *middle row*), there is an increased activation of the rostral SMA and of M1 ipsilateral to the moving hand. Increasing excitability in the contralateral M1 using high-frequency rTMS (20 Hz, 90% of motor threshold intensity, 1,600 stimuli; *bottom row*) results in a decrease in activation of rostral SMA. (See figure 9.1A.)

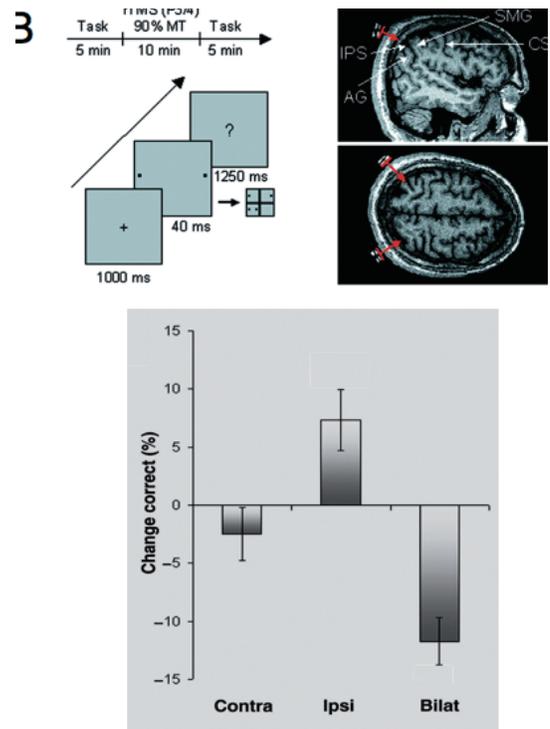

PLATE 9 (B) Impact of image-guided rTMS to the right parietal cortex on a visual detection task. During the task subjects were presented with carefully titrated visual stimuli on the right, left, or bilateral side of a computer monitor (*top left*) and had to respond by pressing the appropriate response button (right, left, or both). TMS was applied guided by the subject's own anatomical MRI using a frameless stereotaxic system (*top right*). There was a decrease in contralateral performance (neglect) but an even greater increase in performance ipsilateral to the parietal rTMS location (*bottom*). This summed up to a significant decrease in bilateral stimuli, where subjects neglected the contralateral stimulus and responded as if only the ipsilateral one had been presented (extinction of double simultaneous stimulation). (B modified from Hilgetag, Theoret, & Pascual-Leone, [2001]). (See figure 9.2B.)

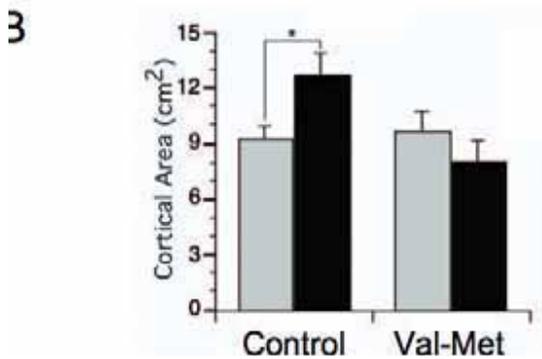

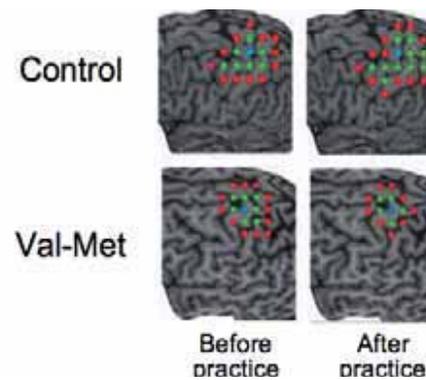

PLATE 10 (B) Histogram displaying the size of the cortical output maps before (gray bars) and after exercise (black bars) in control subjects and subjects with a val66met polymorphism for BDNF (*left side*). Following exercise, control subjects had significantly larger representations than at baseline, whereas subjects with a Met allele did not show a significant change. This difference is further illus-

trated by the representative motor maps from control and Val-Met polymorphism subjects superimposed onto a composite brain MRI image of the cortex (*right side*). Sites from which TMS evoked criterion responses in the target muscle are marked in green; negative sites are marked in red. (Modified from Kleim et al., 2006.) (See figure 9.3B.)

Deaf greater than hearing: Periphery (right visual field)

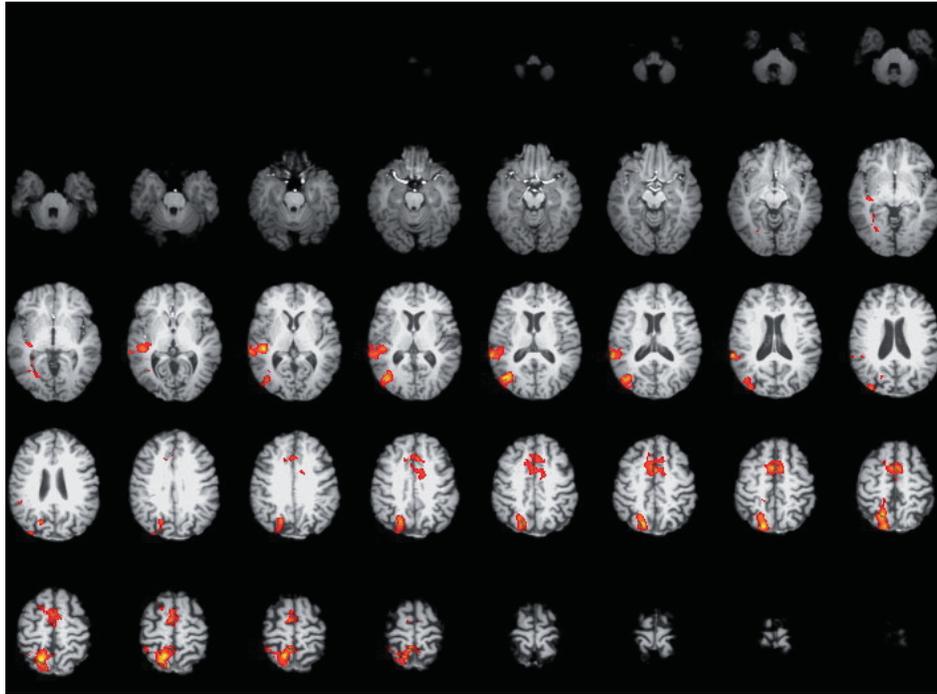

PLATE 11 Deaf and hearing participants completed a visual retinotopy experiment that included mapping of far peripheral visual space. The data show regions where activation was greater in deaf versus hearing participants in response to more peripheral

visual stimuli presented in two distinct experiments (45–56° versus 11–23° and 11–15° versus 2–7°). Significant clusters included contralateral auditory cortex, STS, MT, anterior visual cortex, IPS, and anterior cingulate. (See figure 11.2.)

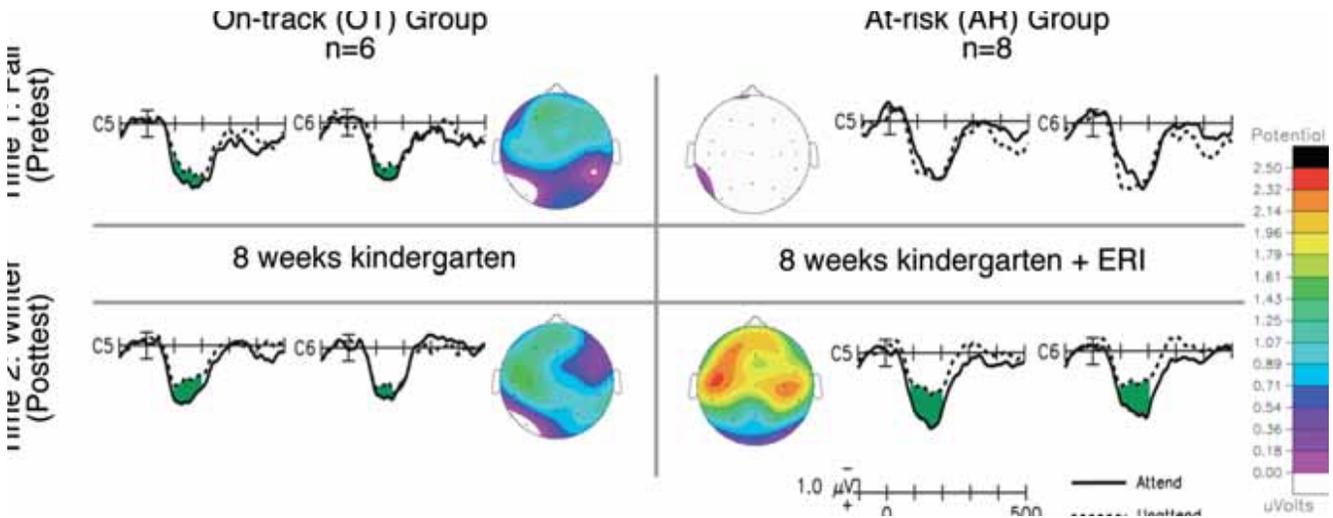

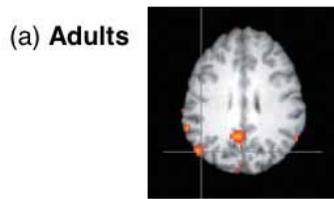

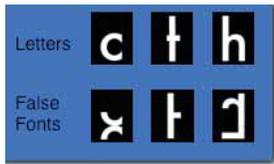

PLATE 12 Grand average ERP waveforms from the selective auditory attention paradigm show the effects of attention on sensorineural processing in kindergarten children of diverse early reading ability across the first semester of kindergarten. Top row shows data from pretest, and bottom row shows data from posttest for five-year-old kindergarten children on track (OT) in early literacy skills or at risk (AR) for reading difficulty. The OT group received eight weeks of kindergarten between pretest and posttest. The AR group received eight weeks of kindergarten with 45 minutes of daily, supplemental instruction with the Early Reading

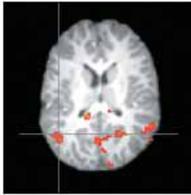

Intervention (ERI). Voltage map indicates the magnitude and distribution of the attention effect (Attended-Unattended). Changes in the effects of attention differed from pretest to posttest in the two groups ($P < .05$), with the OT group showing no change ($P = .92$) and the AR group showing a significant increase in the attention effect ($P < .01$). At pretest, the OT group tended to have a larger attention effect than the AR group ($P = .06$). At posttest, the AR group had a nonsignificantly larger attention effect than the OT group ($P = .17$). (See figure 11.7.)

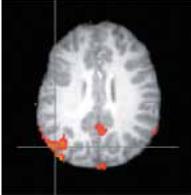

Kindergarteners:

On-track Group

(c) 3 months later

Regular K

At-risk Group

Regular K plus interventio

PLATE 13 Functional MRI activations for letter > false font while performing a 1-back task in adults and kindergarten children of diverse reading ability across the first semester of formal reading instruction. (A) Adults performing the task displayed activation in classic left temporoparietal regions. (B) In contrast, at the beginning of kindergarten, children on track in early literacy skills (upper panel) showed bilateral temporoparietal activation, and children at risk for reading difficulty (lower panel) showed no regions of greater activation. (C) Following one semester of kindergarten and, for children in the at-risk group, daily supplemental instruction with the Early Reading Intervention, on-track children showed left-lateralized activation in temporoparietal regions, and at-risk children showed bilateral temporoparietal activation and large activation of frontal regions, including the ACC. The left hemisphere is displayed on the left. In the upper left corner are example stimuli. (See figure 11.8.)

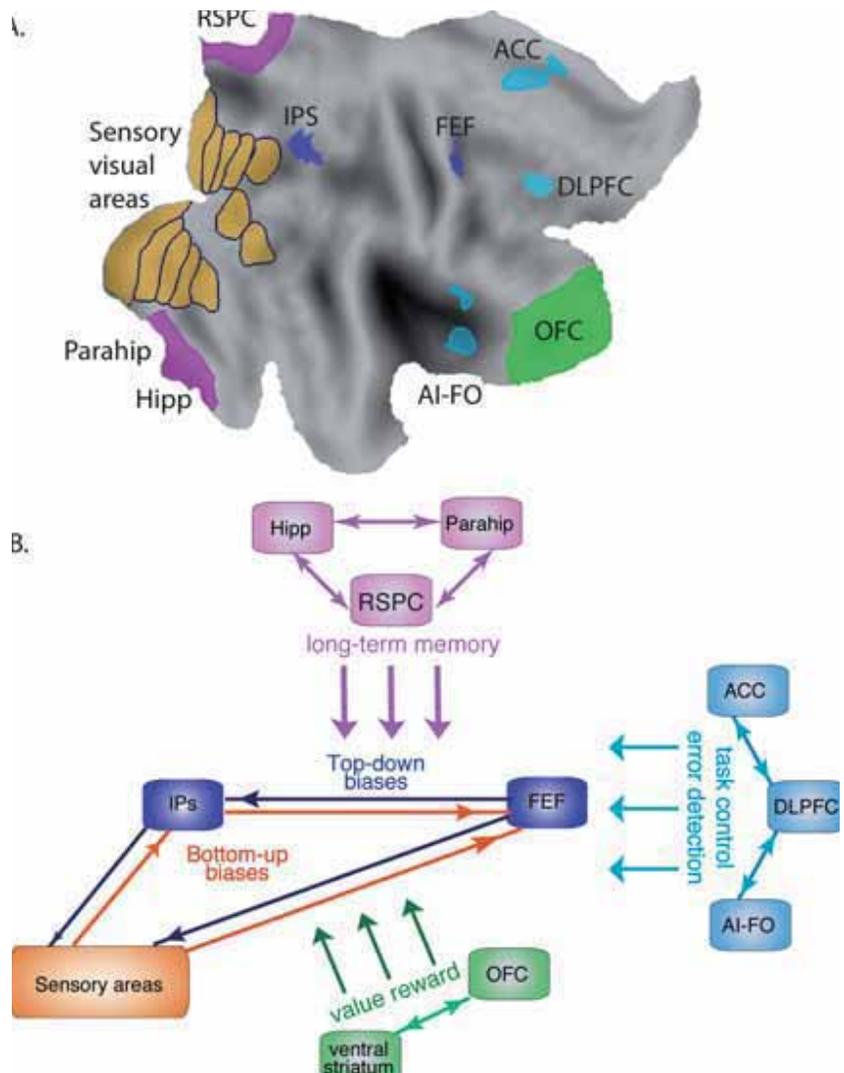

PLATE 14 (A) Control and data-processing networks. Flat map of right hemisphere on which regions and different networks involved in control are superimposed. Dark blue: dorsal frontoparietal attention network. IPS: intraparietal sulcus; FEF: frontal eye field. Orange: sensory visual areas. Purple: Long-term memory retrieval network. RSPC: retrosplenial cortex; Parahip: parahippocampus; Hipp: hippocampus. Azure: executive control network. ACC: anterior cingulate; DLPFC: dorsolateral prefrontal cortex; AI-FO: anterior insula–frontal operculum. Green: reward value network. OFC: orbitofrontal cortex; ventral striatum (not shown). (B) Wire diagram. Dorsal attention network feeds top-down and receives bottom-up biases to/from sensory cortices for stimulus and response selection. Other networks bias sensory processing via interaction with dorsal attention network. (See figure 14.1.)

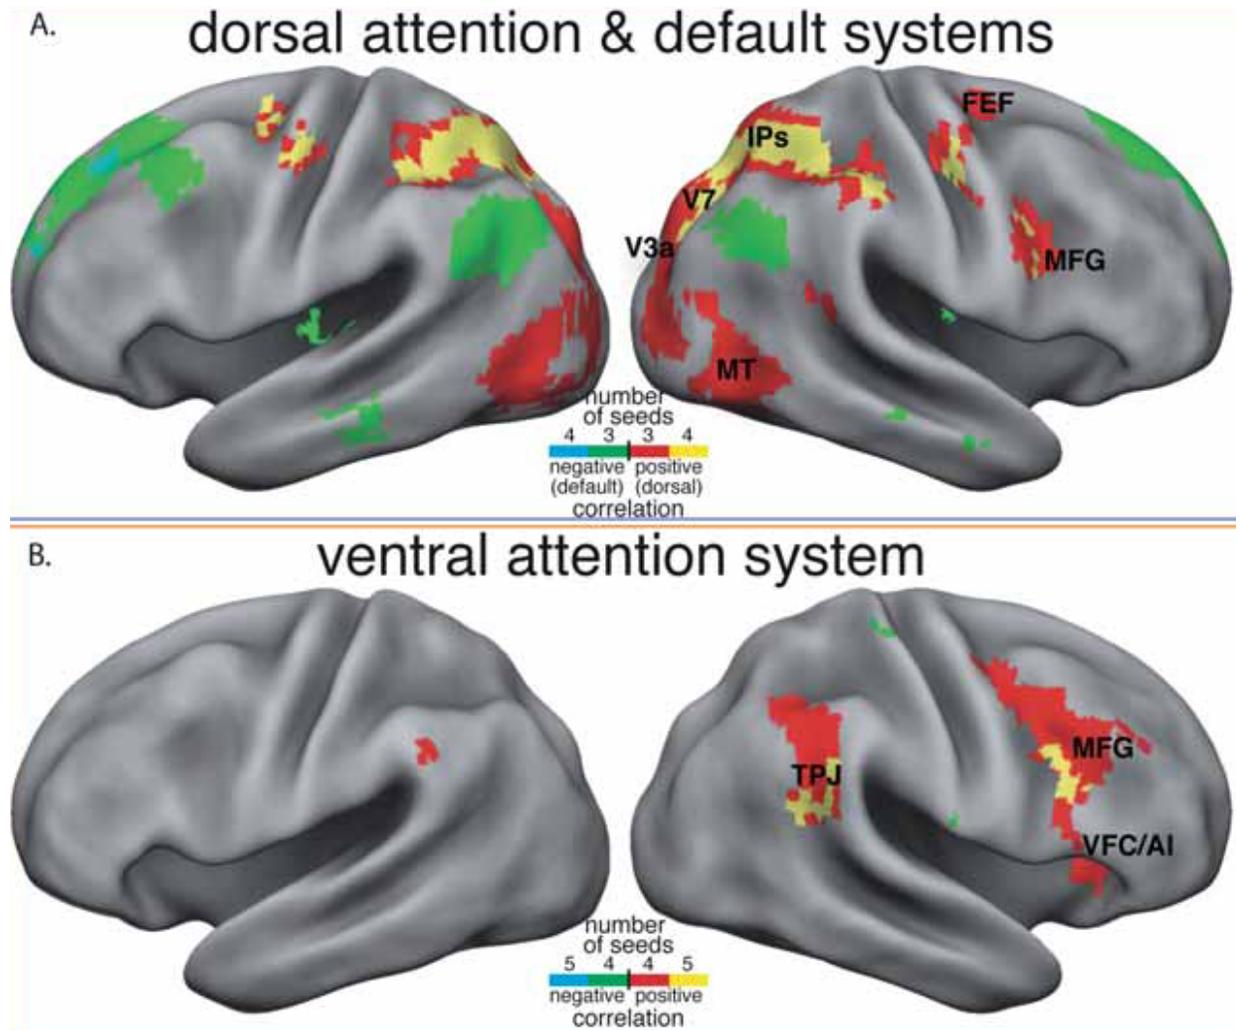

PLATE 15 Functional connectivity by fMRI (fcMRI) defines separate dorsal and ventral networks. (A) Dorsal attention and default networks. The map indicates regions that showed significant positive correlations with three (red) or four (yellow) of the seed regions in the dorsal attention network (IPS, FEF, V7, MT+). The dorsal network is largely reproduced in the resting state FC maps. Regions that show significant negative correlations with three (green) or four (blue) of the seed regions are also shown and

roughly reproduce the default network, possibly indicating a push-pull relationship between the two networks. (B) Ventral attention network. Five ventral regions (R TPJ, R VFC, R MFG, R PrCe) were used as seeds for an FC analysis. Regions showing consistent positive correlations largely reproduce the ventral network, but negative correlations in default regions are not observed. The posterior MFG near the inferior frontal sulcus appears to be connected to both networks. (He et al., 2007.) (See figure 14.2.)

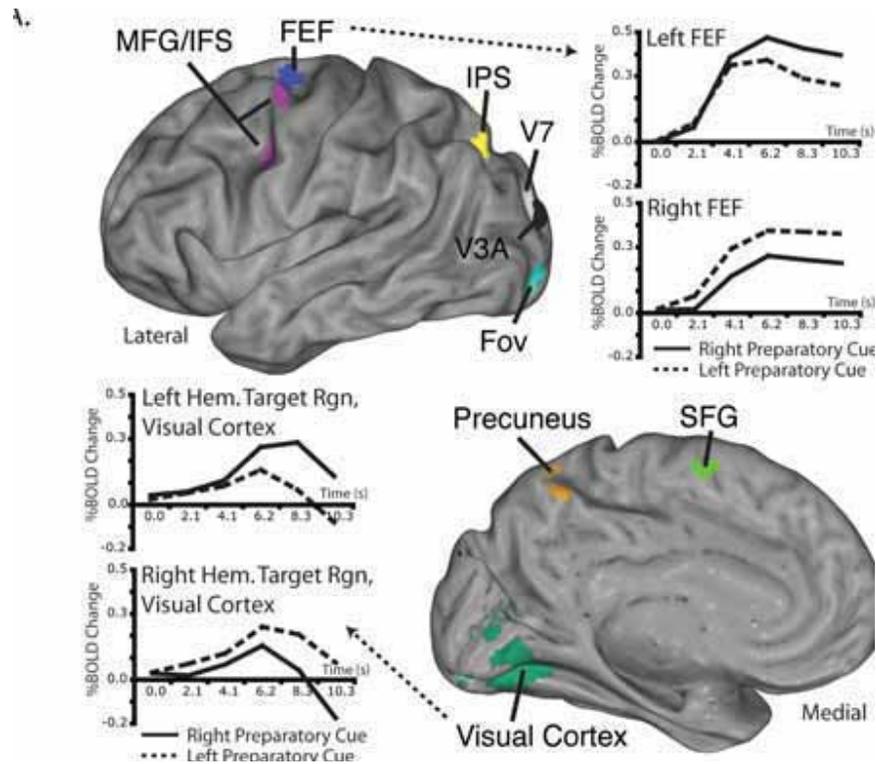

PLATE 16 (A) Frontoparietal areas and visual cortex modulated by anticipatory signal for spatial attention. Areas with spatially selective preparatory signals following an auditory cue directing attention to a left or right location. MFG/IFS: middle frontal gyrus/inferior frontal sulcus; FEF: frontal eye field; IPS: intrapari-

etal sulcus; Fov: foveal region of V1–V3; SFG: superior frontal gyrus. BOLD signal time series following spatial auditory cues show anticipatory signals that are stronger for cue directing attention to contralateral visual field locations. (From Sylvester et al., 2007.) (See figure 14.3A.)

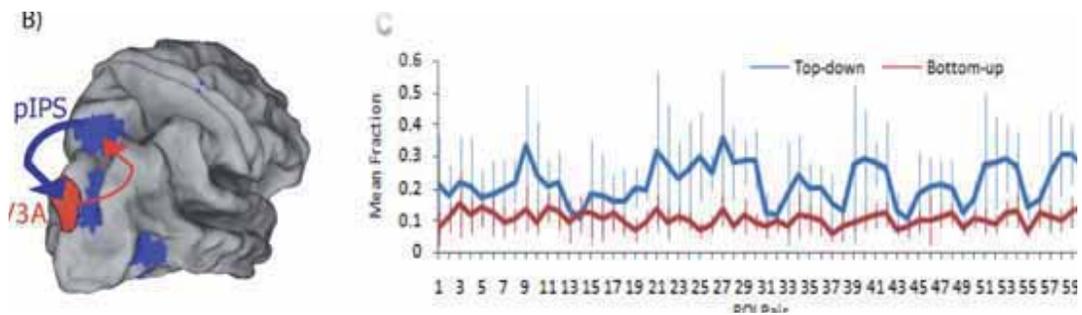

PLATE 17 (B) Granger causality of BOLD signal time series during anticipatory spatial attention. *Left*: “Control” area pIPS top-down modulates visual area V3A. The strength of top-down control trial-by-trial correlates with higher accuracy on a difficult visual discrimination task. *Right*: During anticipatory spatial attention the

strength of top-down influences is stronger from control to visual areas than bottom-up influences from visual areas to control areas. (From Bressler, Tang, Sylvester, Shulman, & Corbetta, 2008.) (See figure 14.4B.)

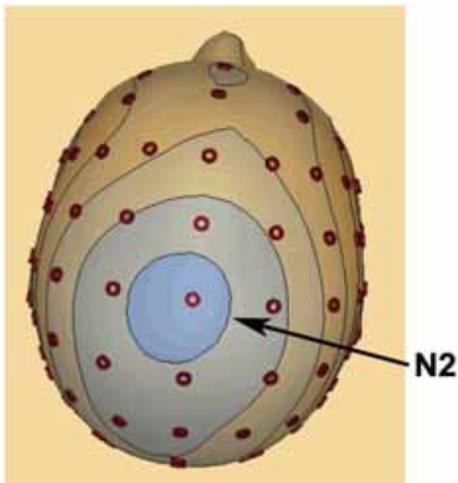

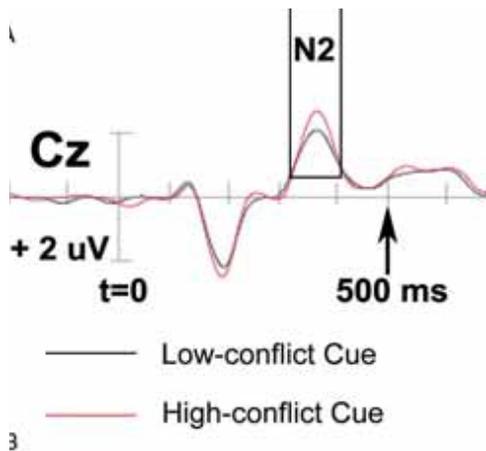

PLATE 18 (A) Grand average ERPs to cues as a function of conflict, recorded from midline central scalp electrode site Cz. Negative voltage is plotted upward, and cue onset is the upright bar at time zero. High-conflict cue ERPs are plotted in red. The box indicates the N2 component, peaking at approximately 360 ms from cue onset. The N2 is significantly greater in amplitude for high-conflict cues. (B) Scalp topography at the peak of the N2 response showing the midline central scalp maximum of the response (blue colors). The nose is at the top of the figure of the scalp, and left is on the left of the image. The small red circles are the locations of the electrodes. (See figure 16.4.)

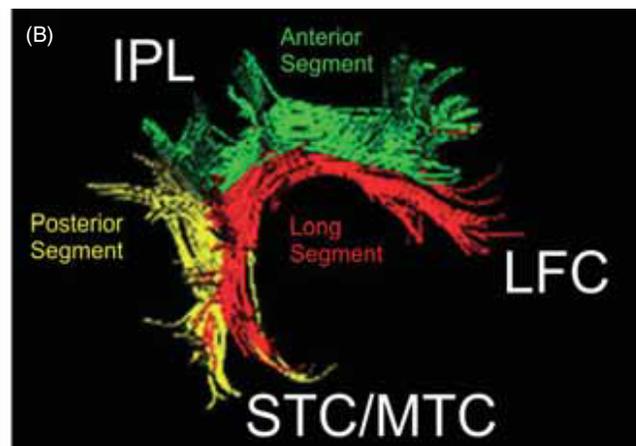

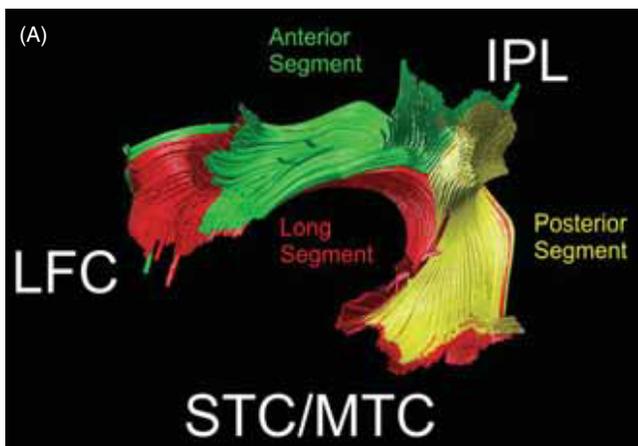

PLATE 19 Averaged tractography reconstruction for fiber connections between the superior/middle temporal, inferior parietal, and lateral frontal cortices by using a two-region-of-interest approach in (A) the human left hemisphere (Catani, Jones, & ffytche, 2005) and (B) the human right hemisphere (Gharabaghi et al., 2009). A long connection was observed linking superior/middle temporal and lateral frontal cortices (shown in red). Two shorter pathways also were found. The posterior segment running

from the superior/middle temporal to the inferior parietal cortex is shown in yellow. The anterior segment running from the inferior parietal to the lateral frontal cortex is shown in green. IPL, inferior parietal lobule; LFC, lateral frontal cortex; STC, superior temporal cortex; MTC, middle temporal cortex. (With modifications from Catani et al., 2005, and from Gharabaghi et al., 2009.) (See figure 17.1.)

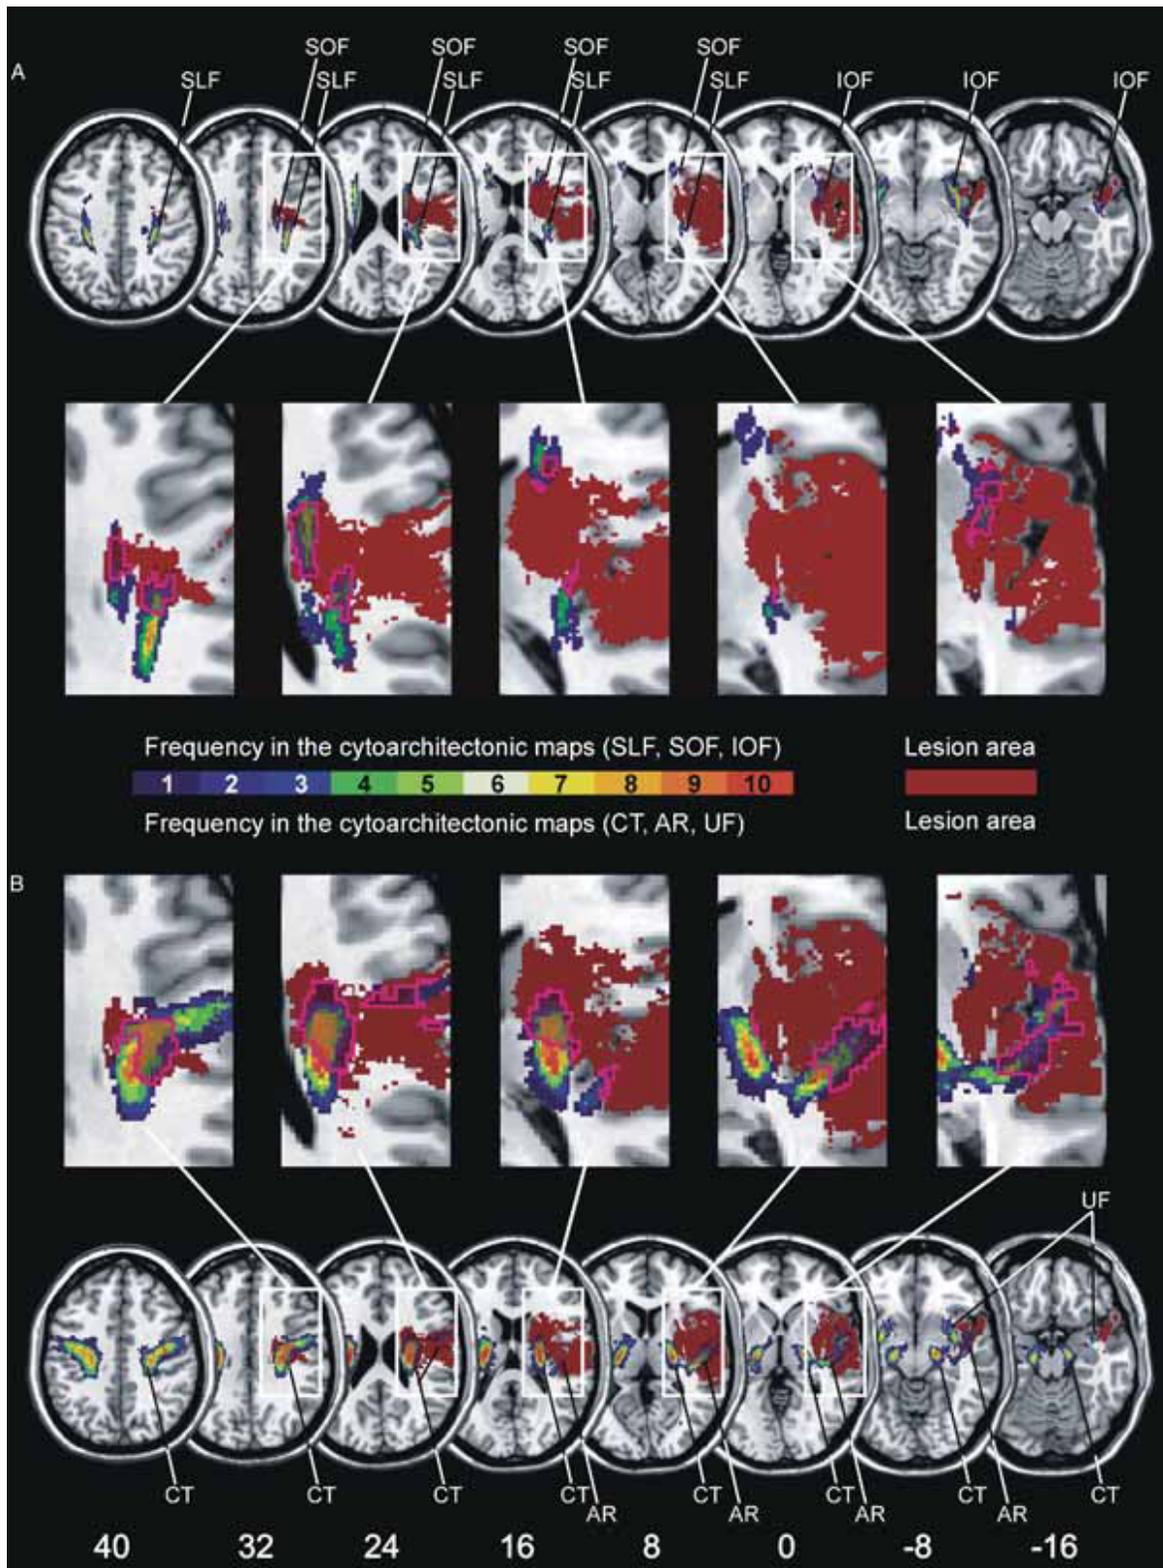

PLATE 20 Overlap of the statistical VLBM lesion map (the brain territory significantly more affected in 78 patients with spatial neglect than in 62 stroke patients without this disorder) with the probabilistic, cytoarchitectonic maps of the white matter association fiber tracts from the Jülich atlas. The statistical lesion map is illustrated in homogeneous brown color. The color coding of the Jülich atlas from 1 (dark blue, observed in 1 postmortem brain) to 10 (red, overlap in all ten postmortem brains) represents the absolute frequency for which in each voxel of the brain a respective

fiber tract was present (e.g., yellow color indicates that the fiber tract was present in that voxel in seven out of ten postmortem brains). The pink contour demarks the area of the fiber tracts affected by the statistical lesion map. (A) Overlap illustrated for perisylvian fiber tracts SFL, superior longitudinal fasciculus; IOF, inferior occipitofrontal fasciculus; and SOF, superior occipitofrontal fasciculus. (B) Overlap illustrated for fiber tracts CT, corticospinal tract; AR, acoustic radiation; and UF, uncinate fascicle. (From Karnath et al., 2009.) (See figure 17.3.)

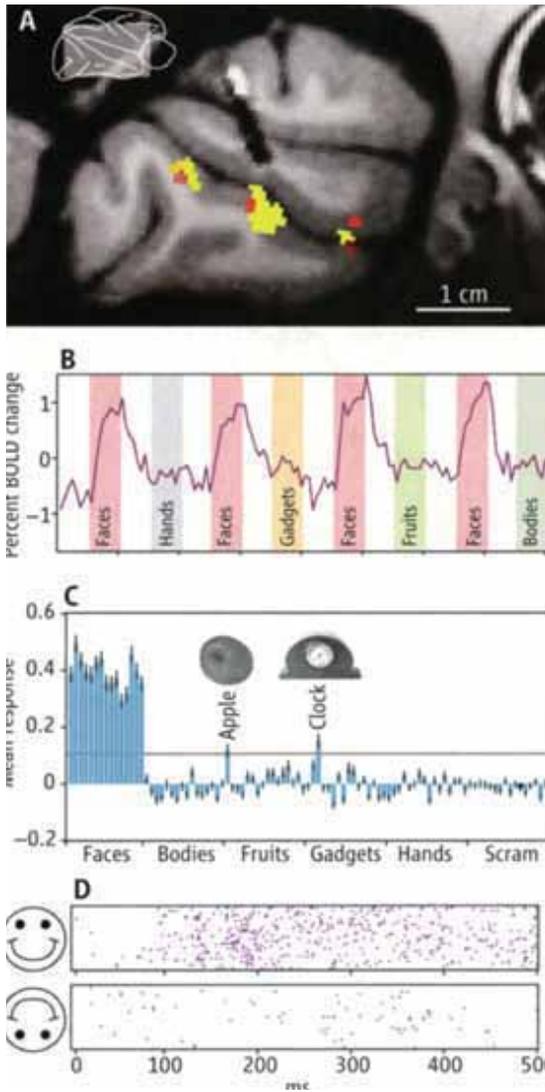

PLATE 21 (A) Three patches of face-selective fMRI activation (yellow regions) in the macaque temporal lobe. (B) Time course from the face patches. Blood flows to these regions increase only when the monkey views faces. (C) Average response across 182 cells from the middle face patch of one monkey to 96 different images. The first 16 images are faces. (D) Responses of a face cell to repeated presentations of an upright and an inverted cartoon face. Each dot represents an action potential. (From Tsao, 2006.) (See figure 21.3.)

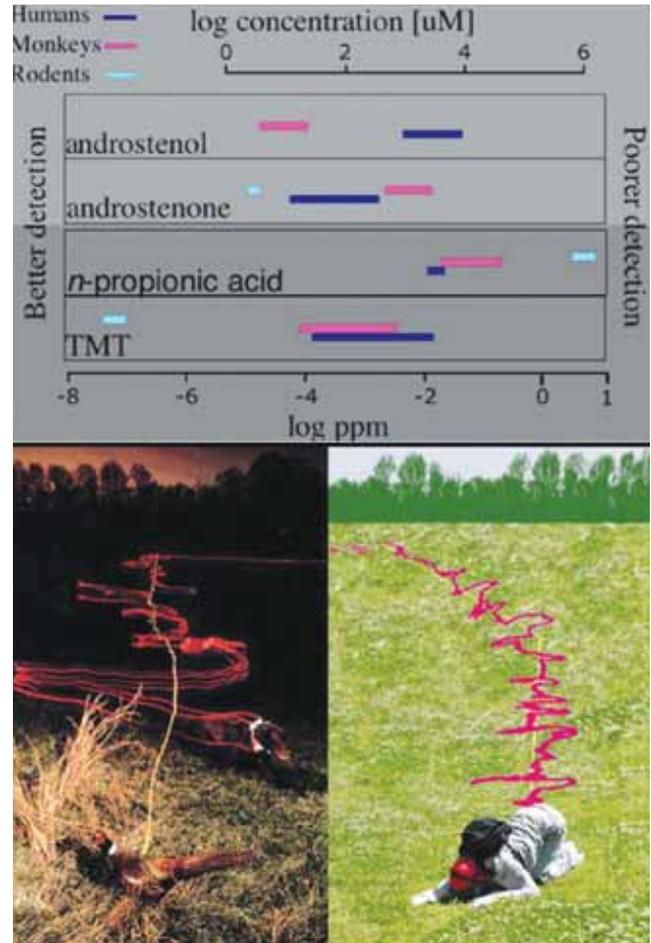

PLATE 22 Olfaction in humans and other animals. *Top panel:* Detection thresholds across species. The data are amassed from studies by Laska and colleagues (1999) and are for detection of the fox odor TMT, *n*-propionic acid, and the two steroidal compounds androstenol and androstenone. The two shades of gray distinguish the units in which results were reported, dark gray in log concentration of the vapor, and light gray in log concentration of the odorant liquid. The extent of the lines reflects the reported variance across studies. The important point illustrated is that each species excels at detecting particular odorants. For example, humans outperform rats and monkeys at detecting *n*-propionic acid. That said, one must keep in mind the limitation of comparing across studies that used different methods of delivery and statistical criteria. *Bottom panel:* Human subject's path following a scent trail, as compared to a dog's path. *Left:* Path of a dog following the scent trail of a pheasant dragged through a field (scent trail in yellow, dog's path in red) (Gibbons, 1986). *Right:* Path of a human following a scent trail of chocolate essential oil through a field (scent trail in yellow, human's path in red). (The background trees were pasted in for esthetics and are part of the data.) (From Porter & Sobel, 2005.) (See figure 22.2.)

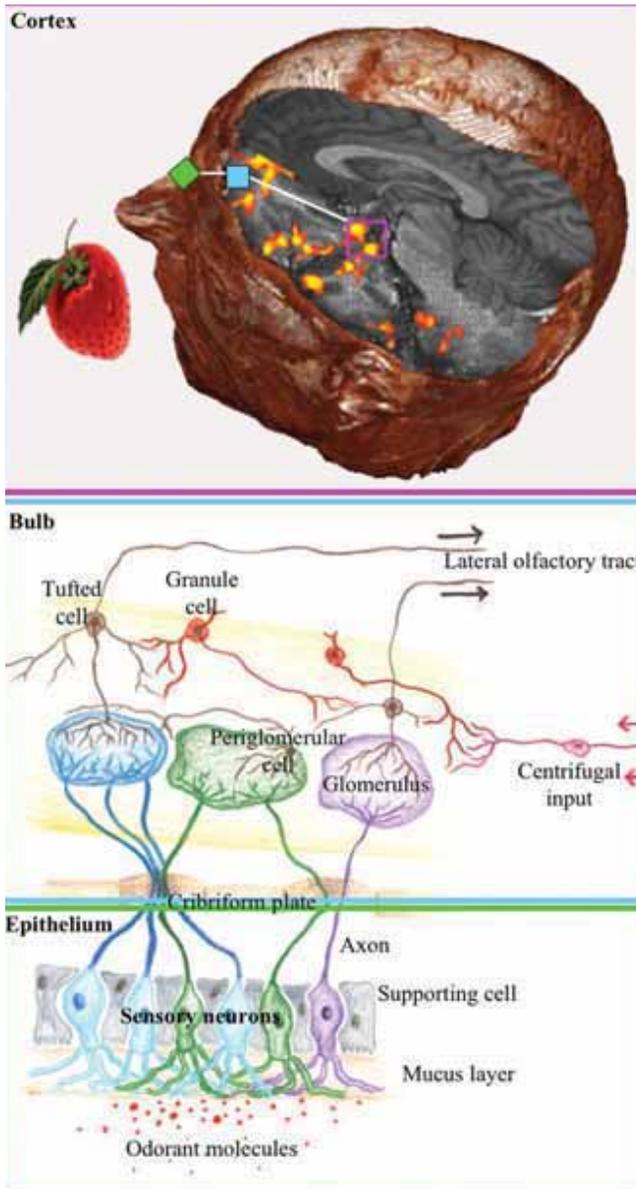

PLATE 23 Structure of the human olfactory system. The human olfactory system can be segregated into three primary compartments: (bottom) epithelium, (middle) bulb, and (top) cortex. Olfactory epithelium: Each olfactory sensory neuron expresses on olfactory receptor gene. Like receptor project to one or a small number of glomeruli. Organization of the olfactory bulb: Glomeruli receive input from olfactory sensory neurons and cortical olfactory regions. Mitral and tufted cell dendrites contact receptor axons within glomeruli. The axons of the mitral and tufted cells project widely to higher brain structures. Lateral processing in the olfactory bulb occurs across two types of interneurons: periglomerular cells and granule cells. A sagittal view of the human head. The olfactory epithelium is in green, bulb in blue, and primary cortex in pink. (Drawing courtesy of Christina Zelano.) (See figure 22.3.)

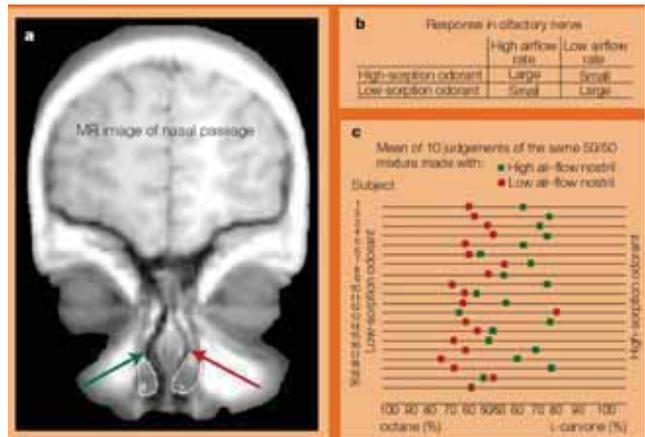

PLATE 24 Different nostrils convey different olfactory information to the brain. (A), Magnetic resonance image of the nasal passages. The swollen (*) and relaxed (#) turbinates, outlined in white, result in an occluded right nostril (red arrow) and a clearer left nostril (green arrow). (B), The size of the response in the olfactory nerve (large or small) as a function of the interaction between airflow rate and odorant sorption (Mozell & Jagodowicz, 1973). (C), On each of 10 trials, subjects were asked to smell an identical mixture of 50% octane and 50% L-carvone using either the left or right nostril. They were then given each individual odorant component to smell separately and judged the composition of the mixture by marking the line. Using the high-flow-rate nostril (green), the average judgment was that the mixture consisted of 55% L-carvone and 45% octane. Using the low-flow-rate nostril (red), the judgment was that it consisted of 61% octane and 39% L-carvone ($t(19)43.74$, $p = 0.001$). (From Sobel et al., 1999.) (See figure 22.4.)

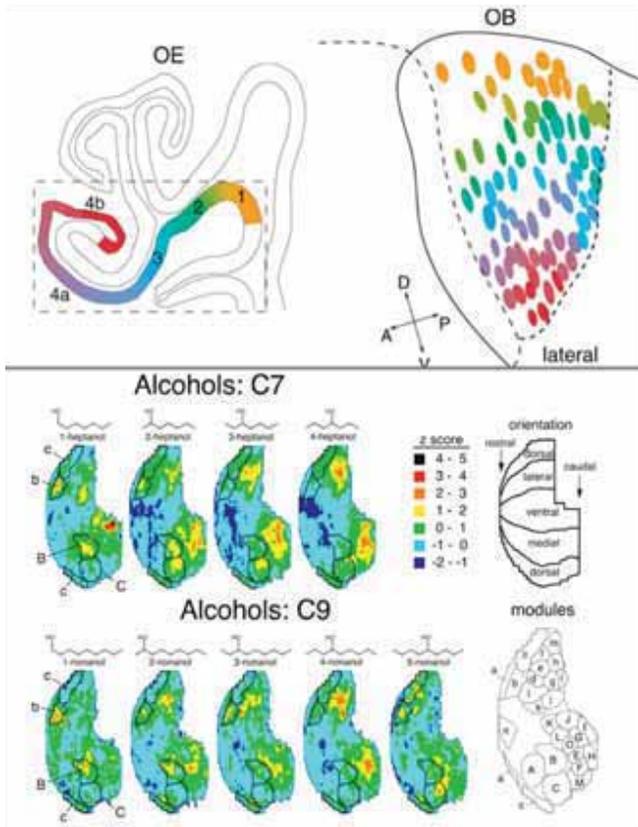

PLATE 25 Spatial mapping from epithelium to bulb. *Top panel:* Color-coded zonal distribution of receptor types in the olfactory epithelium and their projection pattern to glomeruli in the olfactory bulb (Miyamichi et al., 2005). *Bottom panel:* Patterns of 2DG activation on the surface of the rat olfactory bulb as a reflection of odorant identity. For detailed maps, see <http://leonservers.bio.uci.edu/>. (See figure 22.7.)

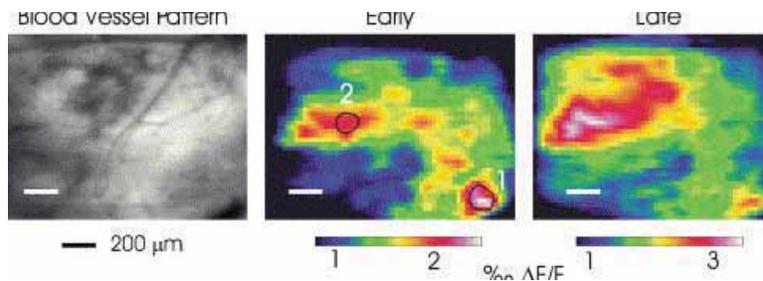

PLATE 26 Temporal development of odor-induced activity. Data from Spors and Grinvald (2002) showing the temporal development of the bulbar response to the odorant ethylbutyrate. The early response is data obtained 150–300 ms following stimulus onset, and

the late response is data obtained 300–500 ms following stimulation. The spatial pattern of response is clearly modified over time. (See figure 22.8.)

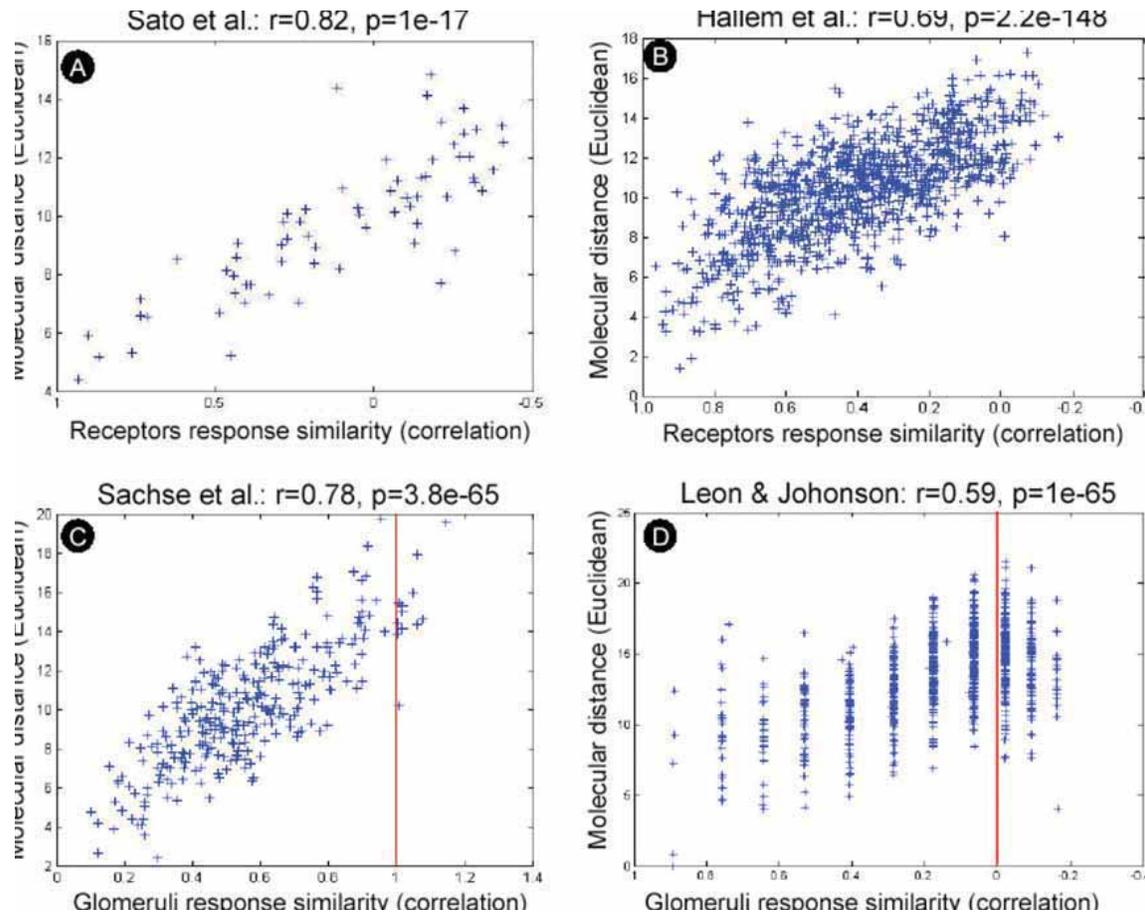

PLATE 27 Correlation plots for unrelated data sets. The graphs demonstrate the ability of the multidimensional olfactory metric to predict neural activity in the olfactory system. Graphs *A* and *B* are from data set reporting RN responses (the similarity was the measured Pearson correlation and thus can range from 1 to -1). Graphs *C* and *D* are from data sets reporting GLO responses. In the *C* and

D data sets, the r value was positive as long as the response pattern similarity was between 0 to 1, and it was either negative or low when the response pattern similarity was negative (the right part of the red line). (*A*) Hallem et al. data set. (*B*) Sato et al. data set. (*C*) Sachse et al. data set (*D*) Leon and Johnson data set. (See figure 22.14.)

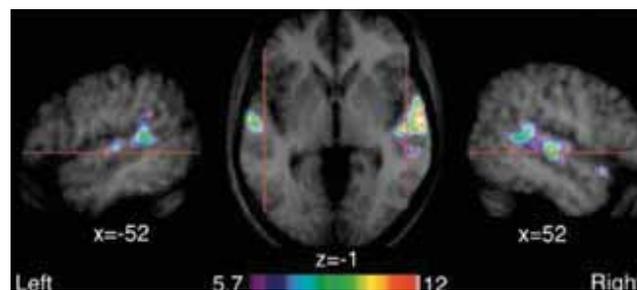

PLATE 28 Activation during passive listening to voices (Belin et al., 2000). The numbers refer to planes defined in millimeters in Talairach space (Talairach & Tournoux, 1988). (See figure 25.5.)

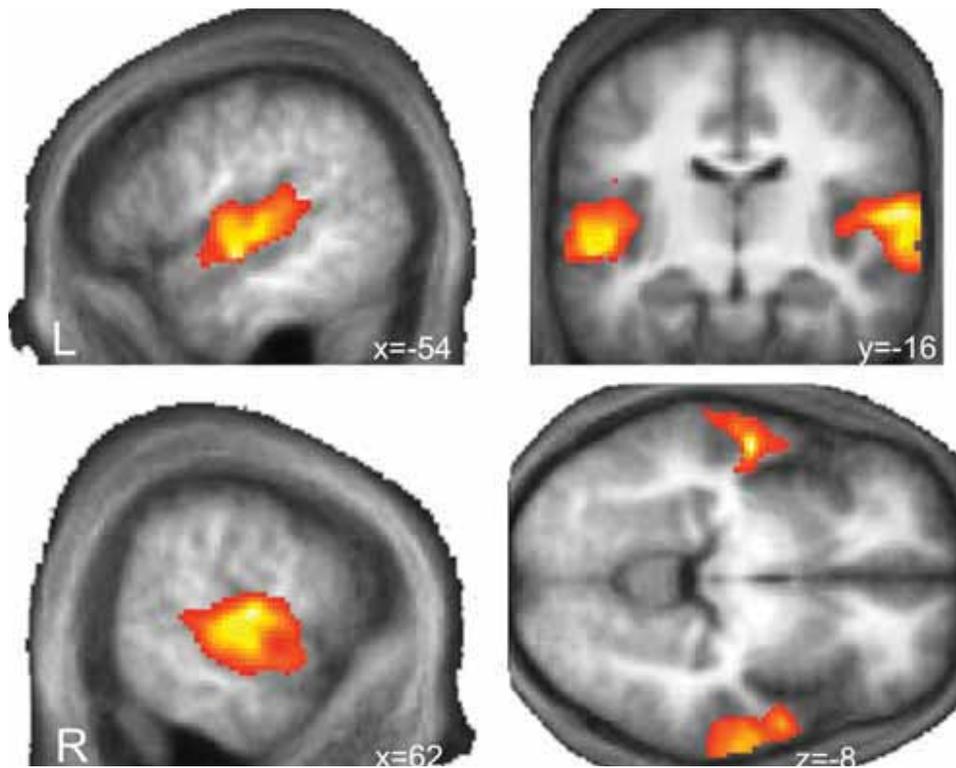

PLATE 29 Activation due to passive listening to changing resonator scale and sound class in the three types of harmonic sounds shown in figure 25.2 (von Kriegstein et al., 2007). (See figure 25.6.)

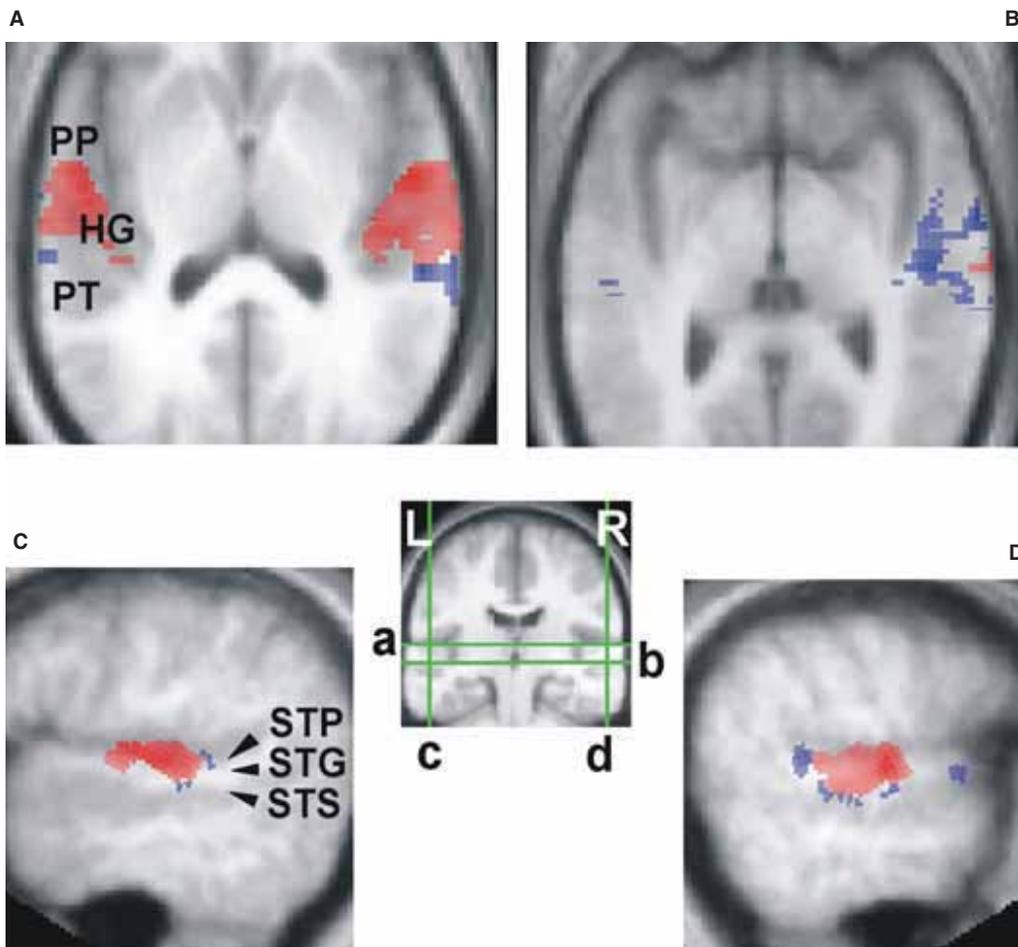

PLATE 30 Activation due to passive listening to changing spectral envelope (Warren et al., 2005). HG, Heschl's gyrus; PT, planum temporale; PP, planum polare; STS, superior temporal sulcus. (See figure 25.7.)

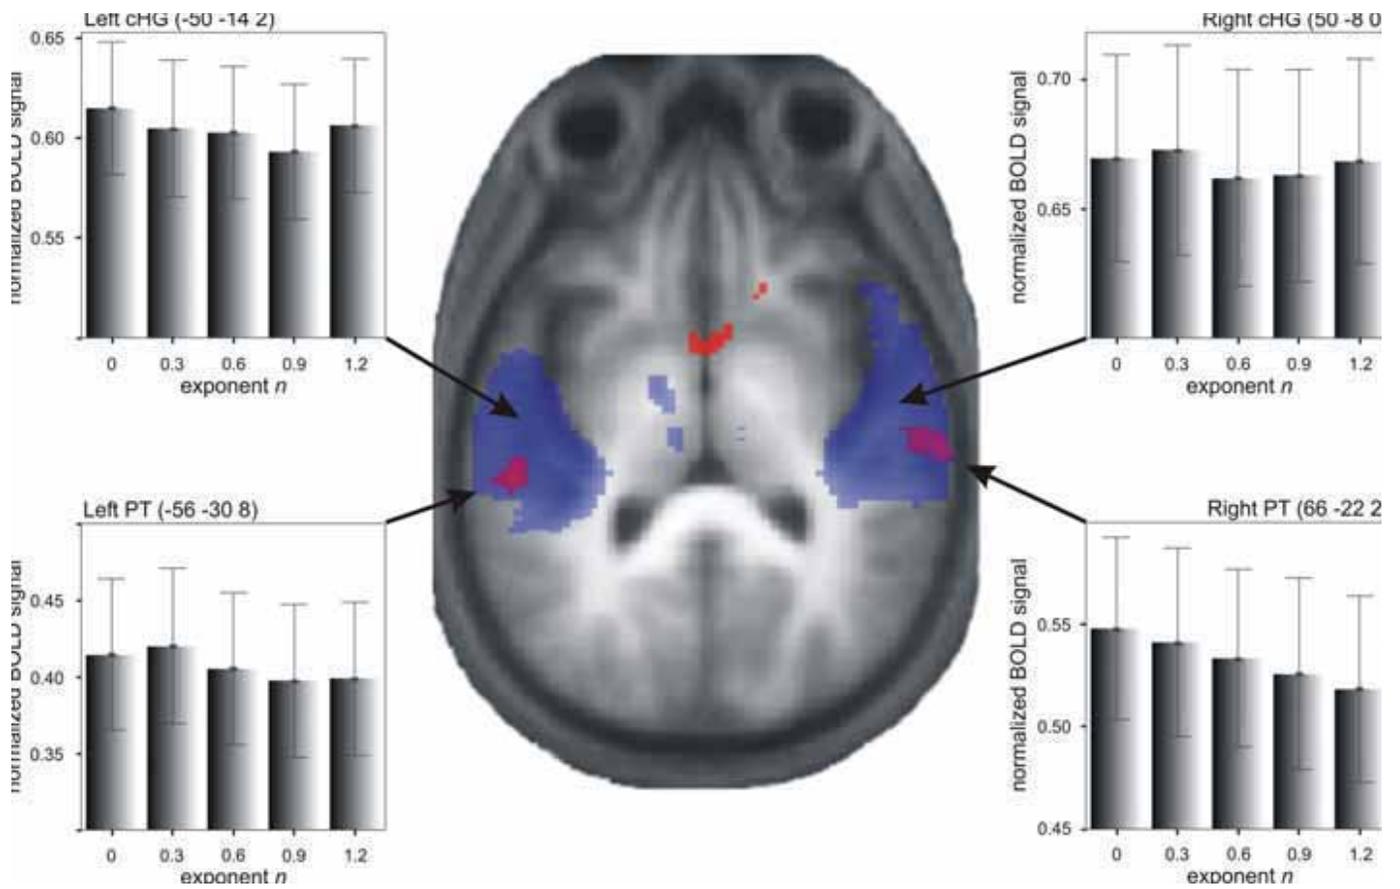

PLATE 31 Activation as a function of information content of pitch sequences during the encoding of pitch sequences. A significant effect of pitch-sequence information content (which decreases as n increases) is shown in the planum temporale (PT) but not

in Heschl's gyrus (HG). Numbers in parentheses are Talairach coordinates in millimeters where the BOLD values were measured. (See figure 25.8.)

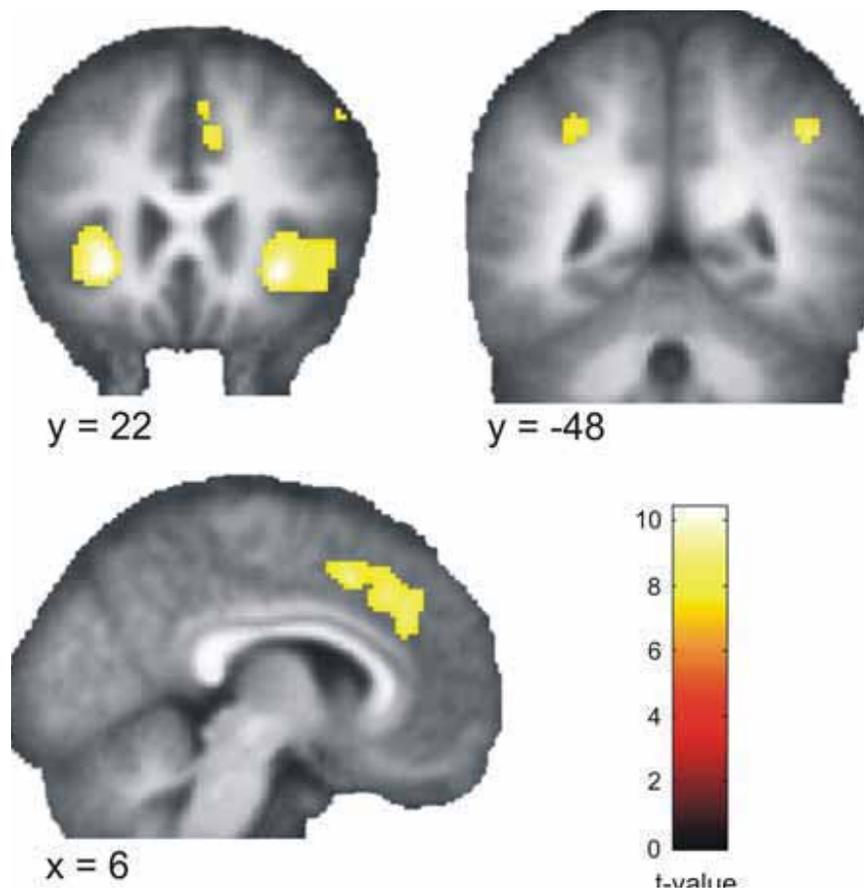

PLATE 32 Contrast to demonstrate activation associated with pitch-sequence retrieval in an active listening task. (See figure 25.9.)

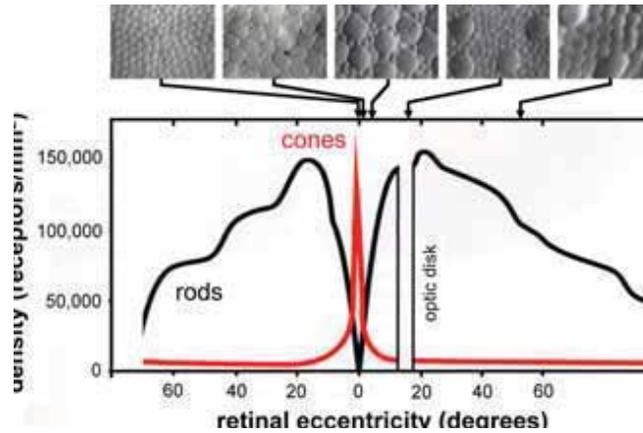

PLATE 33 Nonuniform distribution of rods and cones in the human retina. Plot of photoreceptor density as a function of retinal eccentricity. The top panels show ex vivo images of the photoreceptor mosaic from Curcio, Sloan, Kalina, and Hendrickson (1990). The leftmost image is from the all-cone fovea; the remaining panels contain both rods (smaller cells) and cones (larger cells). While rod density increases dramatically in the peripheral retina, rod diam-

eter remains relatively constant (about $2\ \mu\text{m}$). Conversely, the cone photoreceptors increase from about $2\ \mu\text{m}$ in diameter at the fovea to about $8\ \mu\text{m}$ at about 10 degrees eccentricity, after which point they remain relatively constant (Samy & Hirsch, 1989). (Modified from Webvision (<http://webvision.med.utah.edu>), with permission.) (See figure 26.1.)

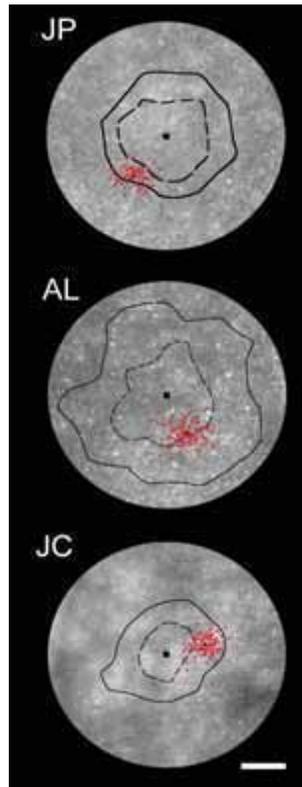

PLATE 34 The area of highest cone density is not always used for fixation. Shown are retinal montages of the foveal cone mosaic for three subjects. The black square represents the foveal center of each subject, as defined by the location of peak cone density. The dashed black line is the isodensity contour line representing a 5%

increase in cone spacing, and the solid black line is the isodensity contour line representing a 15% increase in cone spacing. Red dots are individual fixation locations. Scale bar is $50\ \mu\text{m}$. (Reproduced from Putnam et al., 2005, with permission.) (See figure 26.2.)

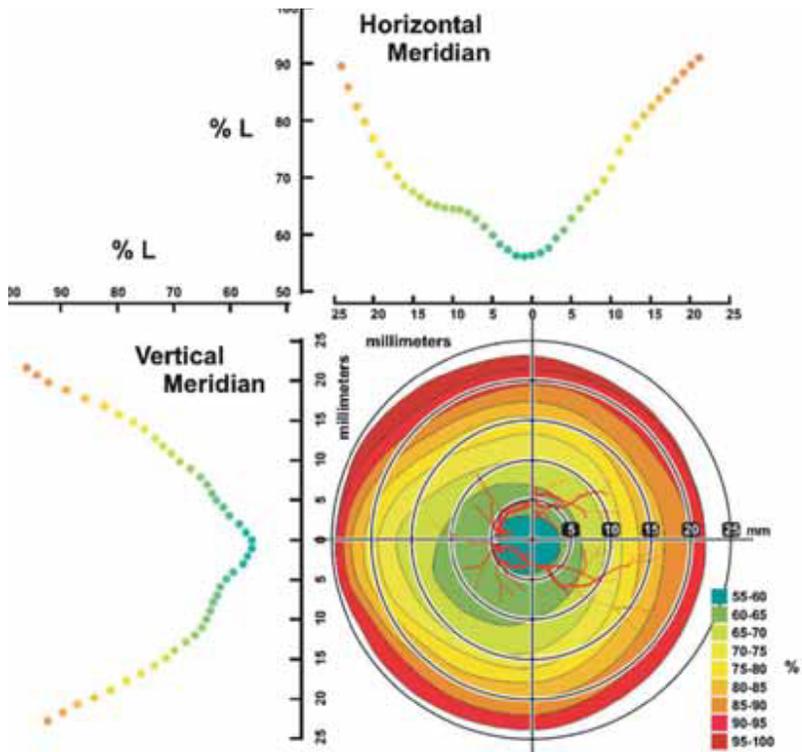

PLATE 35 The L-to-M cone ratio is not constant across the retina. The lower right panel shows a topographical map of the percent of L-opsin mRNA in a human donor retina. The proportion of L-opsin to M-opsin mRNA is directly related to the relative numbers of L and M cones at a locus, assuming that L and M cones produce the same absolute amounts of mRNA. Horizontal and vertical meridian slices show the dramatic increase in percent of L as a function of eccentricity. (Reproduced from Neitz et al., 2006, with permission.) (See figure 26.4.)

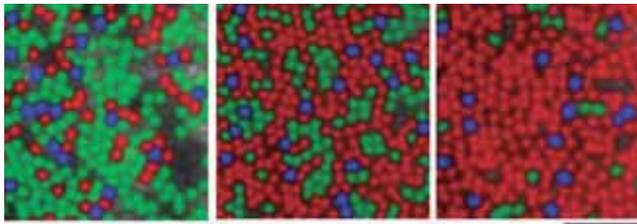

PLATE 36 Intersubject variation in L-to-M cone ratio. False color images showing the arrangement of L (red), M (green), and S (blue) cones in the retinas for three human subjects. The identity of each cone as L, M, or S was inferred from retinal densitometry measurements obtained with an adaptive optics fundus camera. The proportion of S cones does not vary significantly between subjects; however, the L-to-M cone ratio can vary by a factor of 40 across individuals with normal color vision. Scale bar is 5 arcmin. (See figure 26.5.)

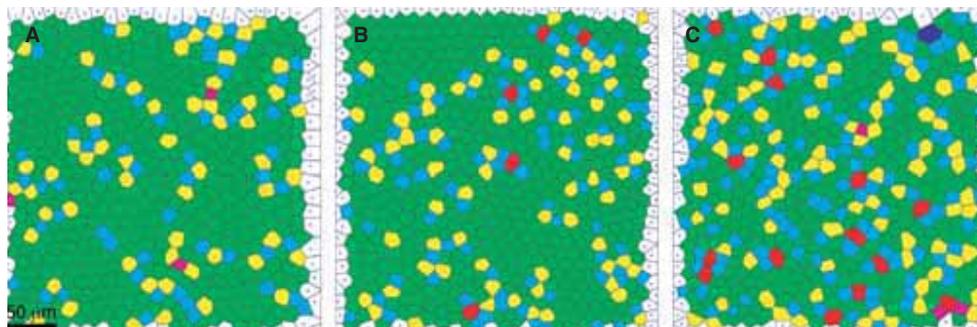

PLATE 37 Regularity of the human cone mosaic. Voronoi domain associated with each cone photoreceptor in a patch of retina from (A) a normal trichromat, (B) a 34-year-old female with a mild tritan defect, and (C) a 57-year-old male with a severe tritan defect. The color code indicates the number of sides on each Voronoi polygon (magenta = 4, cyan = 5, green = 6, yellow = 7, red = 8, purple = 9). Large regions of six-sided polygons indicate a regular triangular lattice, whereas other colors mark points of disruptions in the

hexagonal packing of the foveal mosaic. Despite the fact that the father and the daughter carried the same heterozygous mutation in their S-opsin genes (predicting a tritan phenotype), the regularity of the father's mosaic was significantly disrupted, while the daughter's was indistinguishable from normal. Scale bar is 50 μm . (Reproduced from Baraas et al., 2007, with permission.) (See figure 26.6.)

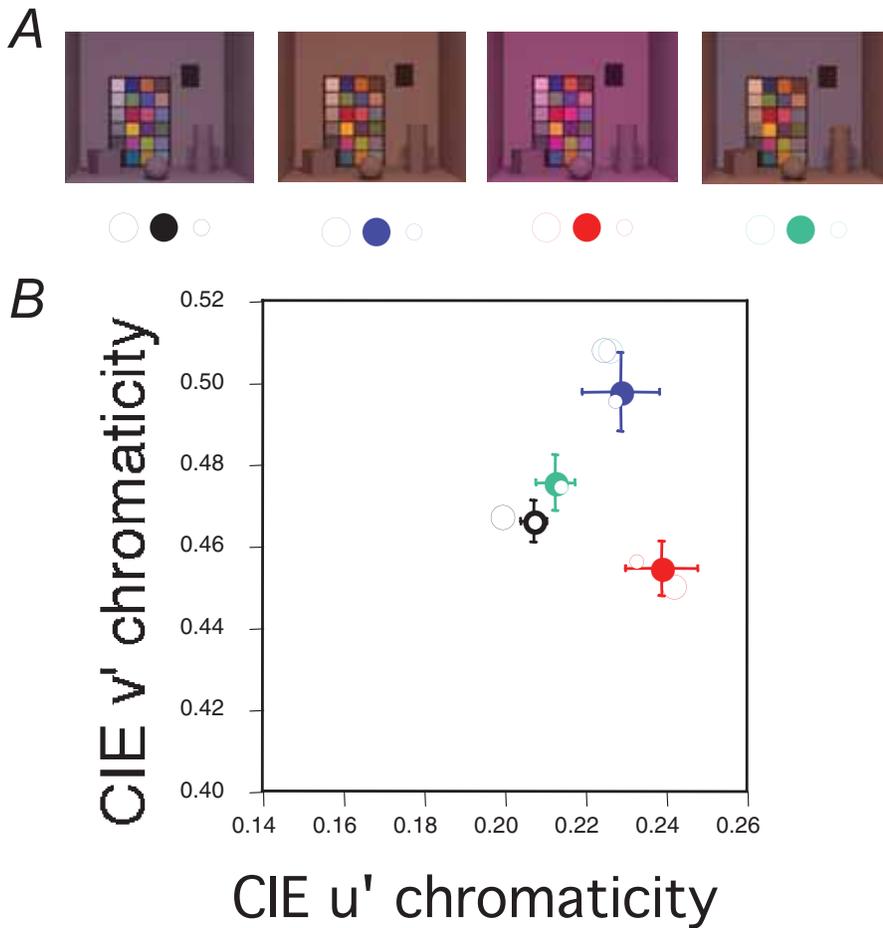

PLATE 38 Color constancy performance. (A) Images of 4 of 17 simulated scenes used to compare human performance and a model derived from a Bayesian illuminant estimation algorithm. Each scene has the same spatial structure. In the first three images, from left to right, the illuminant varies. In the rightmost image, the illuminant is the same as that in the second image, but the background surface has been changed so that the light reflected from it matches that reflected from the background surface in the leftmost image. (Reproduced from Brainard et al., 2006, figure 1.) (B) Illuminants, achromatic loci, and model predictions plotted in the CIE $u'v'$ chromaticity diagram. This is a standard color representation that preserves information about the relative responses of the L, M, and S cones but not about intensity. Large open circles show the scene illuminants, with the color key as indicated beneath the images in panel A. Large solid circles show the achromatic loci measured by observers who adjusted a test patch at the location indicated by the black rectangle in each image. The small open circles show the model's predictions of the achromatic loci. (Reproduced from figure 7 of Brainard et al., 2006.) (See figure 27.4.)

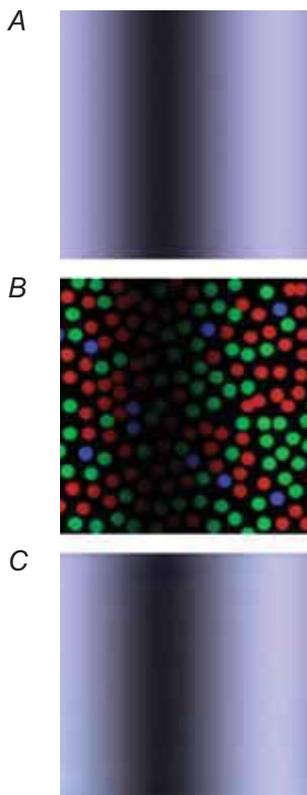

PLATE 39 Trichromatic reconstruction. (A) Small patch of sinusoidal isochromatic grating. (B) The intensity of each colored spot represents the isomerization rate of a cone. The class of each cone is indicated by whether it is plotted in red (L), green (M), or blue (S). (C) The isochromatic grating as reconstructed by the Bayesian algorithm. The grating shown corresponds to a spatial frequency of 6 cycles per degree presented at about 1 degree of eccentricity for a human observer; the mosaic is of observer AP of Hofer and colleagues (2005). Brainard and colleagues (2008) provide additional reconstruction examples that show similarly veridical performance for low-spatial-frequency isoluminant gratings and for an additional mosaic. (See figure 27.5.)

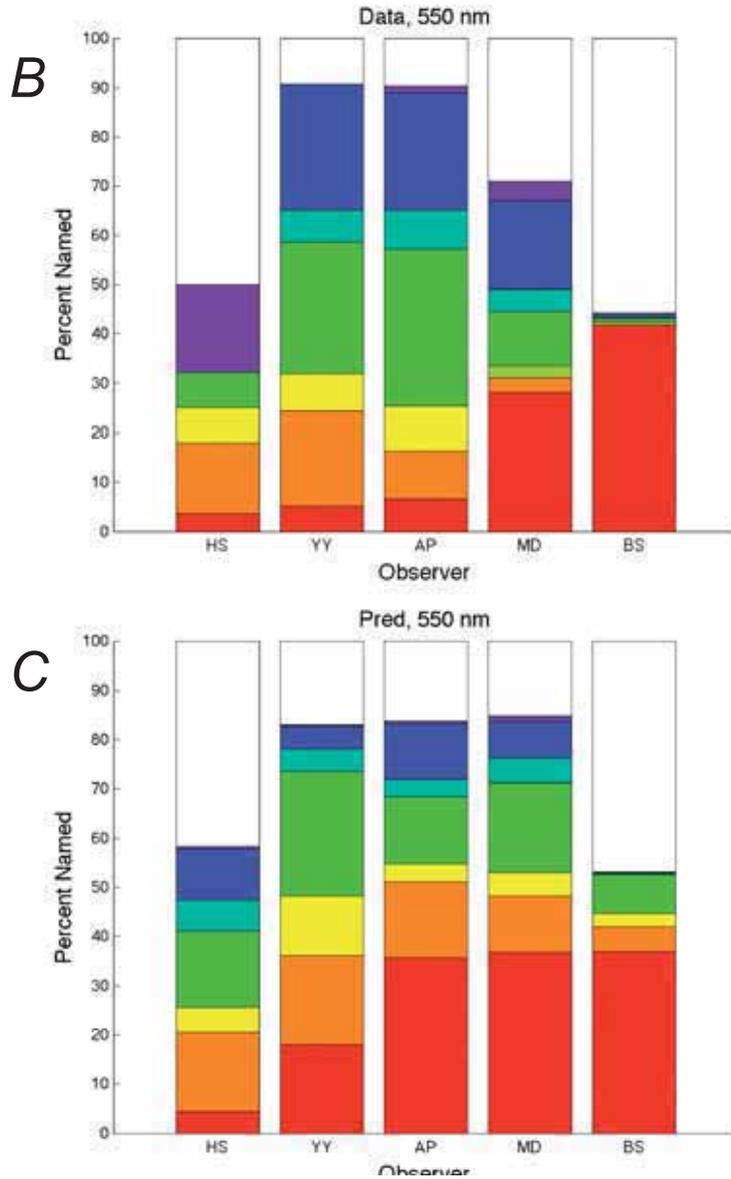

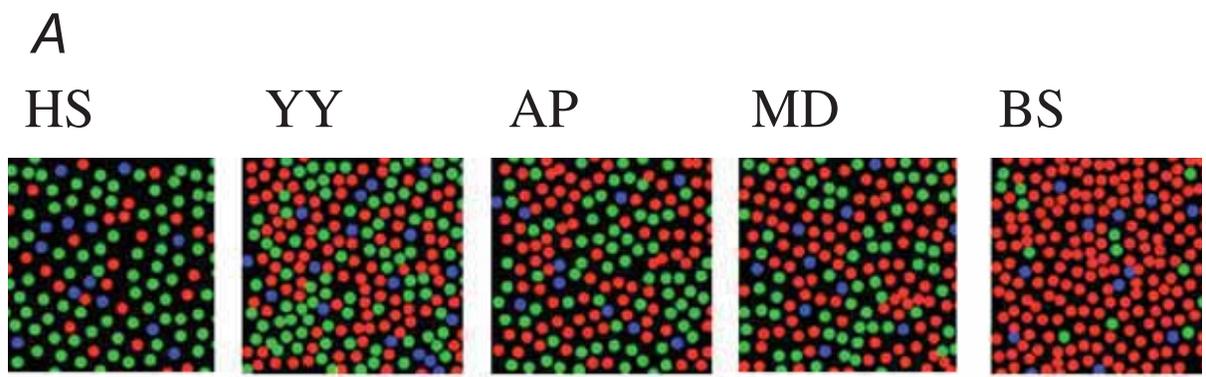

PLATE 40 Small spot experiment. (A) Schematic of five individual observer cone mosaics. Red, green, and blue circles show locations of L, M, and S cones. Mosaics represent approximately 12 by 12 feet of visual angle at 1 degree of eccentricity. (Reproduced from Brainard et al., 2008, figure 2 (top panel).) (B) Data from Hofer and colleagues (2005) for 550-nm spots. Observers named each small spot that they saw and judged namable. The available names were red, orange, yellow, yellow-green, green, blue-green, purple, and white. For each observer, the histogram shows the proportion

of each color named used, with the color code corresponding to the name. Note that the white region of the bars represents the proportion of white responses. Not all observers used all available names. (Reproduced from figure 11 of Brainard et al., 2008.) (C) Predictions from the Bayesian model, obtained as described in the text, for the experimental conditions corresponding to the data in B. (Reproduced from figure 11 of Brainard et al., 2008), which also shows data and predictions for 500-nm and 600-nm spots.) (See figure 27.6.)

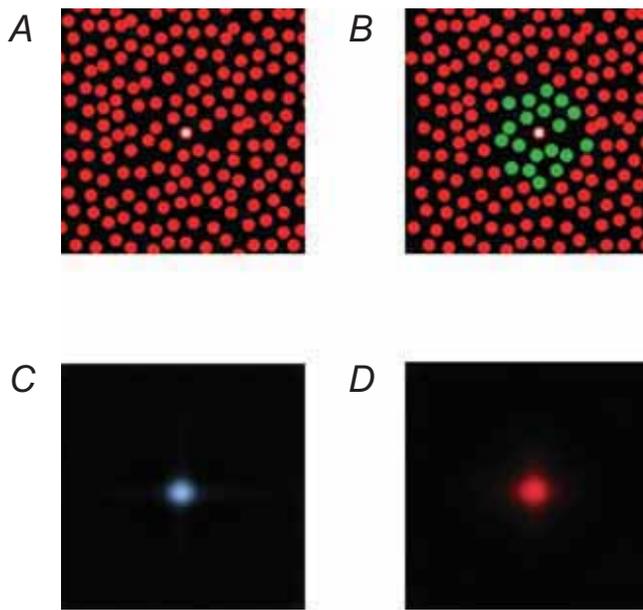

PLATE 41 Small spot intuitions. (A) A mosaic consisting only of L cones. The white spot in the center indicates a single cone whose stimulation was simulated. (B) This mosaic is identical to the one shown in panel A, with the exception that the cones surrounding the central L cone have been changed to M cones. (C) Model output when the central cone in panel A is stimulated. The result is a bluish-white spot. As described by Brainard and colleagues (2008), a windowing procedure was applied to model output here and in panel D to reduce visible ringing in the reconstruction. (D) Model output when the central cone in panel B is stimulated. The result is a reddish spot. (Reproduced from figure 7 of Brainard et al., 2008.) (See figure 27.7.)

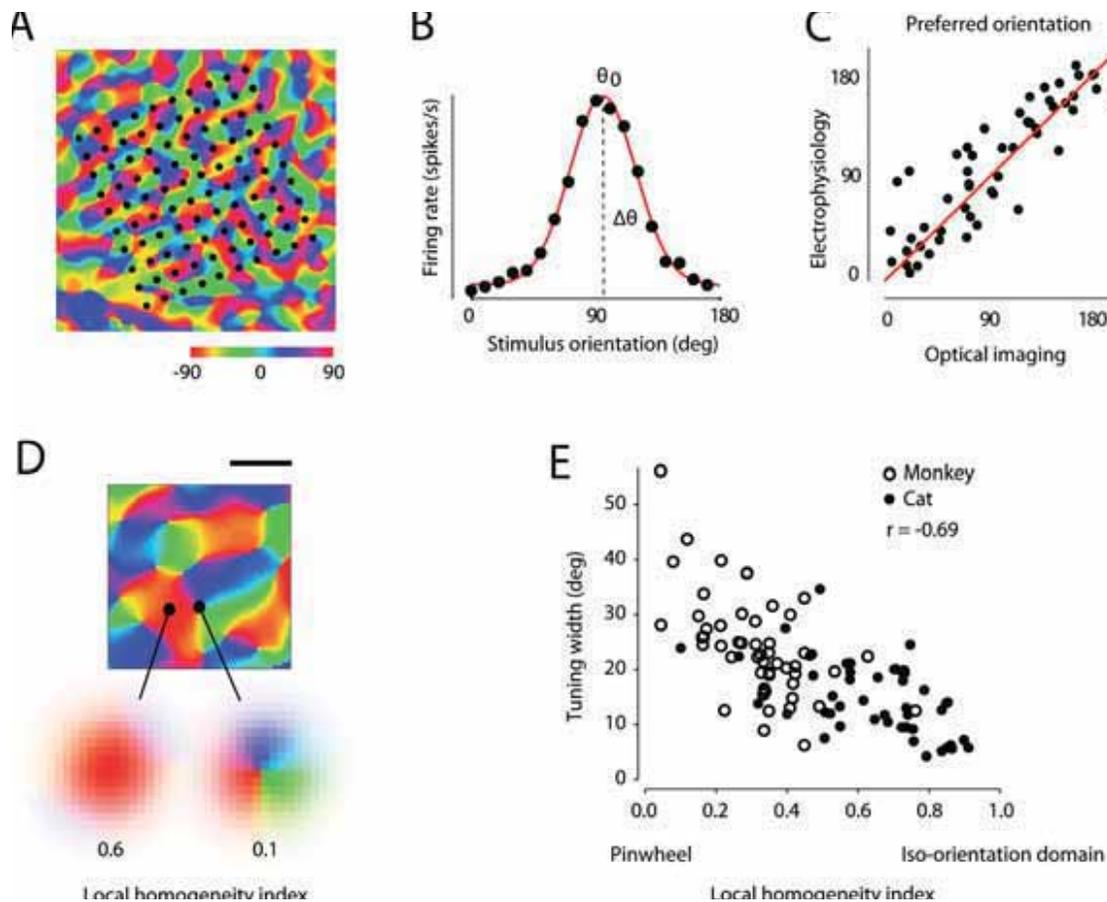

PLATE 42 Orientation tuning bandwidth and local map structure. (A) Example of an orientation preference map in macaque visual cortex along with the recovered location of the microelectrode array. (B) Reverse correlation in the orientation domain (Ringach et al., 1997) was used to measure the tuning curves at each electrode site simultaneously. The example here shows the average spike rate triggered to the presentation of each orientation in a rapid stimulus sequence, yielding a preferred orientation, θ_0 , and tuning width, $\Delta\theta$. (C) The estimated location of the array (solid dots in panel A) was estimated by finding the optimal translation/rotation parameters for which the preferred orientations as measured via reverse correlation matched those measured optically. The scat-

terplot illustrates the optimal correlation in one instance. (D) A local homogeneity index was defined to capture the diversity of orientation preferences around each cortical point. The example illustrates two locations with a low homogeneity index of 0.1 attained near a pinwheel and a location with a high index of 0.6 in an iso-orientation domain. (E) Spatial distribution of the local homogeneity index for the same patch of cortex as the one shown in panel D. (F) Isolation of single units. Only units that could be very well isolated, as is typical of the principal component analysis here, were used in our analyses of tuning bandwidth and local map structure. (See figure 28.2.)

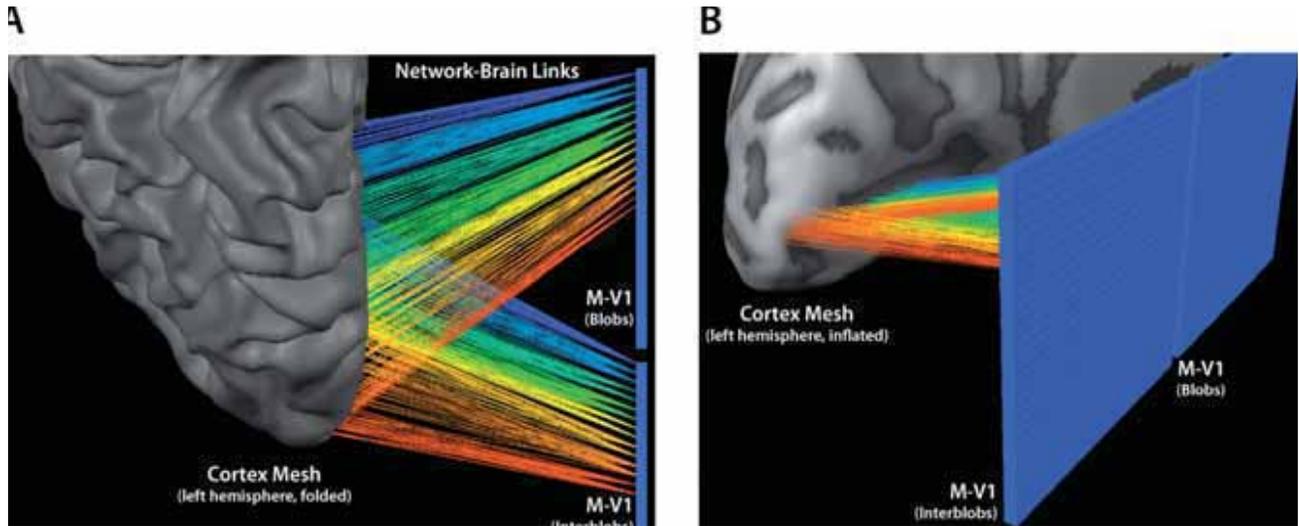

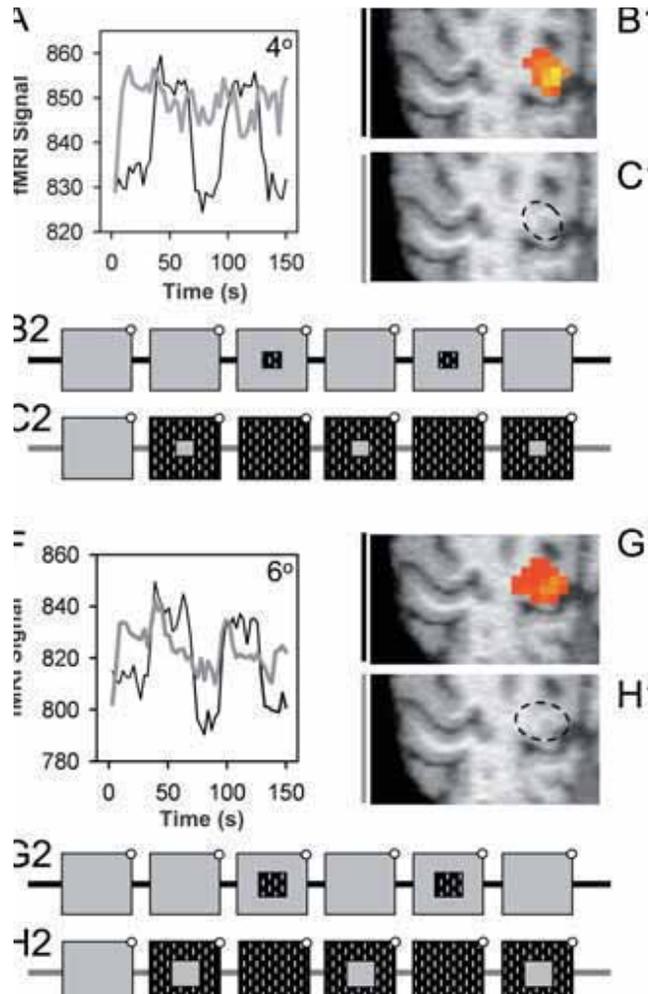

PLATE 43 Selected network-brain (NB) links connecting cortical column units from one layer of the boundary processing system (interblobs) and one layer of the surface processing system (blobs) of M-V1 to a left hemisphere cortex mesh of a subject. Colored lines indicate NB links from foveal (red) to increasingly peripheral (orange, yellow, green, blue) locations within the model layers and corresponding regions within the calcarine sulcus of the subject's

cortex as identified by a fMRI retinotopic mapping experiment. (A) Top view depicting the cortex mesh in a folded state. (B) Lateral view depicting the cortex mesh in an inflated view. Note that NBLs originating from the same retinotopic position of the boundary-processing M-V1 layer and surface-processing M-V1 layer are connected to the same position at the cortex mesh. (See figure 30.4.)

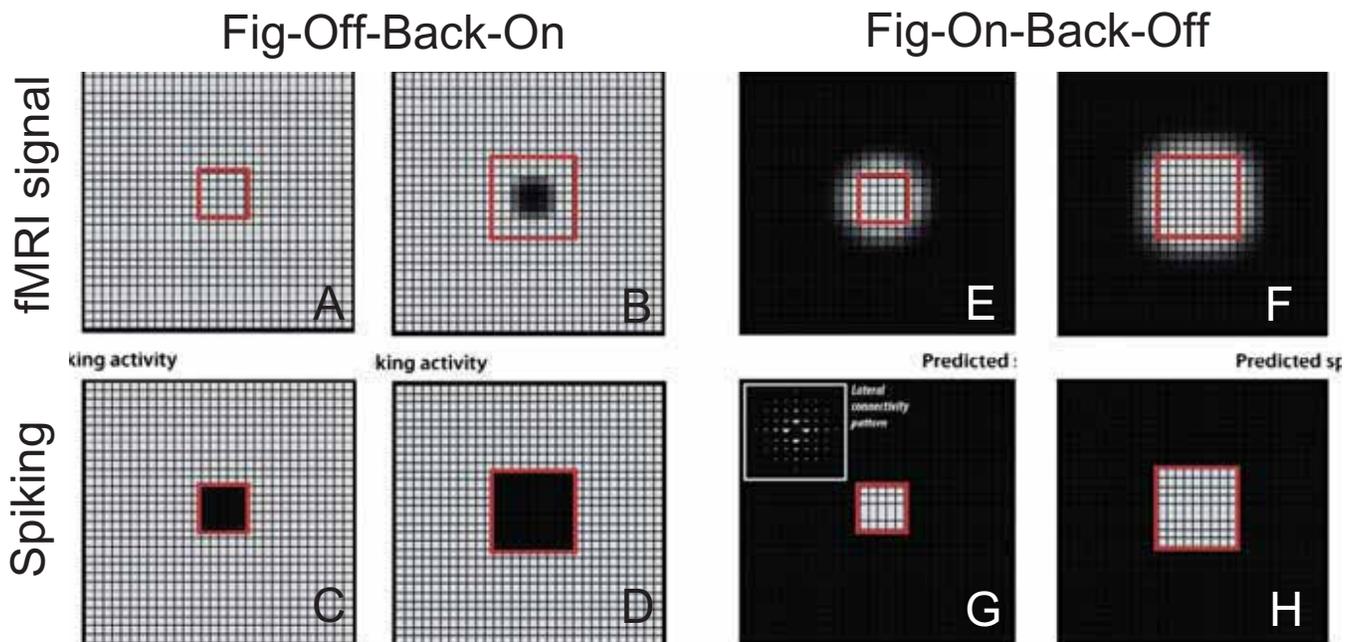

PLATE 45 Simulation of spiking activity and fMRI signals when an “empty” square is surrounded by dynamic texture (Fig-Off-Back-On) or vice versa (Fig-On-Back-Off). As indicated by red outlines, stimuli were presented with a small square (5×5 rectangle; *A, C, E, G*) or a large square (9×9 rectangle; *B, D, F, H*). Each panel shows the activity state of the same layer from the surface-processing system of M-V2. The lateral connectivity pattern of each unit within this layer is shown in *G*. The activity state of a processing unit is indicated by a black-to-white color range corresponding to weak-to-strong activity. The predicted fMRI data in

the Fig-Off-Back-On condition show inflow from texture background into the figure representation (*A, B*), and only for the larger square (*B*) the interior is spared (shown in dark). Predicted spiking data (*C, D*) show a perfect representation of the square, without noticeable inflow from the background. The predicted fMRI data in the Fig-On-Back-Off condition show outflow of fMRI activity from the representation of the texture square into the empty background (*E, F*), while such outflow is unnoticeable for spiking data (*G, H*). (See figure 30.6.)

PLATE 44 Empirical data from a single subject illustrating limitations in fMRI resolution using 1.5 Tesla Signa Horizon Echospeed system. Similar data were obtained from a second subject, and data in both subjects were replicable across sessions. Functional scans were obtained with a gradient echo EPI sequence (BOLD images), using a 64×64 matrix, a FOV of 14–16 cm, coronal slices with $\text{Thk} = 4$ mm, $\text{TE} = 40$ ms, and $\text{TR} = 4$ s. Functional data were overlaid on high-resolution structural scans of the same person’s brain. Structural scans were obtained by using 3D-SPGR, a $512 \times 384 \times 128$ matrix, with $\text{TE} = 5$ ms, $\text{TR} = 24$ ms, and a flip angle of 45 degrees. The testing of the effects of interest resulted in Wilkinson’s maps, which were converted into z -maps. Single voxels were considered significant when the corresponding z -score exceeded 3.07. The coronal slice shown was positioned 16 mm anterior from the occipital pole. Dynamic texture stimuli (see figure 30.1*A*) were equiluminant with the background (24 cd/m^2). (*A–C*) fMRI signal as a function of time (*A*) during two block designs (*B, C*). In the first design (*B2*), two 30-s blocks of presentation of 4 degree square at 7.2 degrees eccentricity in lower left quadrant were interleaved with three 30-s periods of gray background. In the second design (*C2*), two 30-s blocks of presentation of a textured background were alternated with three 30-s periods of presentation of a gray 4-degree square at 7.2 degrees eccentricity. An initial period of baseline measurement without stimulus was discarded from analysis. Fixation spot (where subjects performed a demanding T/L discrimination task) is indicated at the top right of each stimulus panel. When the square was defined by dynamic texture on a grey background (*B2*), significant activity (black plot in *A*) was found in

a large number of voxels in the upper bank of the calcarine sulcus (*B1*) using a regressor corresponding to the timing of the texture square in the block design in panel *B2*. When a full texture background was shown in blocks with or without a gray square (*C2*), there was no significant activity (*C1*) for the regressor corresponding to the physical filling-in of the gray square with texture (*C2*). The gray plot in panel *A* shows activity in the region of interest (ROI) defined by the response to the textured square (ROI is shown as a dashed oval in *C1*) during data from the block design shown in *C2*. For the design in *C2*, the data suggest spread of fMRI signal from the background texture into the gray figure. (*F–H*) Same conventions as in panels *A–C*, but the square size was 6 degrees. The gray plot in panel *F* shows a small, transient response to physical filling-in of the texture (design *H2*) that did not lead to significant activity in *H1* (based on regressor corresponding to design *H2*). The fMRI signal in designs *C2* and *H2* inside the figure representation was not due to perceptual filling-in, as the signal was present from the beginning of stimulation (gray plot in panels *A* and *F*). Based on data in block designs showing a texture square on a gray background alternated with a gray background (as in *B2* and *G2*), we found (averaged over subjects) activated regions of 158, 230, and 267 mm^2 for square sizes of 1, 4, and 6 degrees, respectively, while based on retinotopy (Serenó et al., 1995), activated regions of approximately 3, 45, and 110 mm^2 were expected. Averaged over subjects and conditions, a Gaussian filter of 7 mm (HWHM) was required to simulate the blurring of expected signal by fMRI. (See figure 30.5.)

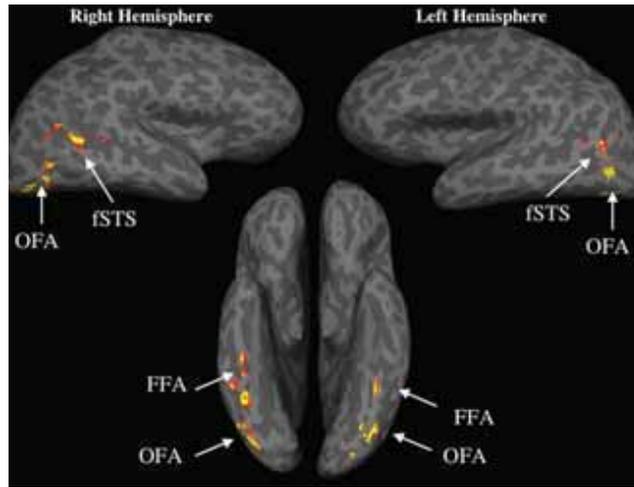

PLATE 46 Face-selective activation (faces > objects, $p < 0.0001$) on an inflated brain of one adult subject, shown from lateral and ventral views of the right and left hemispheres. Three face-selective regions are shown: the FFA in the fusiform gyrus along the ventral

part of the brain, the OFA in the lateral occipital area, and the fSTS in the posterior region of the superior temporal sulcus. For studies of face identification (rather than expression, etc.), the FFA and OFA are of greatest interest. (See figure 32.1.)

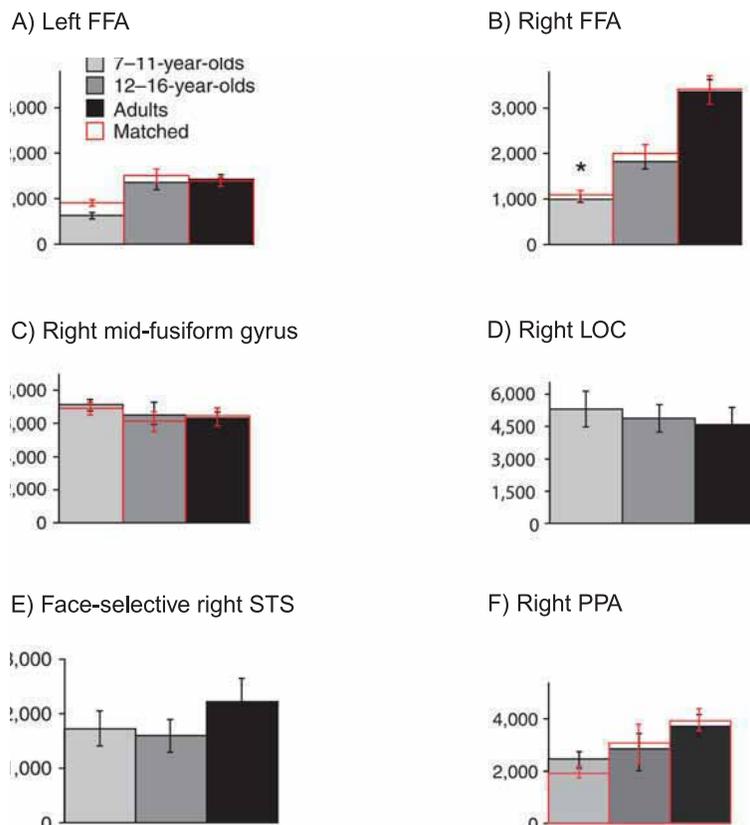

PLATE 47 Mean volume across subjects in each age group of individually defined (A) left and (B) right FFA, (C) anatomically defined right mid-fusiform gyrus, (D) functionally defined right LOC, and functionally defined (E) face-selective right STS and (F)

right place-selective PPA. Red bars indicated values in subsets of subjects matched for BOLD-related confounds. (From Golarai et al., 2007.) (See figure 32.4.)

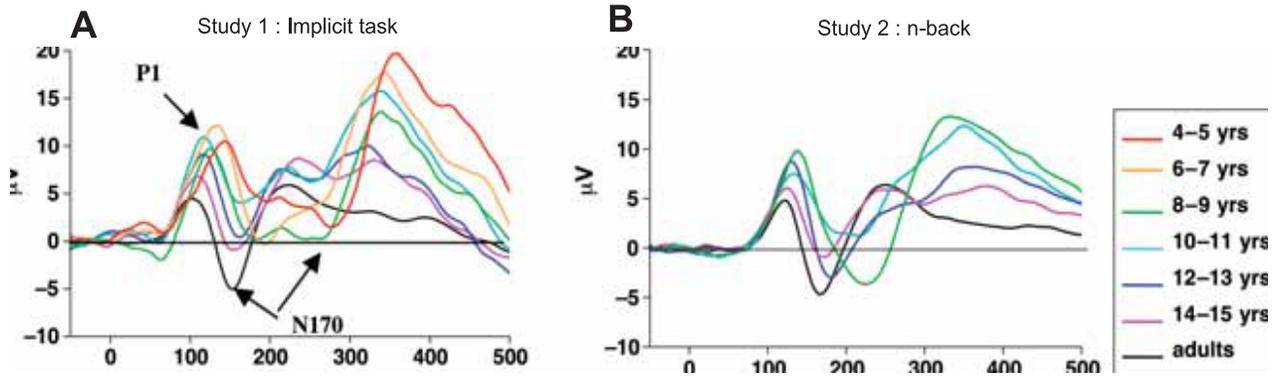

PLATE 48 ERPs from right posterior temporal scalp locations in response to face stimuli, separately for each age group. (From Taylor et al., 2004.) (See figure 32.5.)

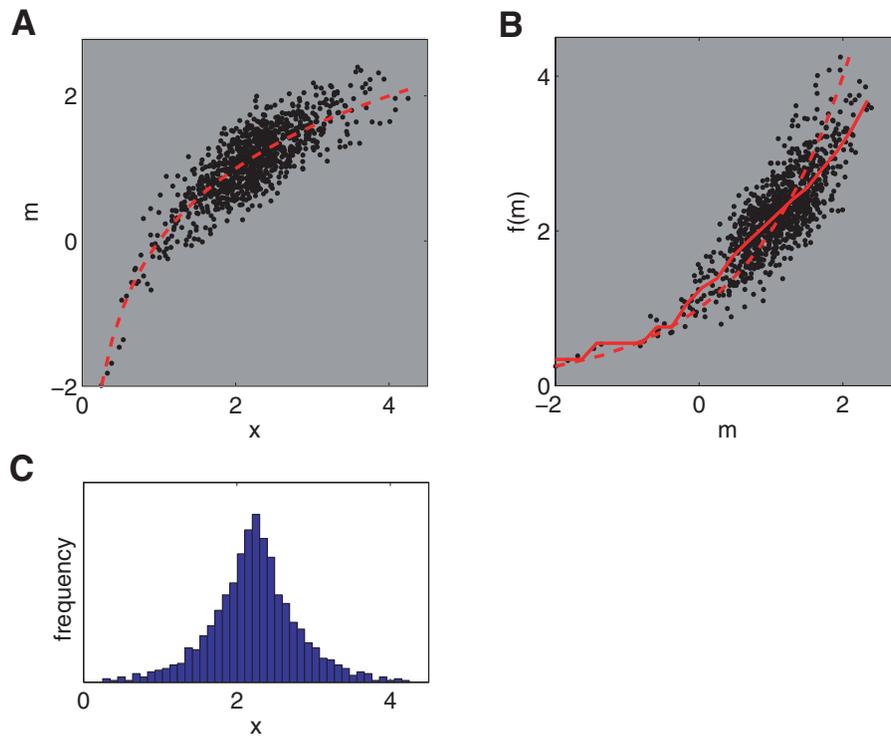

PLATE 49 Regression formulation of the optimal estimation problem, illustrated for a one-dimensional signal and measurement. (A) The measurement process (also known as the *encoding* process). We assume a set of data pairs (plotted points), $\{x_n, m_n\}$, indexed by $n \in [1, 2, \dots, N]$, representing true signal values and associated noisy measurements. The dashed line indicates the average measurement as a function of the true signal value. (B) The estimation (or *decoding*) process. The estimator $f(m)$ maps measure-

ments back to estimated signal values. The optimal estimator (solid line) does this so as to minimize a specified loss function. Note that this need not be (and is generally not) the inverse of the average measurement function (dashed line). Note also that the optimal estimator will depend on the signal values that are included in the data set, which are summarized by the histogram shown in panel C. (See figure 36.1.)

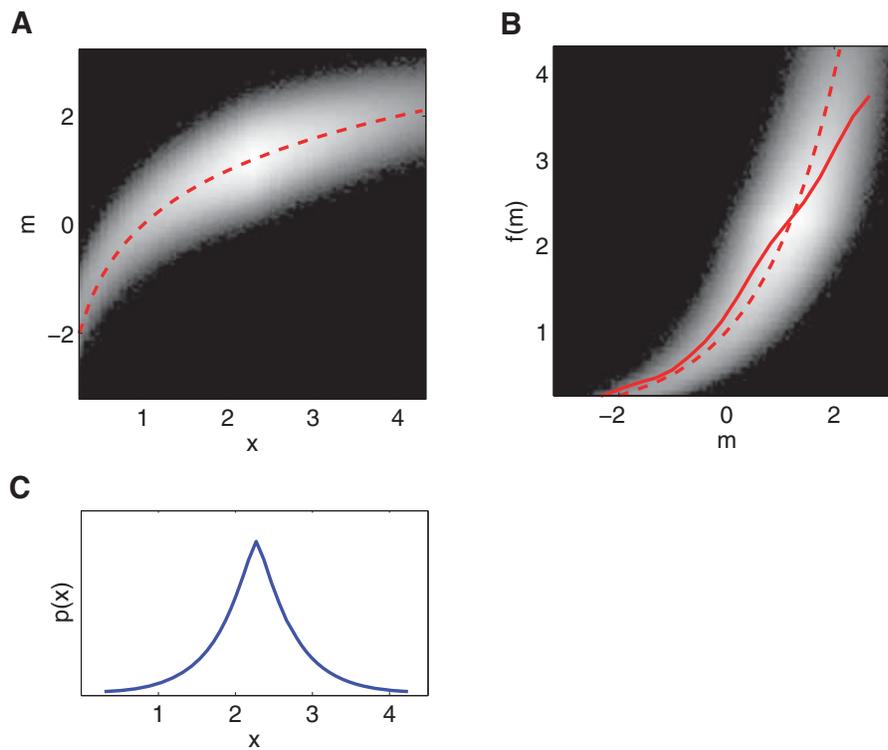

PLATE 50 Bayesian formulation of the optimal estimation problem. (A) The measurement density, $P(m|x)$, shown as a gray-scale image, where intensity indicates log probability. The dashed line indicates the mean of the density as a function of x . (B) The

posterior density, $P(x|m)$. The solid line indicates the mean of the density, and the dashed line indicates the (inverted) mean of the measurement density in panel A. (C) the prior density, $P(x)$. (See figure 36.2.)

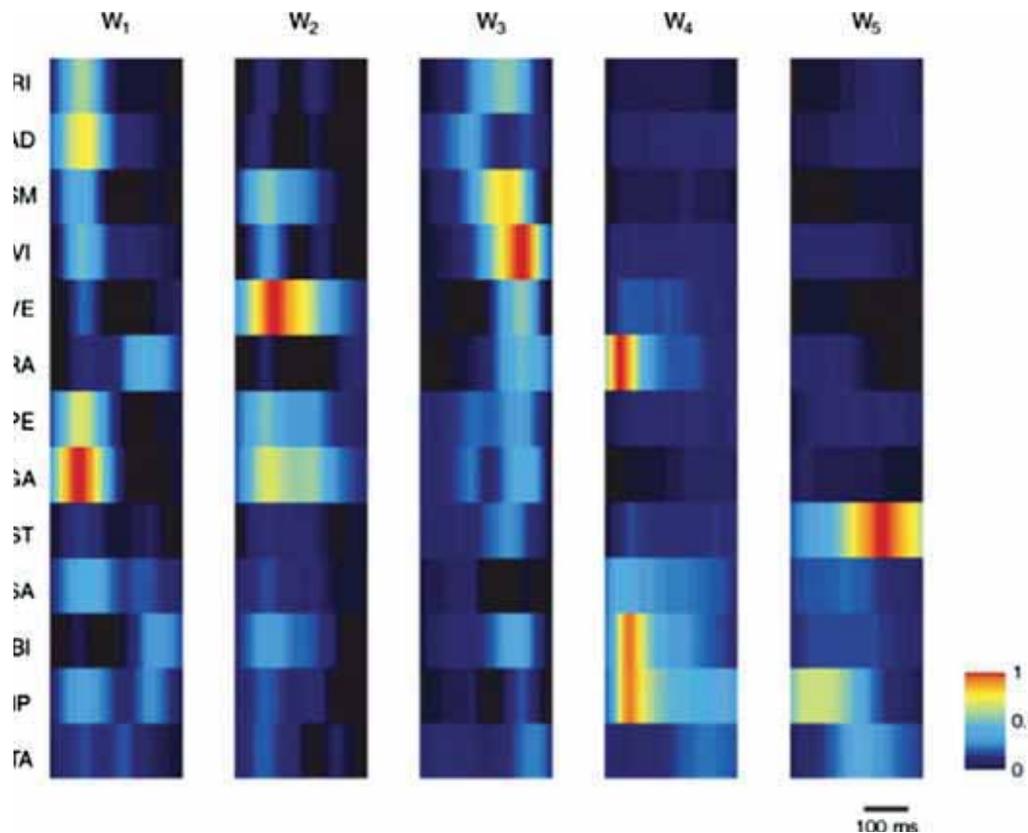

PLATE 51 Time-varying muscle synergies extracted from jumping, swimming, and walking muscle patterns in three frogs. Each synergy (columns W_1 to W_5) represents the activation time course (in color code) of 13 muscles over 30 samples (total duration: 300 ms) normalized to the maximum sample of each muscle. Abbreviations: RI, rectus internus; AD, adductor magnus; SM, semimembranosus; VI, the knee extensor vastus internus; VE,

vastus externus; RA, rectus anterior; PE, the ankle extensors peroneus; GA, gastrocnemius; ST, mainly semitendinosus; SA, semitendinosus; BI, biceps; IP, iliopsoas; TA, tibialis anterior. (From Bizzi, E., Cheung, V. C., d'Avella, A., Saltiel, P., Tresch, M. C., 2008, Combining modules for movement, *Brain Res. Rev.*, 57, 125–133.) (See figure 37.2.)

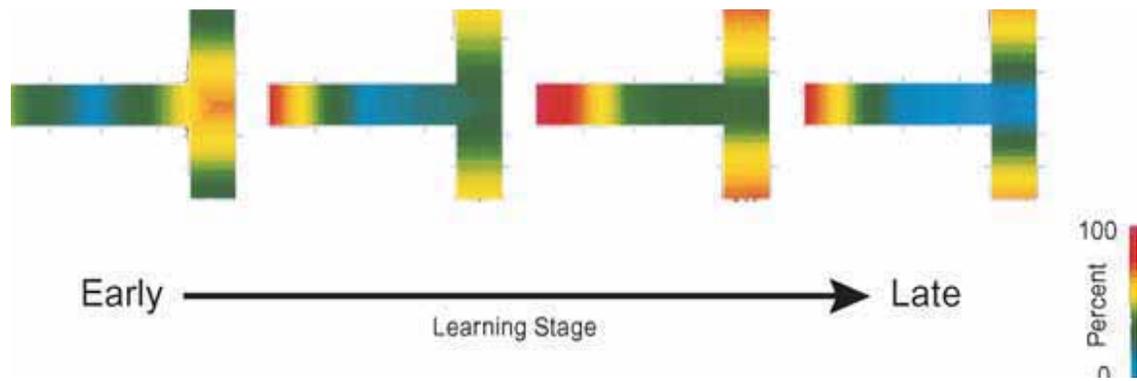

PLATE 52 Event-related ensemble activity of neurons in the dorsolateral striatum of rats recorded during the acquisition and performance of an auditory conditional turning task in a T-maze. Color plots at bottom illustrate schematically the gradual changes

in the response profiles of the striatal neurons during the course of behavioral learning. (Modified from Jog et al., 1999; Graybiel and Kubota, 2003.) (See figure 39.11.)

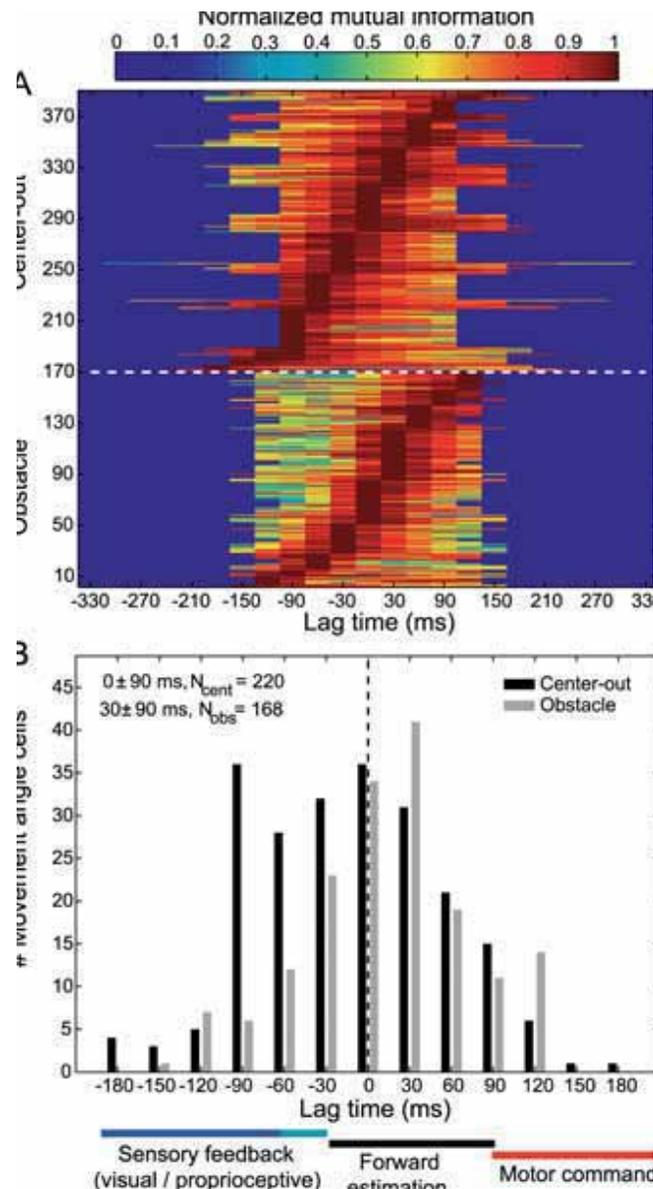

PLATE 53 Population temporal encoding results. (A) Population TEFs plotted for all movement angle neurons showing cell-normalized mutual information as a function of lag time. (B) Histogram summarizing the OLTs for movement angle neurons for both center-out and obstacle tasks (summary statistic in upper-left corner: median \pm interquartile range). Many of these neuron's

OLTs were consistent with a forward estimate of the state of the movement angle, which did not directly reflect delayed sensory feedback to PPC, nor were they compatible with outgoing motor commands from PPC. (Reprinted with permission from Mulliken, Musallam, & Andersen, 2008.) (See figure 41.3.)

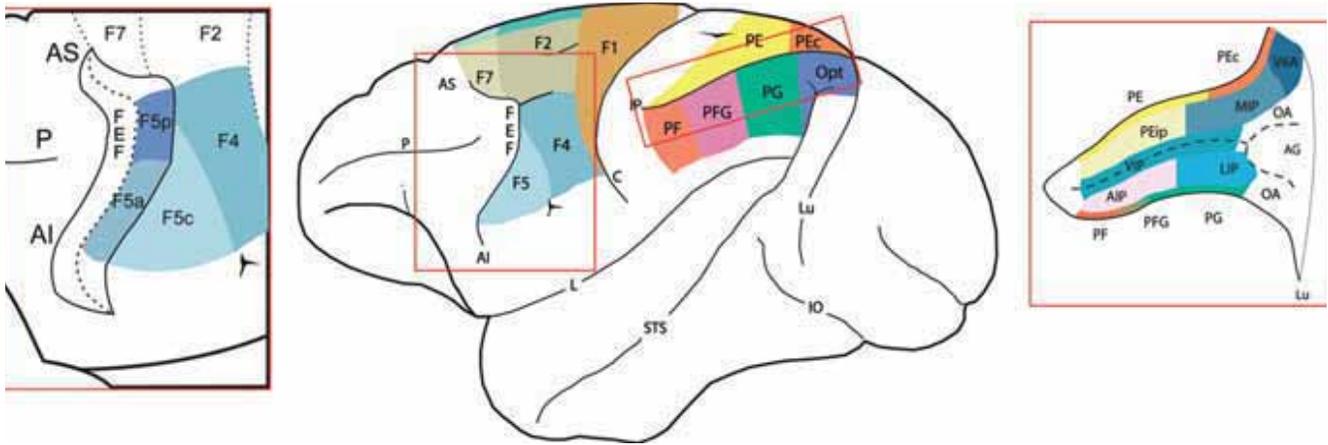

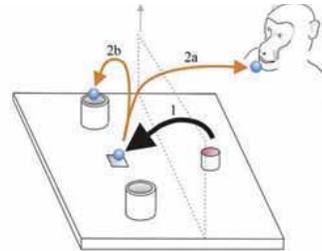

PLATE 54 Lateral view of the monkey brain showing the parcellation of the motor and the posterior parietal cortex. The areas located within the arcuate and the intraparietal sulcus are shown in an unfolded view of these sulci in the left and right parts of the figure, respectively. For the nomenclature and definition, see Rizzolatti, Luppino, and Matelli (1998), Nelissen et al. (2005),

and Gregoriou et al. (2006). Abbreviations: AI, inferior arcuate sulcus; AS, superior arcuate sulcus; C, central sulcus; FEF, frontal eye-fields; IP, intraparietal sulcus; IO, inferior occipital sulcus; L, lateral fissure; Lu, lunate sulcus; P, principal sulcus; STS, superior temporal sulcus. (See figure 43.1.)

Motor responses of parietal neurons

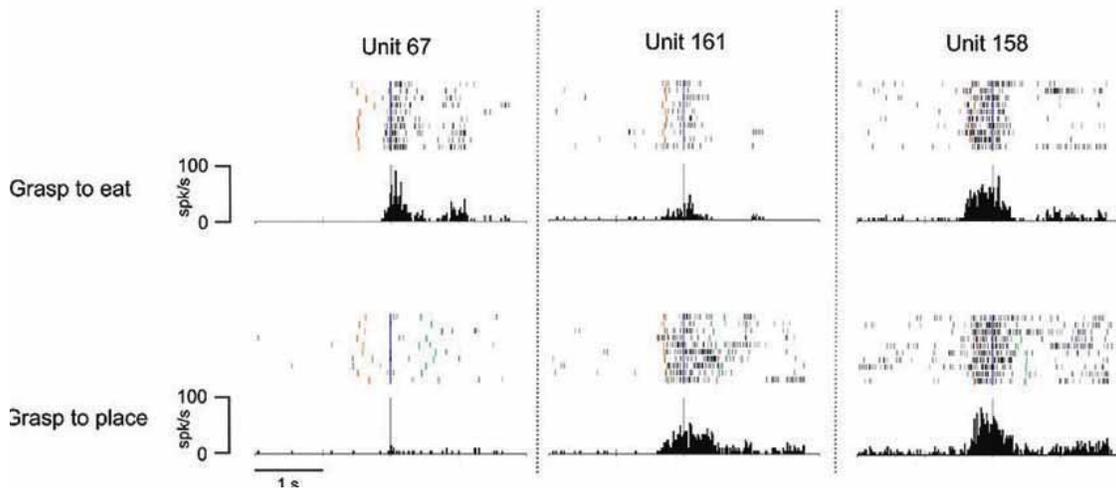

PLATE 55 Examples of the activity of parietal motor neurons during execution of two different actions. (A) Apparatus and paradigm used for the motor task. In one condition (grasping for eating), the monkey reached for and grasped a piece of food located on a plane in front of it (1) and brought the food to its mouth (2a). In another condition (grasping for placing), the monkey reached for and grasped an object located in front of it (1) and placed the object into a container (2b). In the first condition, the monkey ate the food that it had brought to the mouth; in the second condition, the monkey was rewarded after correct accomplishment of the task. (B) Activity of three IPL neurons during grasping in the two experi-

mental conditions. Unit 67 discharges were stronger during grasping to eat than during grasping to place, Unit 161 discharges were stronger during grasping to place. Unit 158 did not show any difference in discharge between the two conditions. Rasters and histograms are aligned with the moment when the monkey touched the object or food to be grasped. Red bars: Monkey releases the hand from the starting position. Green bars: Monkey touches the container. Abscissa: Time, bin = 20 ms; Ordinate: Discharge frequency in spikes per second. (Modified from Fogassi et al., 2005.) (See figure 43.3.)

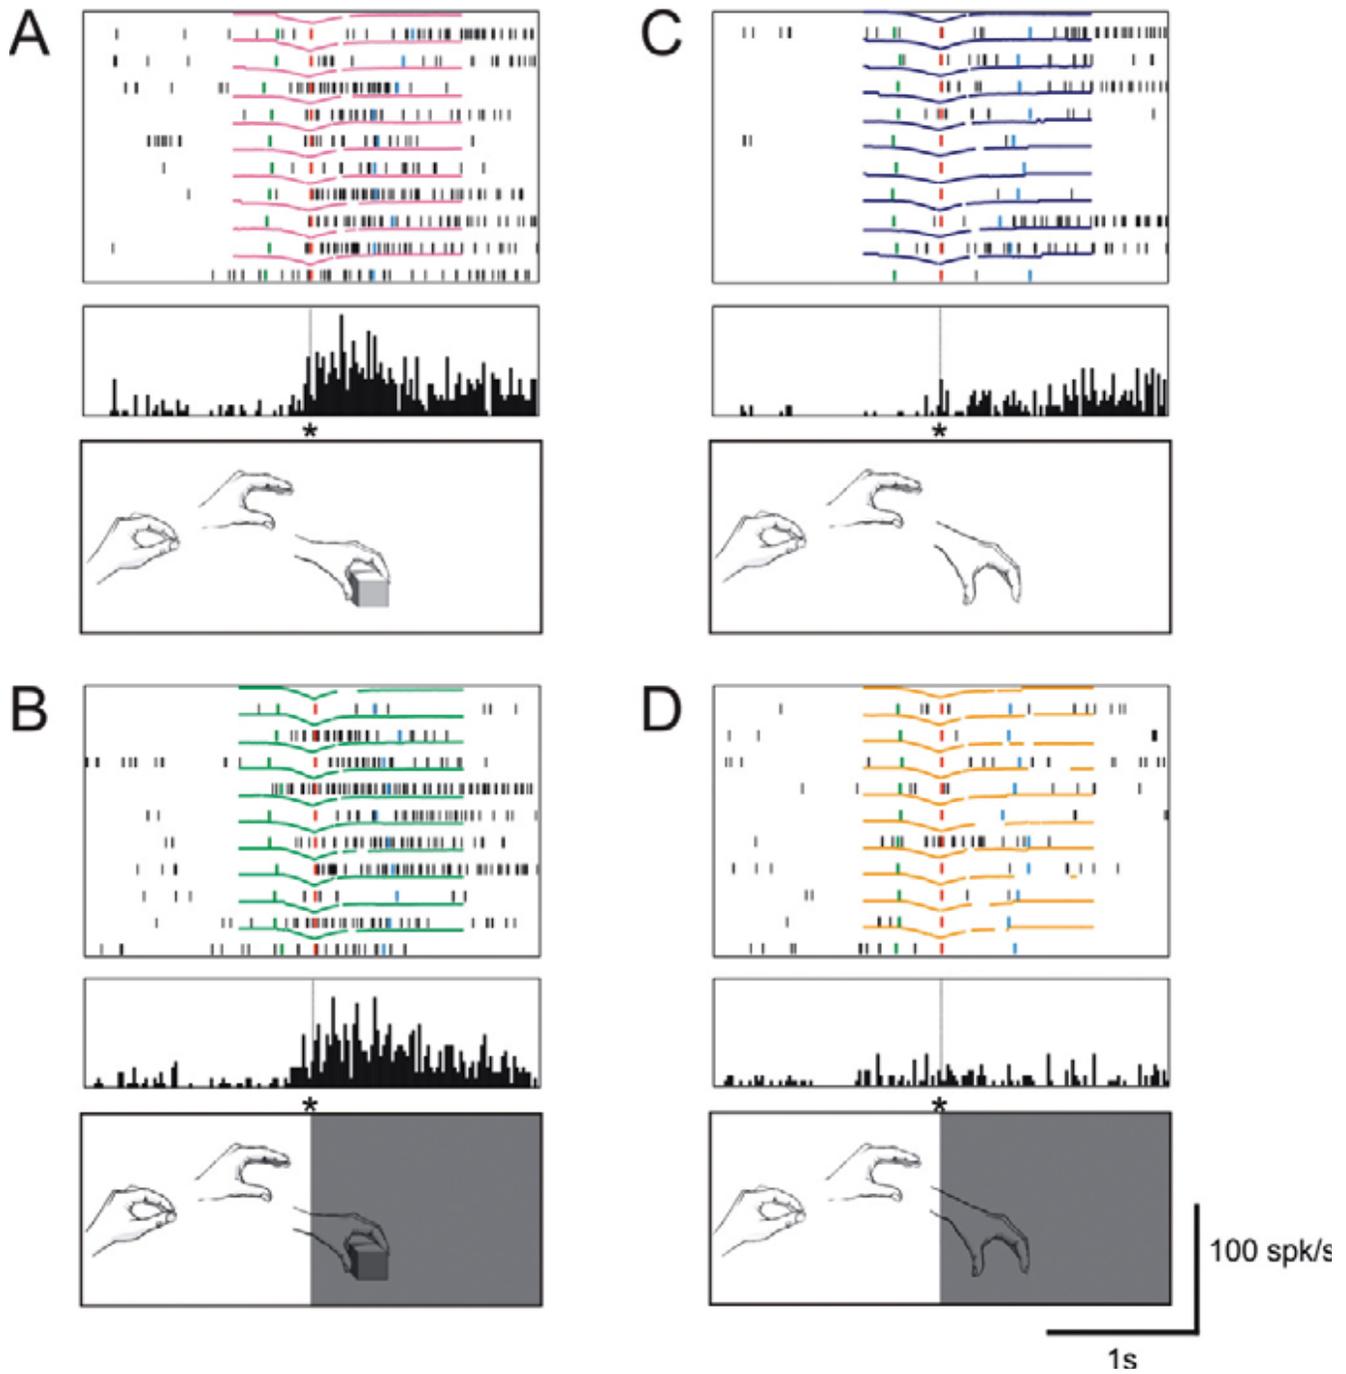

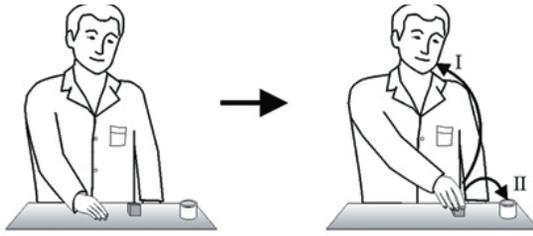

PLATE 56 Example of a mirror neuron responding during observation of grasping in both full vision and “hidden” condition. (*A* and *C*): Observation of goal-directed or mimed grasping, respectively, in full vision. (*B* and *D*): Observation of goal-directed or mimed grasping, respectively, in the hidden condition. In every panel, from top to bottom, rasters and histogram and the schematic drawing of the experimenter motor act are shown. The gray frame in conditions *B* and *D* represents a screen interleaved between the monkey and the experimenter hand in the two hidden conditions.

The asterisk indicates the location of a stationary marker that was attached at the level of the crossing point where the experimenter’s hand disappeared behind the screen in the hidden conditions. The colored line above each raster represents the kinematics of the experimenter’s hand movement; the downward deflection of the line means that the hand is approaching the stationary marker (the minimum corresponding to the moment in which the hand is closest to the marker). Histograms bin width = 20 ms. (Modified from Umiltà et al., 2001.) (See figure 43.5.)

Visual responses of mirror neurons

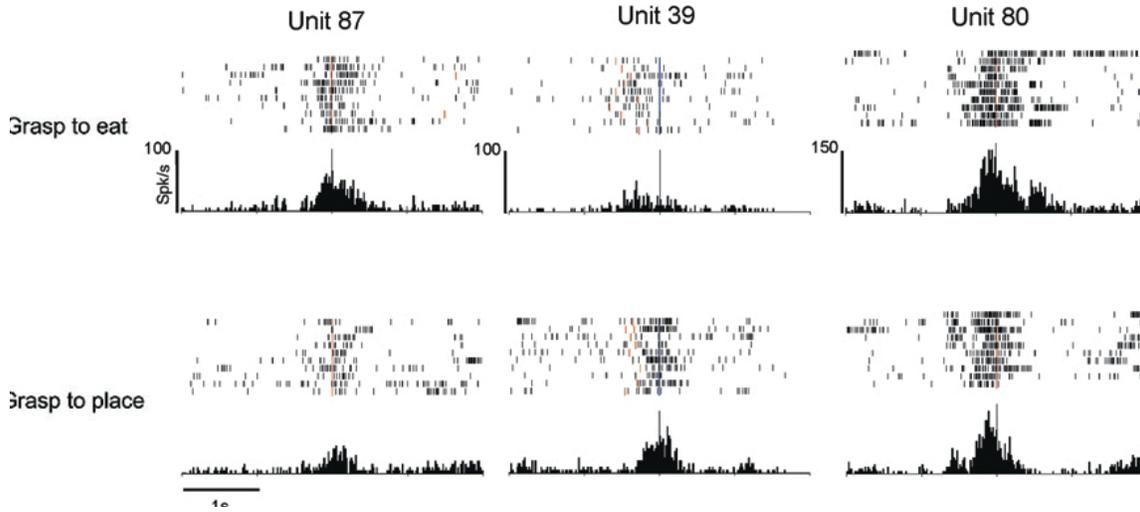

PLATE 57 Examples of visual responses of IPL mirror neurons during the observation of grasping-to-eat and grasping-to-place conditions performed by an experimenter. (A) The paradigm is similar to that used for the motor task shown in figure 43.3, but in this case, the two conditions are performed by the experimenter in front of the monkey, which is simply observing the scene. (B) Activity of three mirror neurons during observation of grasping in the two experimental conditions. Unit 87 discharges are stronger

during observation of grasping to eat than during observation of grasping to place, Unit 39 discharges are stronger during observation of grasping to place. Unit 80 did not show any difference in discharge between the two conditions. Rasters and histograms are aligned with the moment when the experimenter touched the object or food to be grasped. (Modified from Fogassi et al., 2005.) (See figure 43.6.)

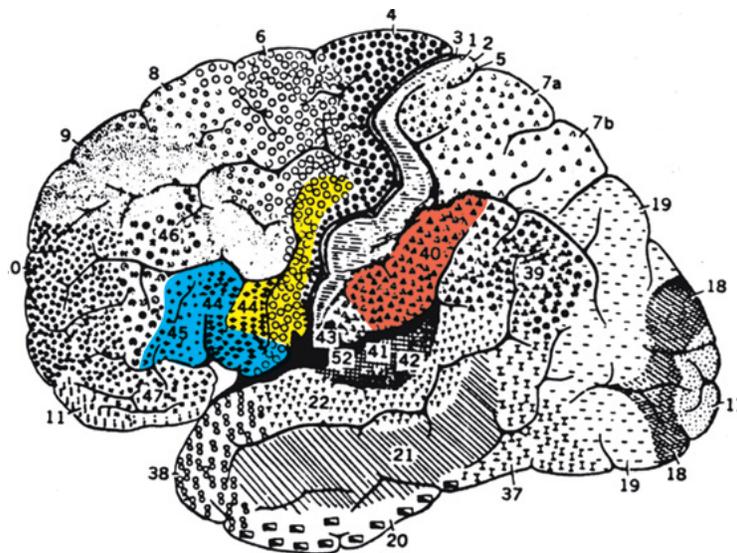

PLATE 58 Lateral view of the human cortex showing the frontal (yellow and blue) and parietal (red) regions constituting the core of the grasping mirror neuron system in humans. Numbers and symbols indicate the different cytoarchitectonic areas according to the parcellation of Brodmann (1909). (See figure 43.7.)

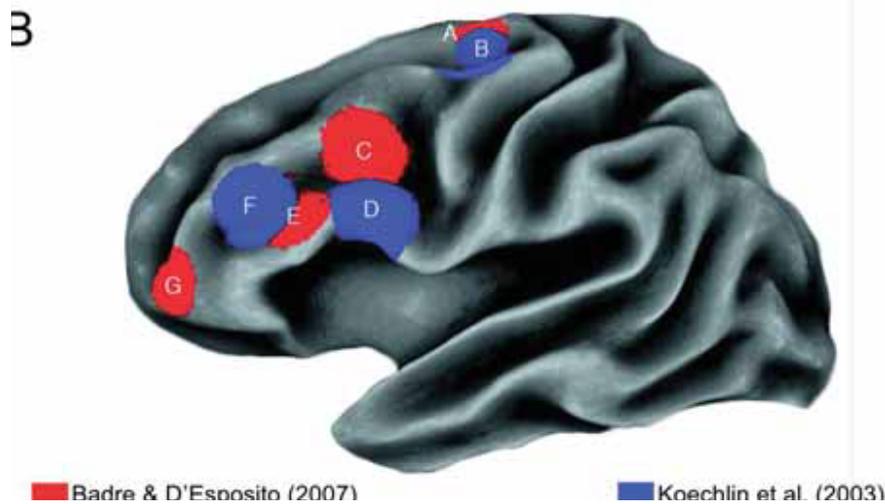

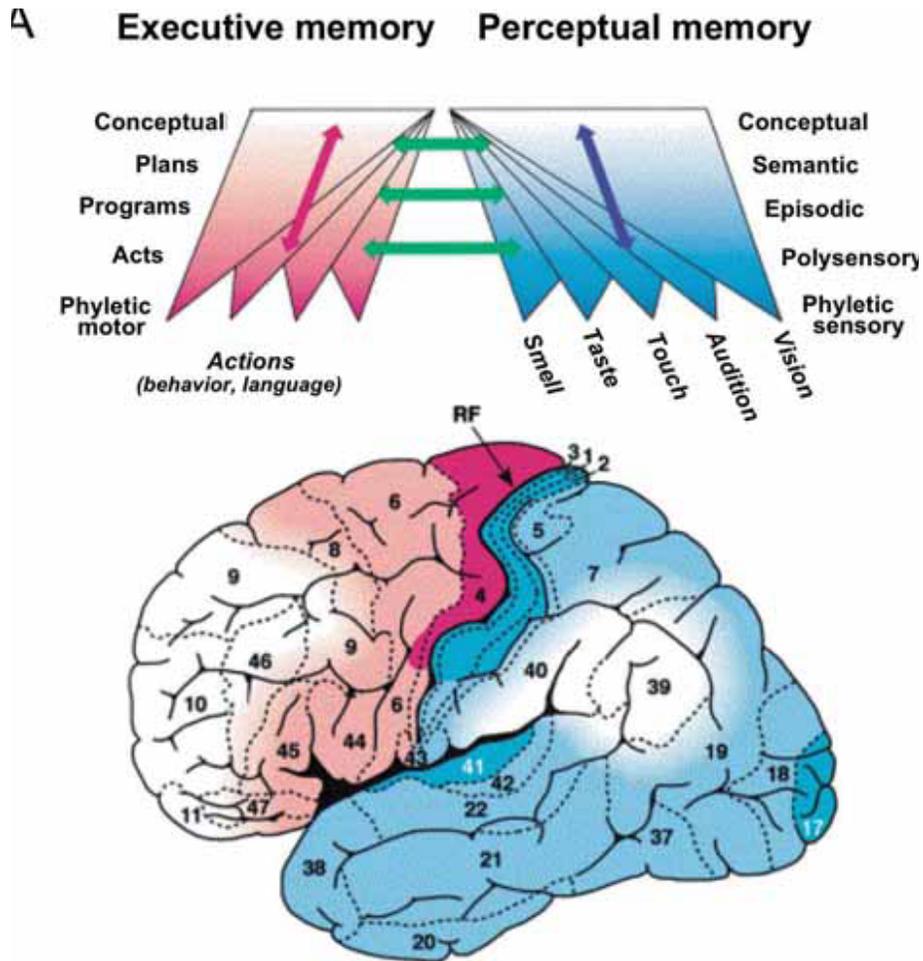

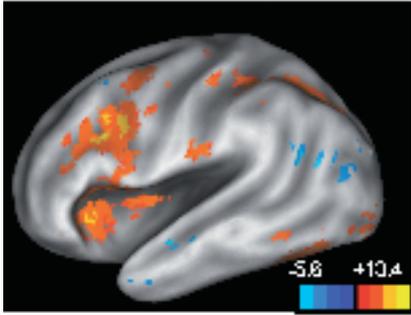

PLATE 60 Hierarchical organization of cognitive representations in lateral cortex. (A) Schema of two hierarchies of cortical memory, executive memory, and perceptual memory, and the distribution of these hierarchies in frontal and posterior cortical regions, respectively. In frontal cortex, representations that are “higher” in the processing hierarchy are mapped to more rostral regions, and “lower”-level representations are mapped to more caudal regions. (Reprinted from J. M. Fuster, 2001, *The prefrontal cortex—An update: Time is of the essence*, *Neuron*, 30, 319–333. Copyright 2001, with permission from Elsevier.) (B) Neuroimaging data providing evidence for representational hierarchies in frontal cortex.

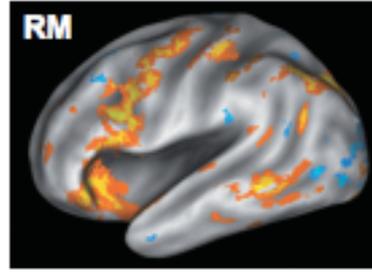

Spheres from Badre and D'Esposito (2007) (red) reflect foci of activation with experimental manipulations at different levels of representation: A, the response level; C, the feature level; E, the dimension level; G, the context level. Spheres from Koechlin, Ody, and Kouneiher (2003) (blue) reflect foci of activation with manipulations of different levels of control: B, sensory control; D, contextual control; F, episodic control. (Adapted with permission from D. Badre & M. D'Esposito, 2007, *Functional magnetic resonance imaging evidence for a hierarchical organization of the prefrontal cortex*, *J. Cogn. Neurosci.*, 19, 2082–2099. Copyright 2007, with permission from the MIT Press.) (See figure 48.3.)

Random effects group map

Contrast between recognition trials and baseline ($p < .001$ u.c.)

Session 1

Session 2

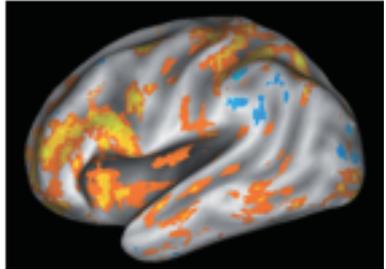

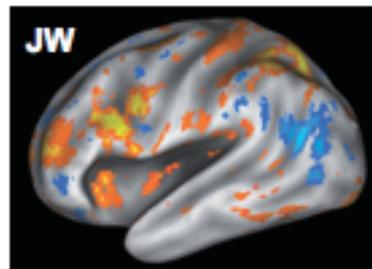

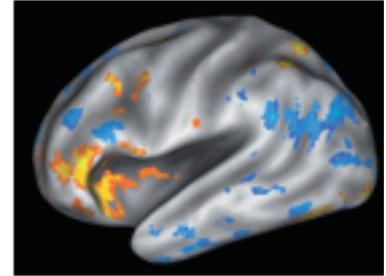

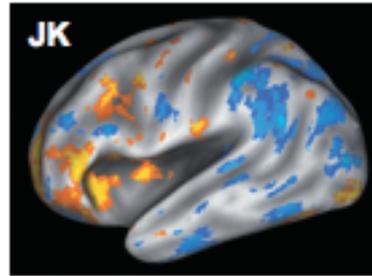

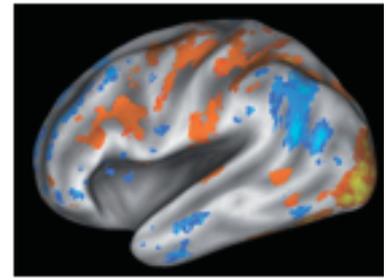

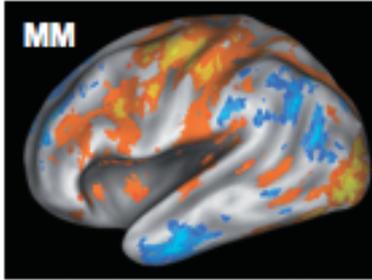

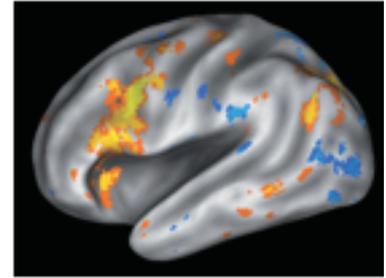

PLATE 61 The left hemisphere patterns of activations and deactivations during an episodic retrieval task for the group and for 4 of the 14 individuals that made up the group. The random-effects group map and the individual t -maps are a contrast between the retrieval condition and baseline, statistically thresholded at $p < .001$ uncorrected for multiple comparisons. The thresholding

was done for visualization purposes only. Displayed for each individual is the t -map for the first and second sessions. The images are representative of the high degree of variability between individuals, yet the relative stability in the individual patterns of activity over time. (From Miller et al., in press.) (See figure 50.1.)

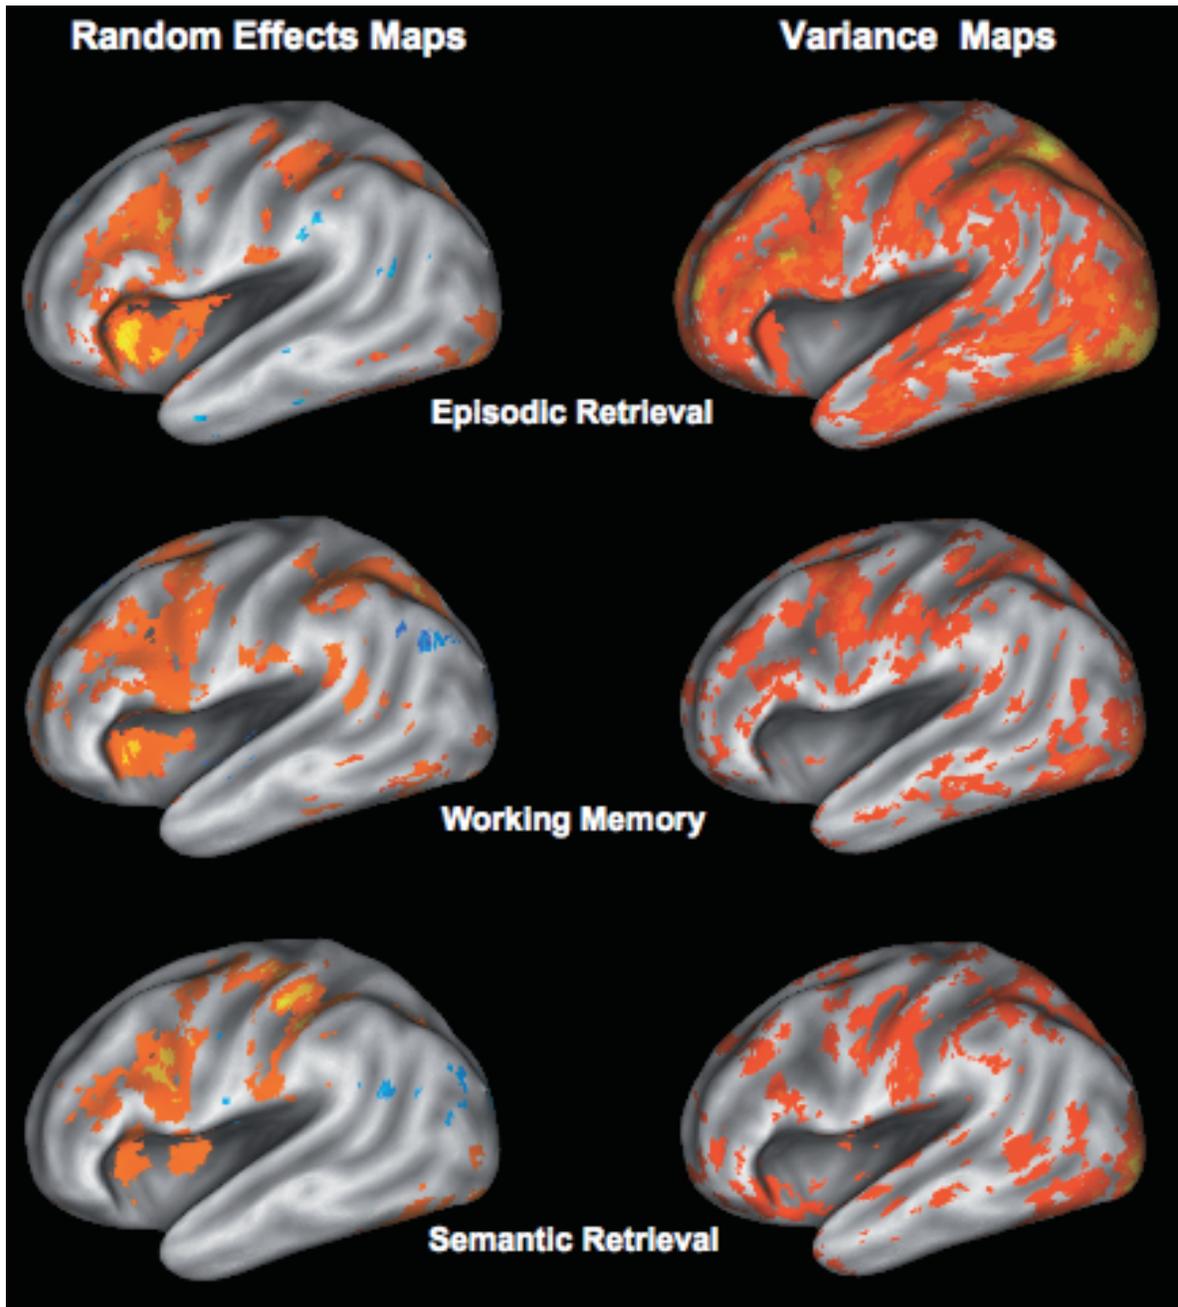

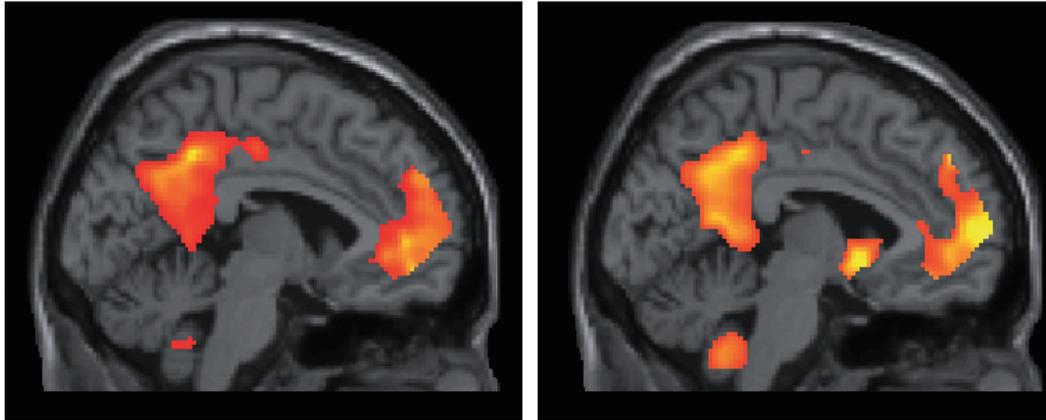

PLATE 62 A comparison of random-effects group maps and variance maps across three memory tasks. The random-effects maps are a statistically thresholded ($p < .001$ uncorrected for multiple comparisons) representation of the common areas of brain activity across 14 individuals. The variance maps to the right display the

standard deviations across the 14 individuals at each voxel above a threshold of 2 standard deviations. As the variance maps indicate, individuals variably engaged much wider regions of the cortex during episodic retrieval than during semantic retrieval or working memory. (See figure 50.2.)

PLATE 64 The dual-stream model of speech processing. (A) Schematic diagram of the dual-stream model. The earliest stage of cortical speech processing involves some form of spectrotemporal analysis, which is carried out in auditory cortices bilaterally in the supratemporal plane. These spectrotemporal computations appear to differ between the two hemispheres. Phonological-level processing and representation involves the middle to posterior portions of superior temporal sulcus (STS) bilaterally, although there may be a weak left-hemisphere bias at this level of processing. Subsequently, the system diverges into

two broad streams, a dorsal pathway (blue) that maps sensory or phonological representations onto articulatory motor representations, and a ventral pathway (red) that maps sensory or phonological representations onto lexical-conceptual representations. (B) Approximate anatomical locations of the dual-stream model components, specified as precisely as available evidence allows. Regions shaded green depict areas on the dorsal surface of the STG that are hypothesized to be involved in spectrotemporal analysis. Regions shaded yellow in the posterior half of the STS are implicated in phonological-level processes. Regions shaded red

PAST AND FUTURE EVENT ELABORATION

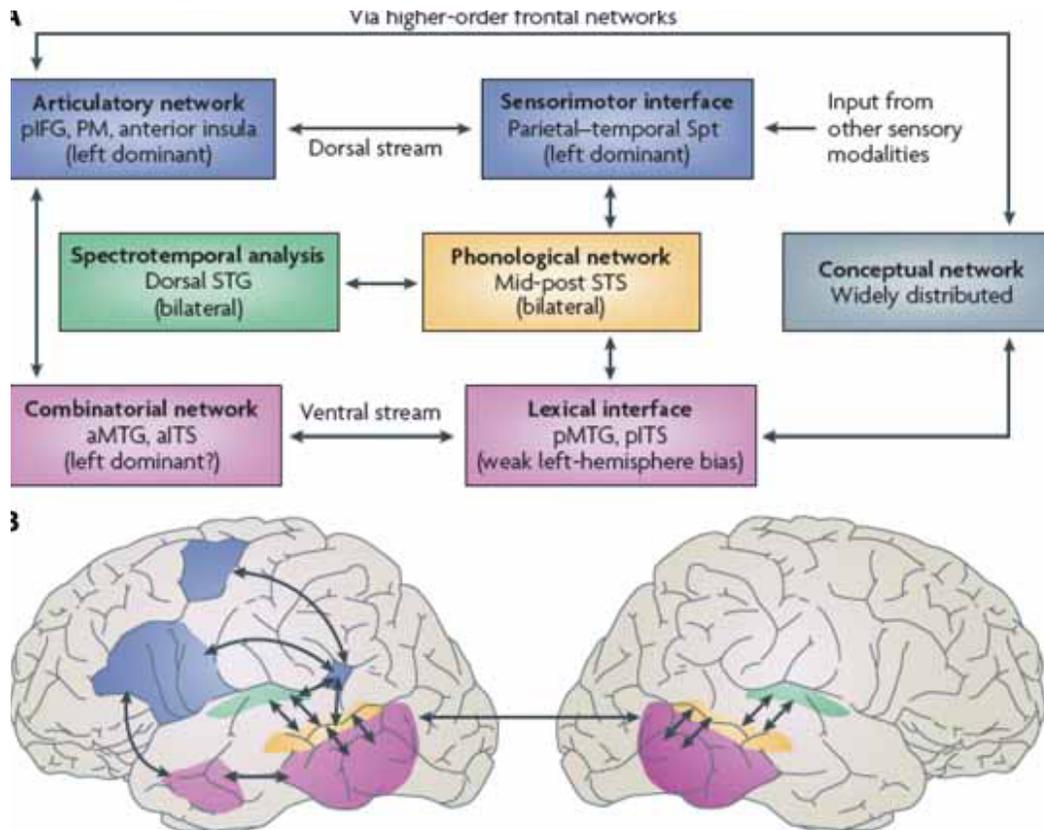

PAST EVENT > CONTROL

FUTURE EVENT > CONTROL

PLATE 63 Sagittal slice ($x = -4$) illustrating the striking commonalities in the medial left prefrontal and parietal regions engaged when remembering the past (*left panel*) and imagining the future (*right panel*). These marked similarities of activation were also evident in areas of the medial temporal lobe (left hippocampus, bilateral parahippocampal gyrus) and lateral cortex (left temporal pole and left bilateral inferior parietal cortex). This extensive

pattern of common activity was not present during the construction of past and future events; it only emerged during the elaboration of these events (shown here, relative to the elaboration phase of a semantic and an imagery control task; significant at $p < .001$, uncorrected; shown at $p < .005$, uncorrected.) (Originally published in Addis, Wong, & Schacter, 2007.) (See figure 51.1.)

represent the ventral stream, which is bilaterally organized with a weak left-hemisphere bias. The more posterior regions of the ventral stream, the posterior middle and inferior portions of the temporal lobes, correspond to the *lexical interface*, which links phonological and semantic information, whereas the more anterior locations correspond to the hypothesized *combinatorial network*. Regions shaded blue represent the dorsal stream, which is strongly

left-dominant. The posterior region of the dorsal stream corresponds to an area in the Sylvian fissure at the parietal-temporal boundary (area Spt), which is hypothesized to be a *sensorimotor interface*, whereas the more anterior locations in the frontal lobe, likely involving Broca's region and a more dorsal premotor site, correspond to portions of the articulatory network. (Figure reproduced from Hickok & Poeppel, 2007.) (See figure 52.2.)

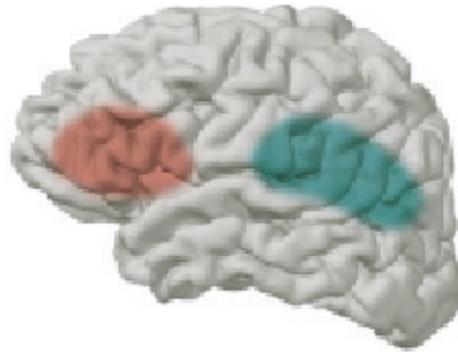

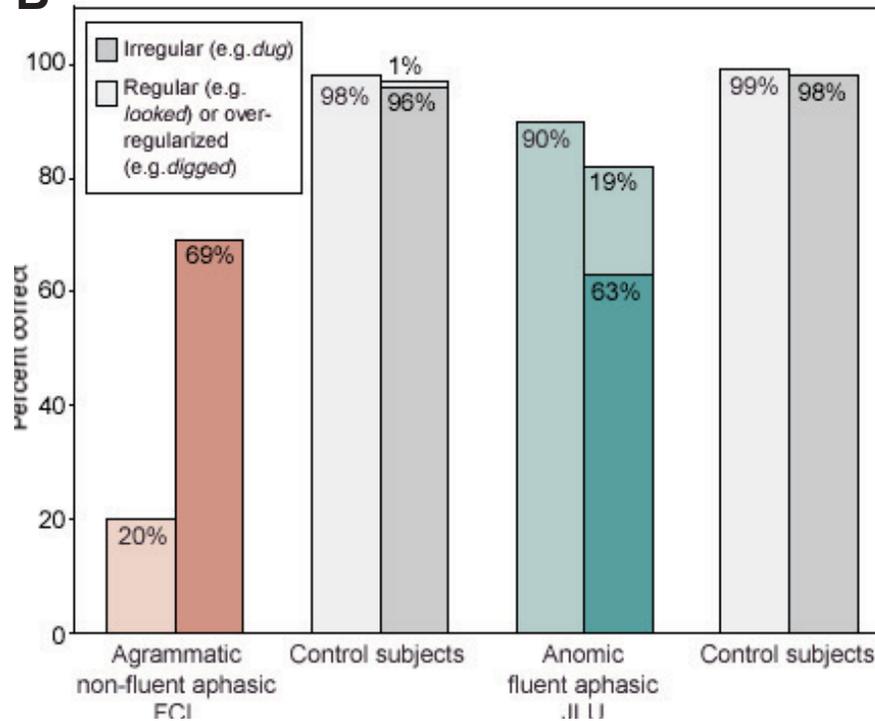

A**B**

PLATE 65 A neuropsychological dissociation in processing regular and irregular verb forms. (A) The approximate lesion sites of patient FCI (red area, left anterior perisylvian regions), who had symptoms of agrammatism, and patient JLU (green area, left temporoparietal region), who had symptoms of anomia. (B) Results of verb inflection tests showed that the agrammatic patient had more trouble inflect-

ing regular verbs (lighter bars) than irregular verbs (darker bars), whereas the anomic patient had more trouble inflecting irregular verbs—and overapplied the regular suffix to many of the irregulars (light green bar on top of dark green bar). The performance of age- and education-matched control subjects is shown in the gray bars. (Reprinted from Pinker & Ullman, 2002.) (See figure 53.1.)

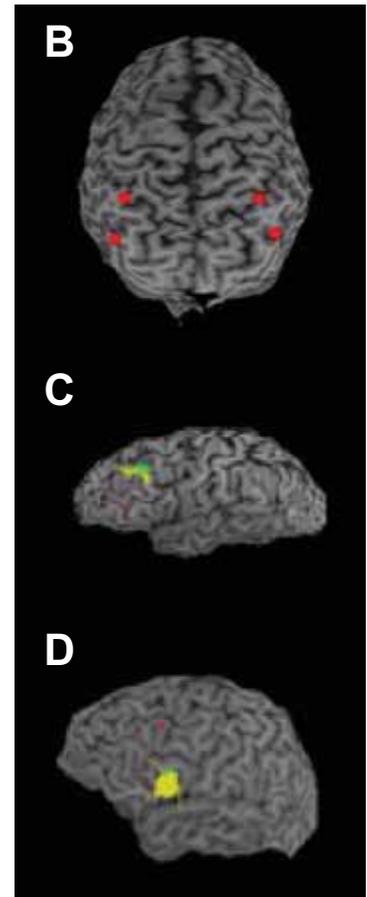

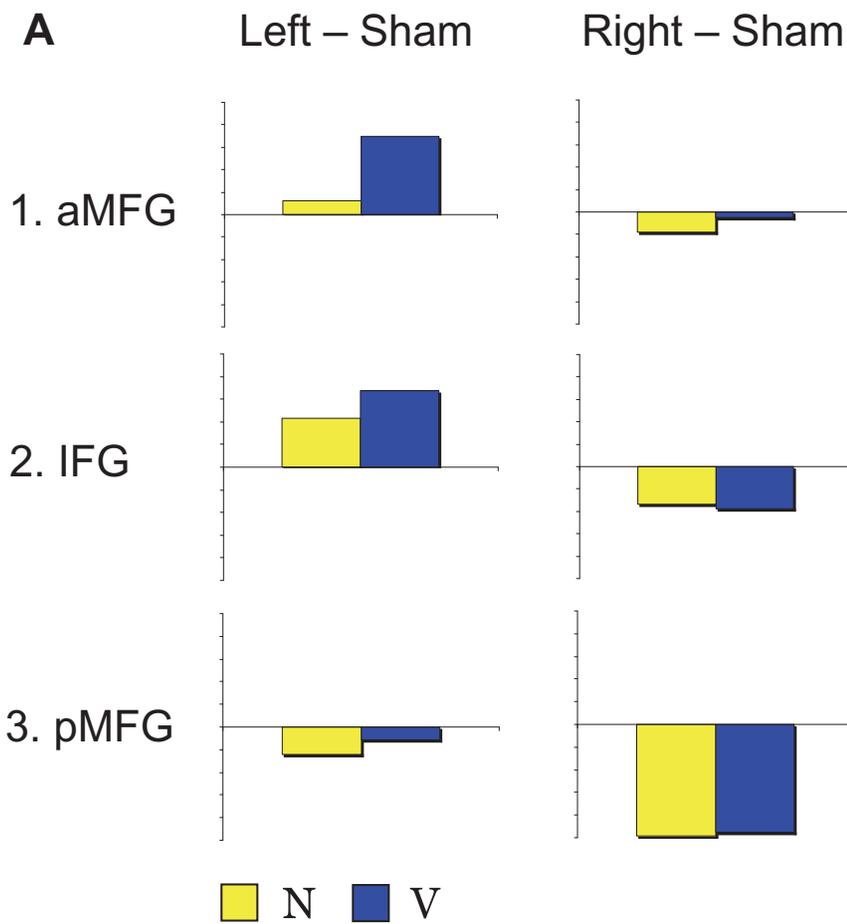

PLATE 66 Results of the rTMS experiment reported by Cappelletti et al. (2008), showing a selective disruption in verb processing following stimulation to the left anterior frontal gyrus. (A) The mean difference in reaction times to nouns and verbs with repetitive TMS compared to sham stimulation in three areas: the anterior middle frontal gyrus (aMFG), inferior frontal gyrus (IFG),

and posterior middle frontal gyrus (pMFG). (B) The sites of stimulation to the IFG and pMFG. The remaining panels demonstrate the stereotactic application of TMS to the left pMFG (C) and left IFG (D). (Modified from Cappelletti, Fregni, Shapiro, Pascual-Leone, & Caramazza, 2008.) (See figure 53.2.)

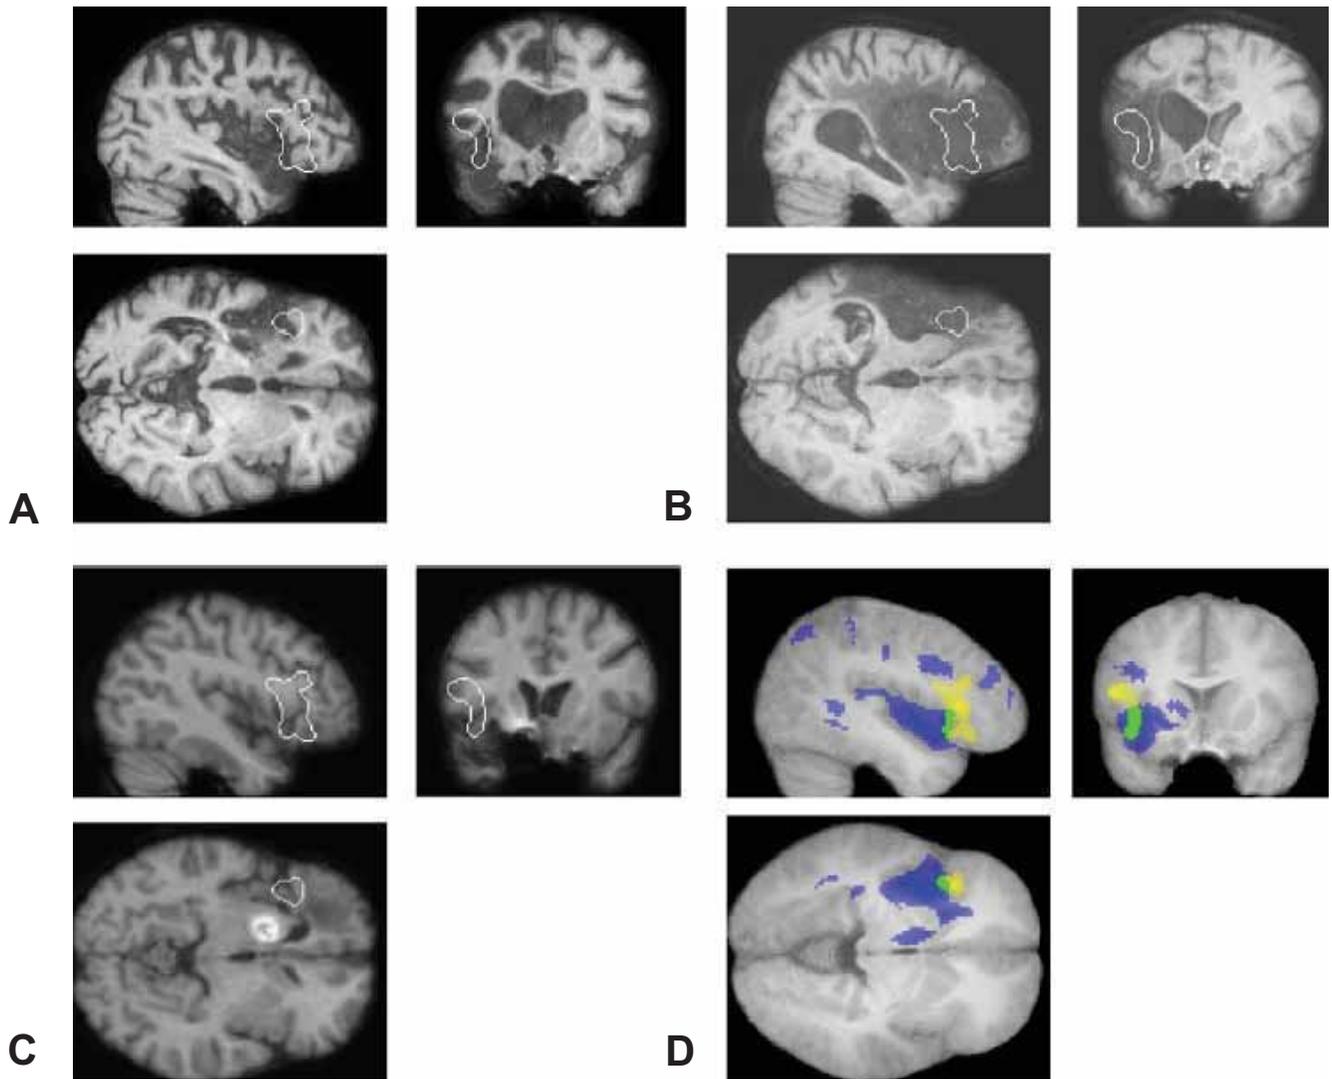

PLATE 67 The area found by Tyler and colleagues (2004) to be more active for inflected verbs than inflected nouns in an fMRI semantic judgment paradigm, compared to the lesion sites of three aphasic patients with deficits in processing regularly inflected verb forms in a priming task. (A–C) T1-weighted MR images of three patients with an outline of the activation found in the verbs-nouns contrast superimposed on them. (D) A mean of the spatially

normalized T1 images of the 12 subjects in the fMRI experiment overlaid with the lesion overlap of the three patients in A–C. Lesion overlap is shown in blue, the significant activation found in the verbs-nouns contrast is in yellow, and the overlap between common lesion volume of the three patients and the activation is in green. (Reprinted from Tyler, Bright, Fletcher, & Stamatakis, 2004.) (See figure 53.3.)

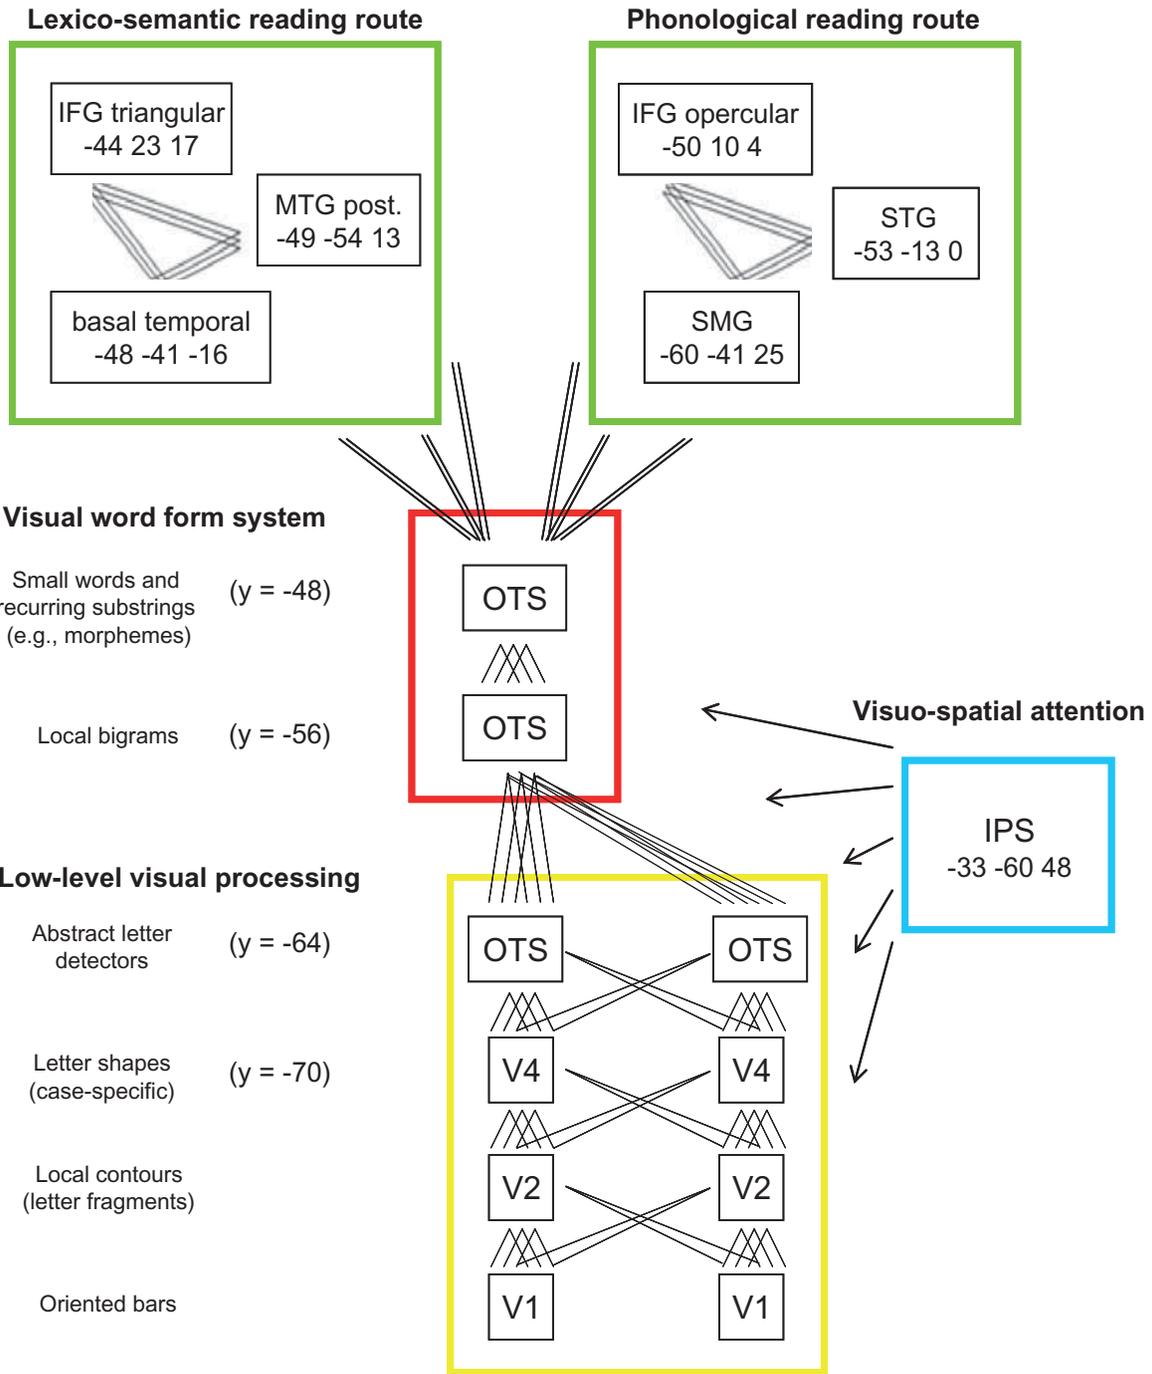

PLATE 68 Synthetic schema of the reading system, merging propositions from Dehaene, Cohen, Sigman, and Vinckier (2005) and Cohen and colleagues (2003). Low-level processing is achieved in each hemisphere for the contralateral half of the visual field (yellow). Information converges on the left-hemispheric Visual Word Form system, where an invariant representation of letter strings is computed (red). The dorsal visual stream exerts a top-down attentional control on the hierarchy of ventral areas (blue). The ventral visual system then feeds the lexicosemantic and phonological reading

routes (green). The proposed normalized coordinates for the lexicosemantic and phonological reading routes are from a meta-analysis of 35 PET and fMRI studies (Jobard, Crivello, & Tzourio-Mazoyer, 2003), and the coordinates of the visuospatial attention system are from Gitelman et al. (1999). IFG: inferior frontal gyrus; MTG: middle temporal gyrus; SMG: supramarginal gyrus; OTS: occipitotemporal sulcus; IPS: intraparietal sulcus. (See figure 54.1.)

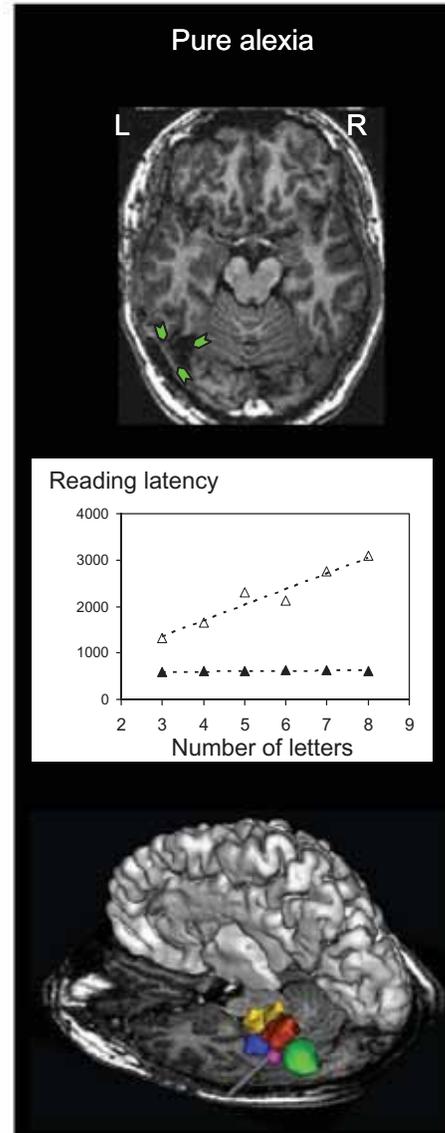

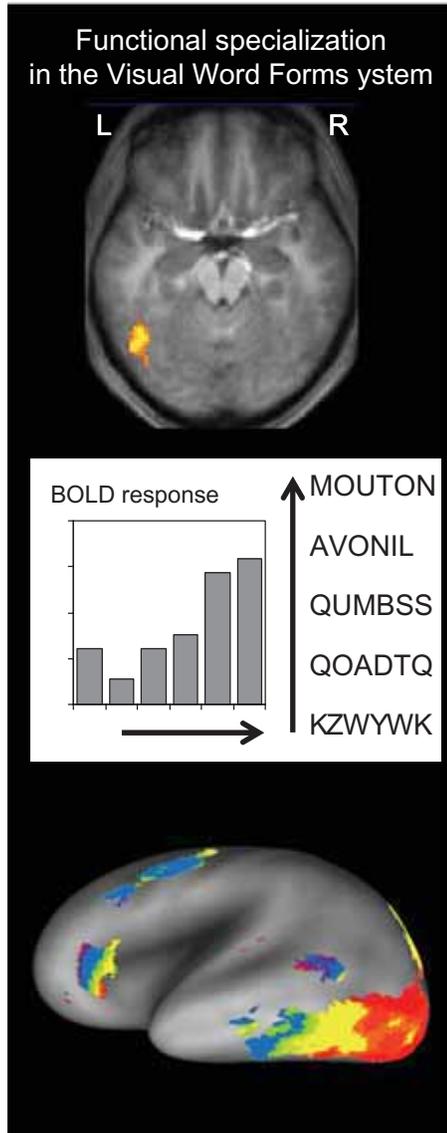

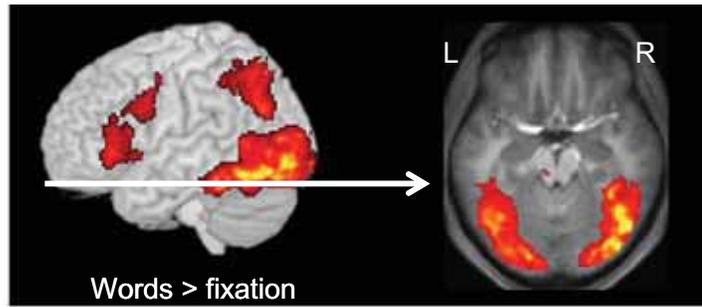

PLATE 69 Word processing in the ventral pathway. *Top panel:* Activations induced by printed words relative to a fixation baseline in the left hemisphere (left) and in the bilateral ventral visual pathway (right). *Left panel:* The VWF system shows a linear increase of activation (top) by letter strings forming closer statistical approximations to orthographically legal strings (middle). This functional specialization increases progressively in more anterior regions within the VWF system (bottom). (Left panel adapted from Vinckier et al., 2007.) *Right panel:* Surgical lesion in the left ventral

cortex responsible for pure alexia (top). Whereas before surgery word reading was fast and constant irrespective of word length, after surgery the patient showed slow letter-by-letter reading (middle). In the same patient, the 3D image shows the relative position of the VWFA (blue), of other category-dependent fMRI activation clusters before surgery, of the brain lesion (green), and of intracerebral electrodes (magenta). (Right panel adapted from Gaillard et al., 2006.) (See figure 54.2.)

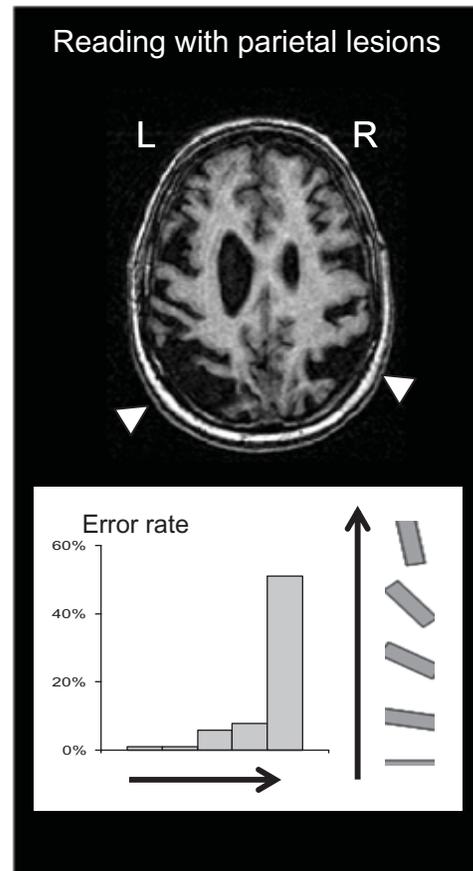

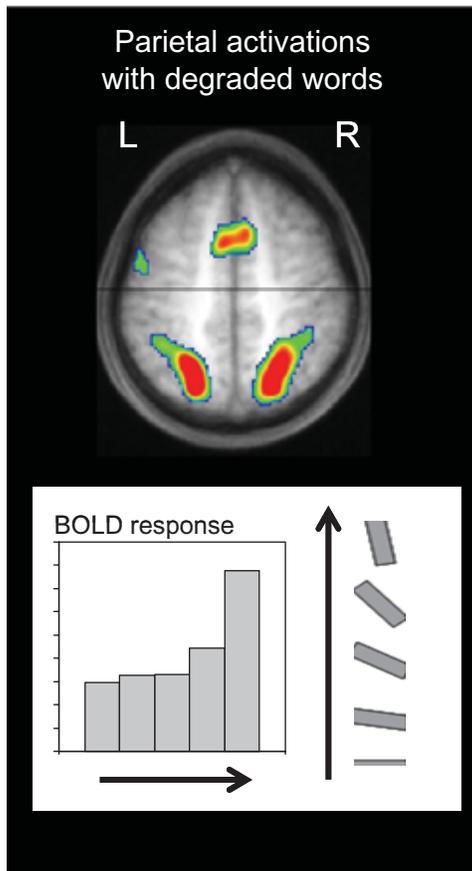

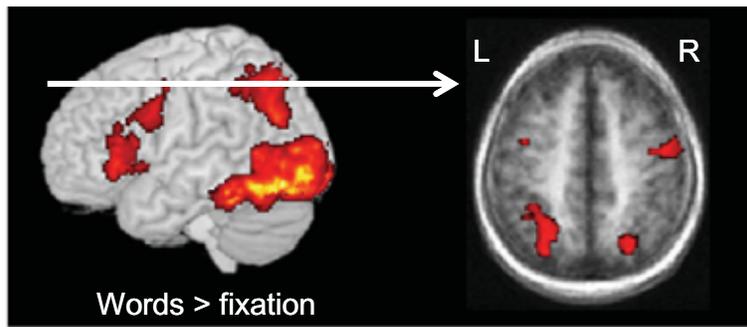

PLATE 70 Contribution of the dorsal pathway to word reading. *Top panel:* Activations induced by printed words relative to a fixation baseline in the left hemisphere (left) and in the bilateral dorsal visual pathway (right). *Left panel:* The bilateral intraparietal cortex shows a nonlinear increase of activation with word degradation, correlated with reaction times (top). For instance, activations increased steeply for words rotated by more than 45° (bottom).

(Left panel adapted from Cohen, Dehaene, Vinckier, Jobert, & Montavont, 2008.) *Right panel:* In a patient with bilateral parietal atrophy and spared ventral cortex (top), there was a severe reading impairment above a similar threshold of rotation angle, demonstrating the role of parietal cortex whenever display degradation exceeds the range of invariance in the ventral cortex. (Right panel adapted from Vinckier et al., 2006.) (See figure 54.3.)

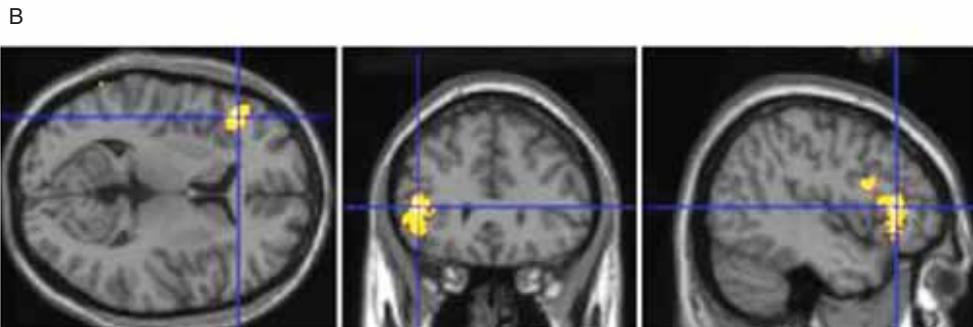

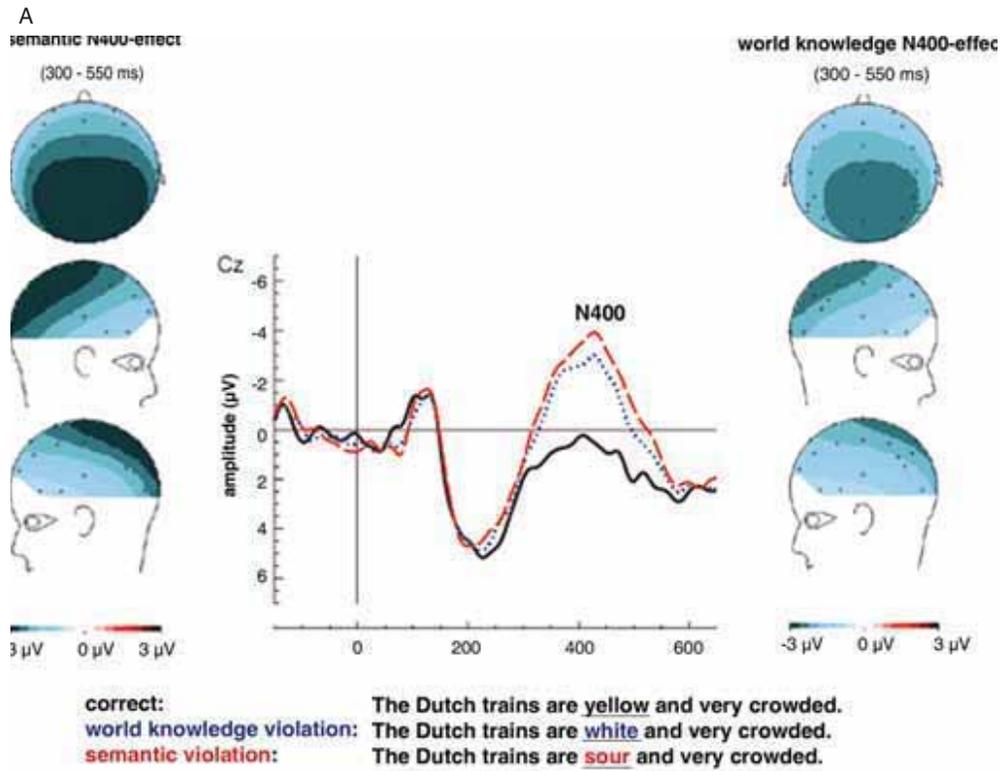

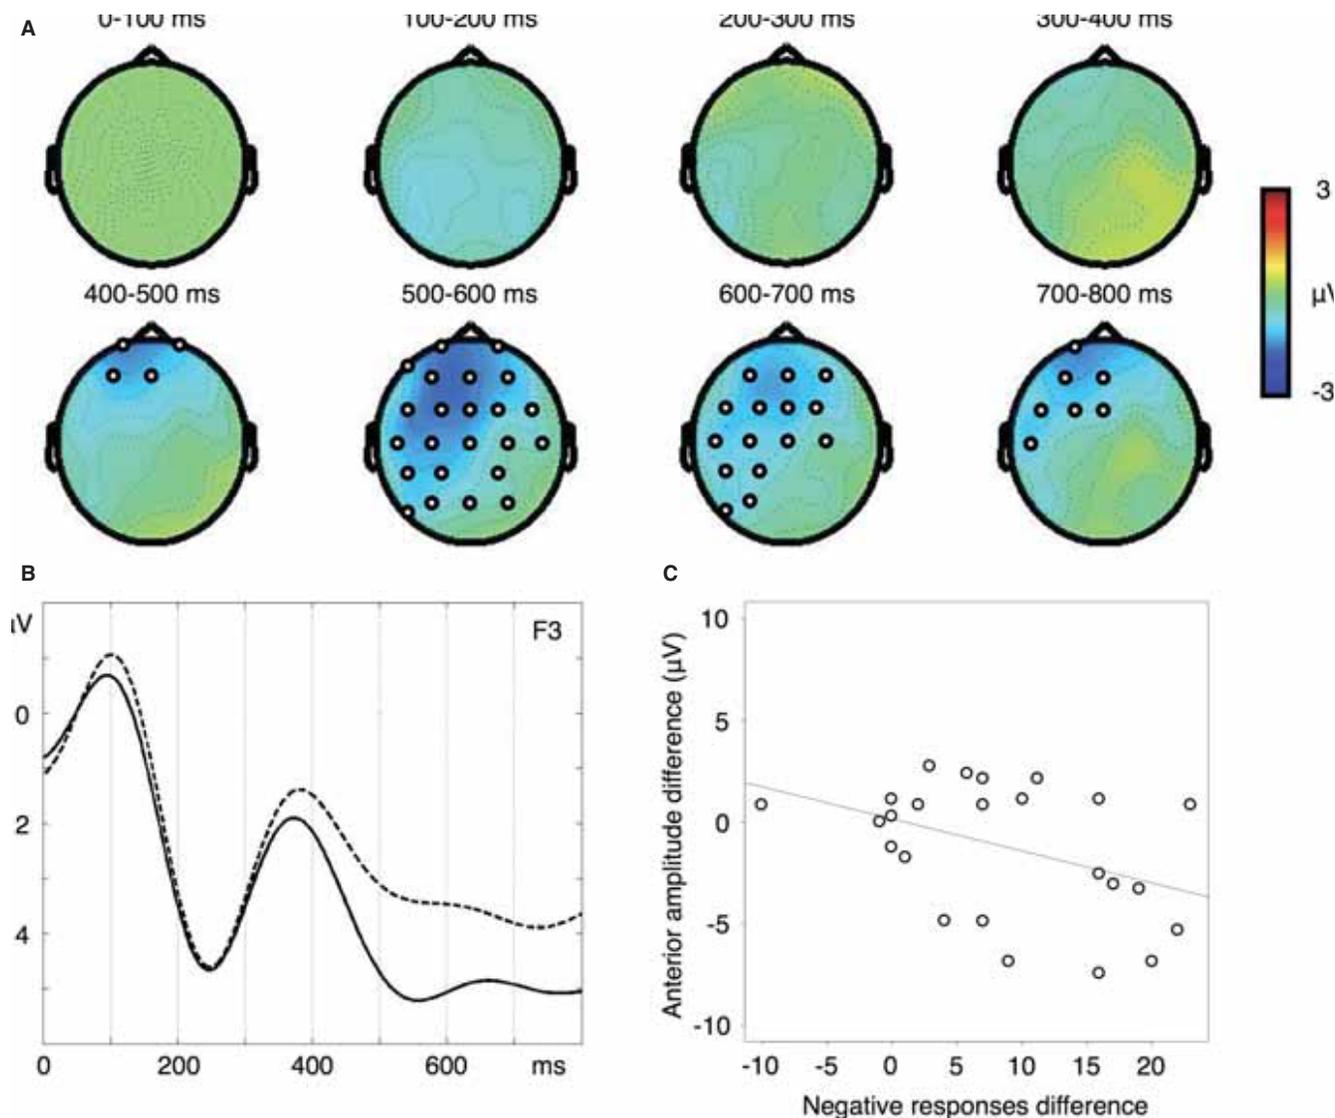

PLATE 71 (A) Grand average ERPs for a representative electrode site (Cz) for correct condition (black line), world-knowledge violation (blue dotted line), and semantic violation (red dashed line). ERPs are time locked to the presentation of the critical words (underlined). Spline-interpolated isovoltage maps display the topographic distributions of the mean differences from 300 to 550 ms between semantic violation and control (left), and between world knowledge violation and control (right). (B) The common activation

for semantic and world-knowledge violations compared to the correct condition, based on the results of a minimum-T-field conjunction analysis. Both violations resulted in a single common activation ($P = 0.043$, corrected) in the left inferior frontal gyrus. The crosshairs indicate the voxel of maximal activation. (Reprinted with permission from Hagoort, Hald, Bastiaansen, & Petersson, 2004.) (See figure 56.2.)

Het meisje was een brief aan het schrijven toen haar vriendin koffie op het tafelkleed morste.

'The girl was writing a letter when her friend spilled coffee on the tablecloth.'

Het meisje was een brief aan het schrijven toen haar vriendin koffie op het papier morste.

'The girl was writing a letter when her friend spilled coffee on the paper.'

PLATE 72 (A) Grand-average topographies displaying the mean amplitude difference between the ERPs evoked by the sentence-final verb when it terminated versus when it did not terminate the accomplishments in the progressive. Circles represent electrodes in a significant ($P < 0.05$) cluster. (B) Grand-average ERP waveforms from a representative site (F3) time-locked to the onset (0 ms) of the verb in terminated versus nonterminated accomplishments. Negative values are plotted upward. (C) Scatter plot displaying the correlation between the amplitude of the sustained anterior negativity elicited by terminated accomplishments and the fre-

quency of negative responses in a button-press, probe-selection task ($r = -0.415$, $T(22) = -2.140$, $P = 0.043$). The mean difference of negative responses between terminated and nonterminated accomplishments is plotted on the abscissa. The mean amplitude difference at frontopolar and frontal electrodes between terminated and nonterminated accomplishments in the 500–700-ms interval following the onset of the sentence-final verb is plotted on the ordinate. (After Baggio, van Lambalgen, & Hagoort, 2008.) (See figure 56.3.)

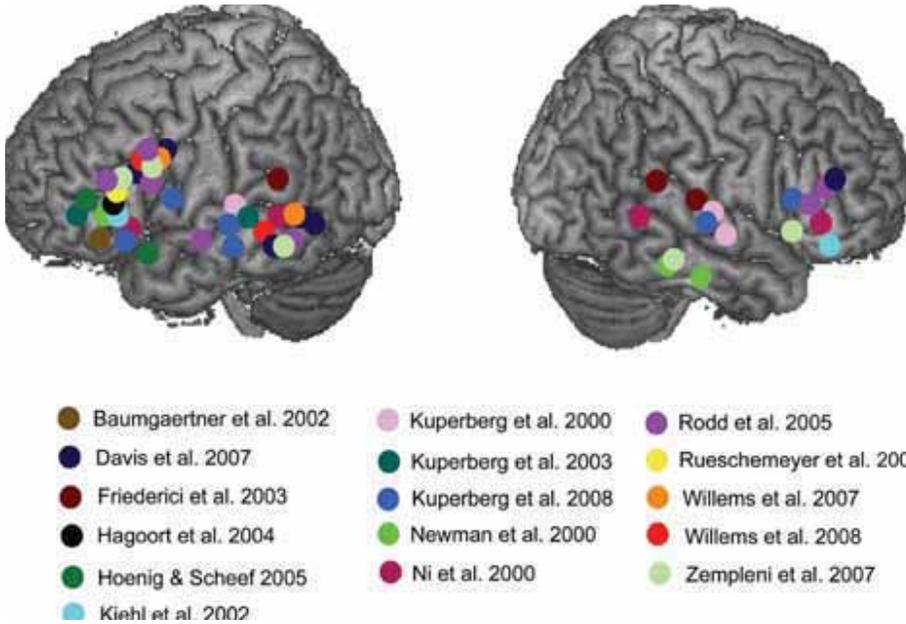

PLATE 73 Overview of local maxima in inferior frontal cortex and in temporal cortex in neuroimaging studies employing sentences with semantic anomalies or semantic ambiguities. The local maxima (in MNI space) of each study were overlaid on a rendering of a brain in MNI space. For local maxima see tables 56.1 and 56.2; for a summary of the results see table 56.3. Rendering was made using MRIcroN. Please note that the local maxima of the Ni and colleagues (2000) and the Kuperberg and colleagues (2003) studies are displayed, but that these are not based on coordinates, since no coordinates were provided. The local maxima are drawn by hand based upon the figures in the respective papers. (See figure 56.6.)

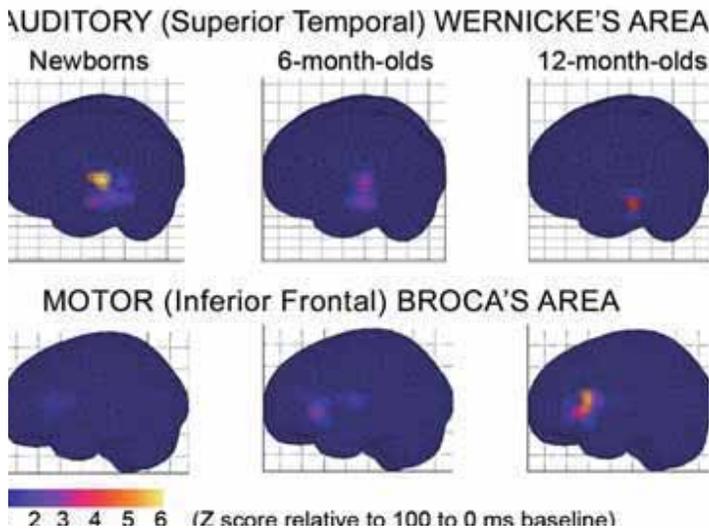

PLATE 74 Neuromagnetic signals were recorded using MEG in newborns, 6-month-old infants, and 12-month-old infants while listening to speech (shown) and nonspeech auditory signals. Brain activation recorded in auditory (*top row*) and motor (*bottom row*) brain regions revealed no activation in the motor speech areas in the newborn in response to auditory syllables. However, activation increased in the motor areas in response to speech (but not nonspeech) in 6- and 12-month-old infants that was temporally synchronized between the auditory and motor brain regions. (From Imada et al., 2006.) (See figure 57.7.)

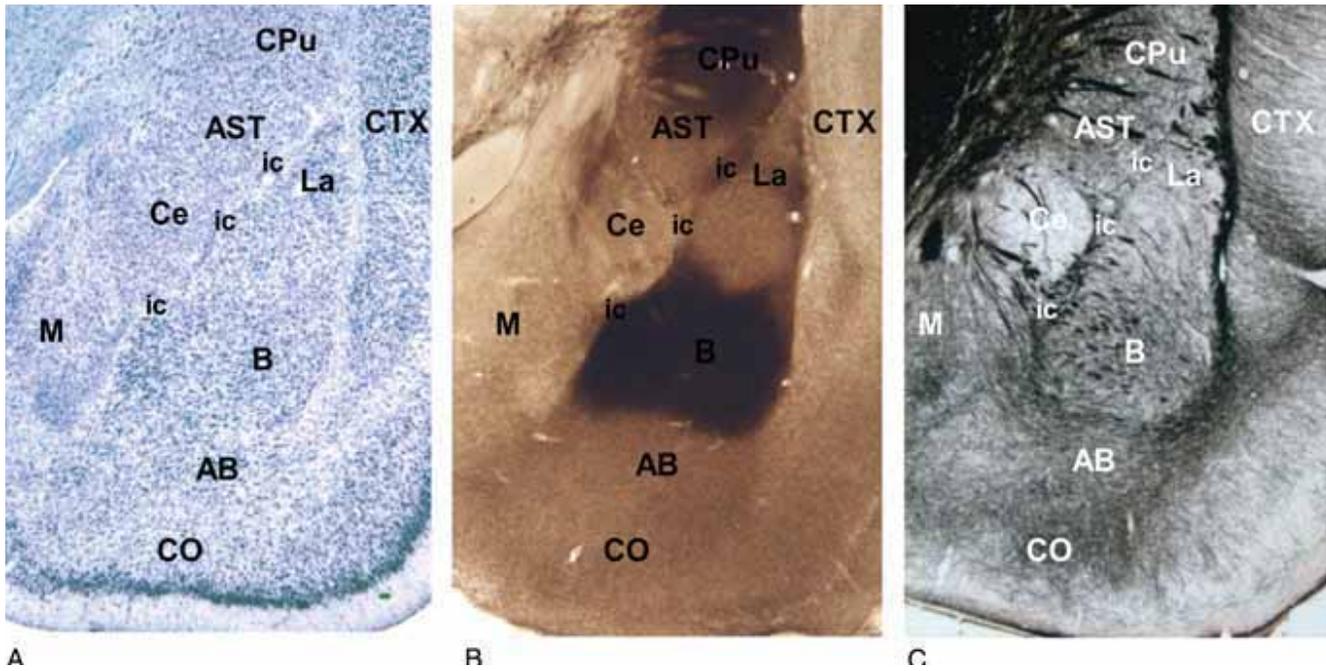

PLATE 75 The rat amygdala. The amygdala of mammals, including humans, consists of at least 12 distinct nuclei. Different staining methods show some of the major nuclei from different perspectives. (A) Nissl cell body stain. (B) Acetylcholinesterase stain. (C) Silver fiber stain. Abbreviations: Amygdala areas: AB, accessory basal; B,

basal nucleus; Ce, central nucleus; CO, cortical nucleus; ic, intercalated cells; La, lateral nucleus; M, medial nucleus. Nonamygdala areas: AST, amygdalo-striatal transition area; CPu, caudate putamen; CTX, cortex. (See figure 61.2.)

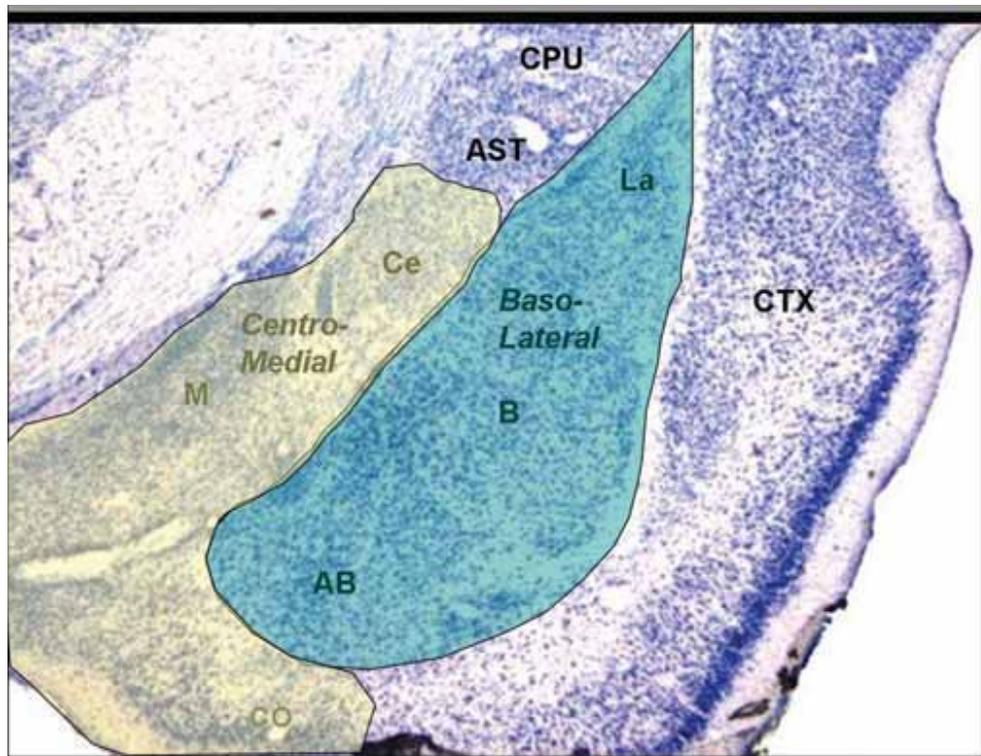

PLATE 76 Groupings of amygdala nuclei. The various nuclei of the amygdala are often partitioned into an evolutionarily old division (the centromedial or corticomedial region) and an evolutionarily newer division (the basolateral region or basolateral complex). While these divisions have some value in understanding the phylogenetic and ontogenetic origins of the amygdala, they do

not represent meaningful function divisions, since functions are mediated by cells within much more localized regions, especially subnuclei and even subdivisions of subnuclei. Abbreviations: AB, accessory basal; AST, amygdalo-striatal transition area; B, basal nucleus; Ce, central nucleus; CPu, caudate putamen; CTX, cortex; La, lateral nucleus; M, medial nucleus. (See figure 61.3.)

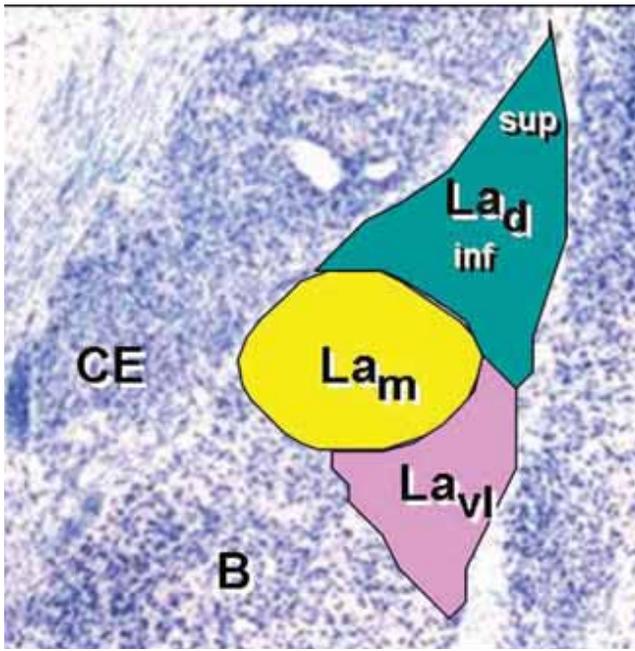

PLATE 77 Subdivisions of the lateral nucleus of the amygdala. The lateral nucleus of the amygdala has three major subdivisions: dorsal (La_d), ventrolateral (La_{vl}), and medial (La_m). Each of these has additional partitions. The dorsal subdivision, for example, contains a superior (sup) and inferior (inf) region. Cells in the superior region have been implicated in the acquisition of fear conditioning, and cells have been implicated in the inferior region in long-term memory storage (see text). Abbreviations: B, basal nucleus; CE, central nucleus. (See figure 61.4.)

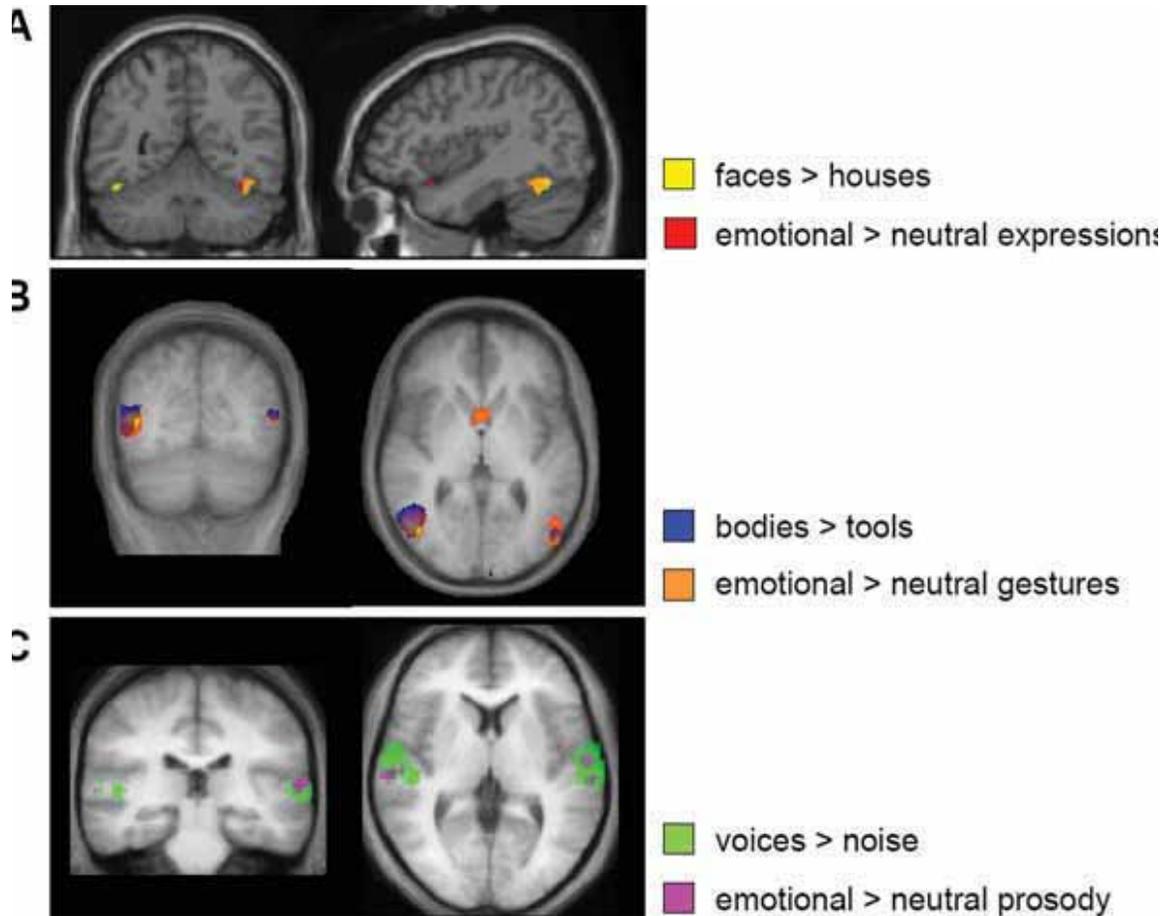

PLATE 78 Emotional enhancement of neural responses in fMRI. (A) Faces with a fearful relative to neutral expression produce increased activation in fusiform cortex, overlapping with the fusiform area selectively activated by faces as compared with houses. (From Vuilleumier et al., 2001.) (B) Bodies with dynamic gestures expressing various emotions (fear, anger, happiness, or disgust) produce increased activation in lateral occipital area cortex, over-

lapping with the extrastriate area selectively activated by bodies as compared with tools. (From Peelen, Atkinson, Andersson, & Vuilleumier, 2007.) (C) Voices with angry prosody produce increased activation in temporal cortex, overlapping with an area in superior temporal gyrus selectively activated by human voices as compared with noises with similar acoustic energy. (From Grandjean et al., 2005.) (See figure 62.1.)

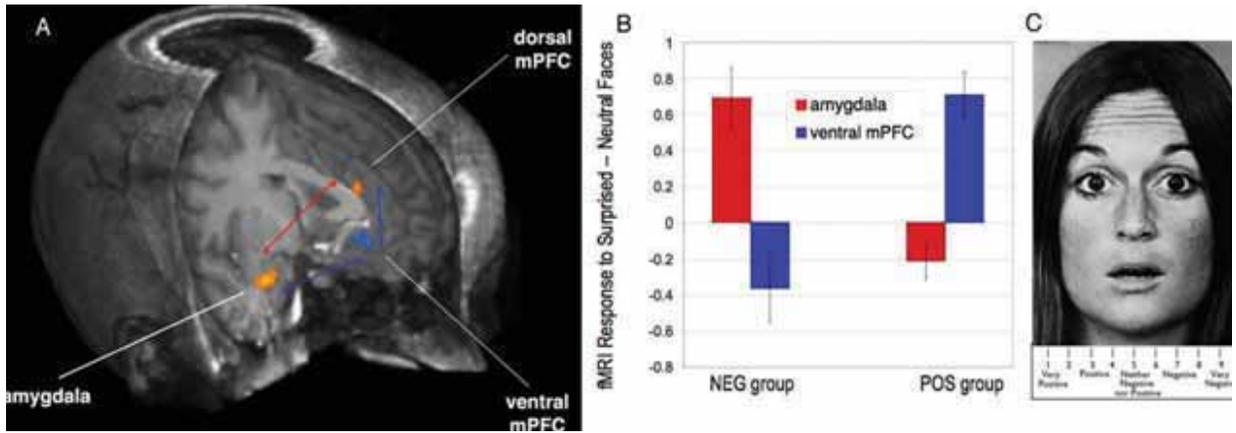

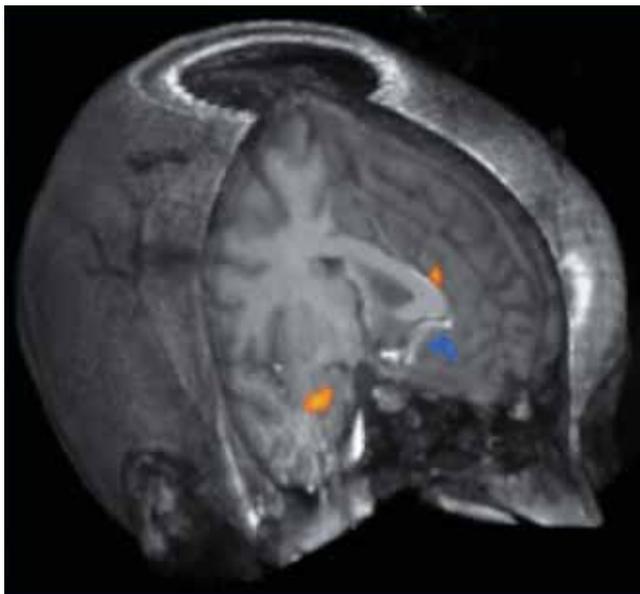

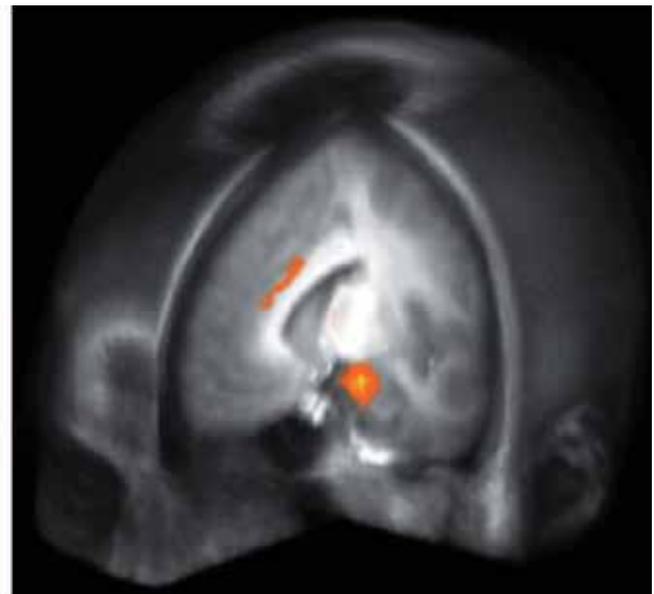

PLATE 79 (A) A three-dimensional depiction of the correlational results of H. Kim and colleagues (2003). Amygdala and dorsal mPFC loci that showed a positive correlation with valence ratings of surprise (colored in orange) are also positively correlated with one another (red arrow, $r = +.66$). The ventral mPFC locus that showed a negative correlation with valence ratings of surprise (colored in blue) is also negatively correlated with amygdala (blue

arrow; $r = -.69$) and the dorsal mPFC (blue arrow; $r = -.62$). (B) Bar graph focusing on the inverse relationship between the amygdala and ventral mPFC in subjects who interpreted the surprised faces either positively (POS) or negatively (NEG). (C) An example of the surprised faces and valence scale used to rate them. (See figure 63.2.)

Undetermined valence

Kim et al. *Neuroreport*. 2003

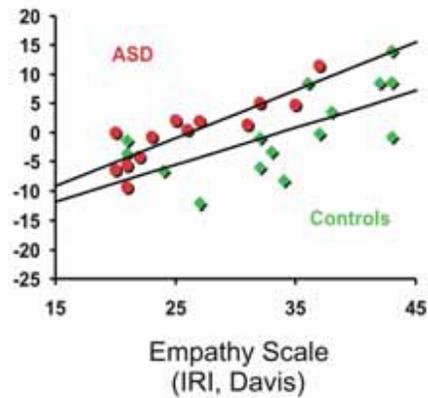

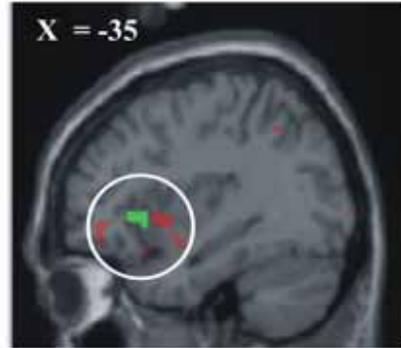

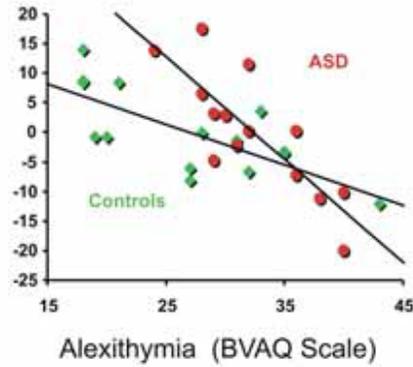

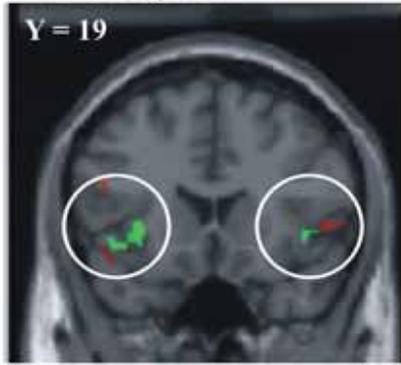

Determined valence

Kim et al. *J Cog Neurosci*. 2004

PLATE 80 Comparison of results of H. Kim and colleagues (2003) with those of H. Kim and colleagues (2004). (See figure 63.4.)

A Interoception

B Empathy

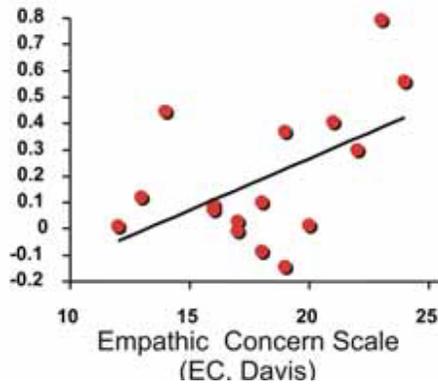

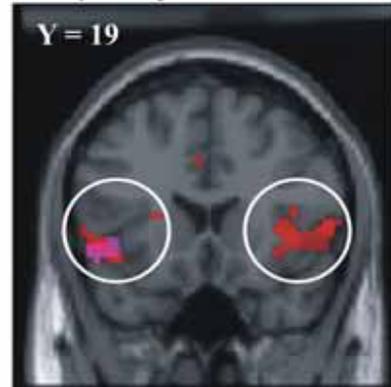

PLATE 81 (A) Bilateral AI activation during interoception about one's own feelings correlates with the degree of alexithymia (measured with the Bermond-Vorst Alexithymia Questionnaire by Vorst and Bermond, 2001; BVAQ-B) and empathy (measured with the Interpersonal Reactivity Index by Davis, 1980; IRI) in healthy controls and in subjects with Asperger syndrome (adapted from Silani et al., 2008). (B) Overlapping brain activity in bilateral AI in

females experiencing pain themselves and empathizing with their partner (red; adapted from Singer et al., 2004) or an unfamiliar but likable person (pink; adapted from Singer et al., 2006) experiencing pain. Individual differences in self-reported empathy (measured with the IRI) covary with activation strengths in AI during empathizing. (From Singer et al., 2004.) (See figure 67.1.)

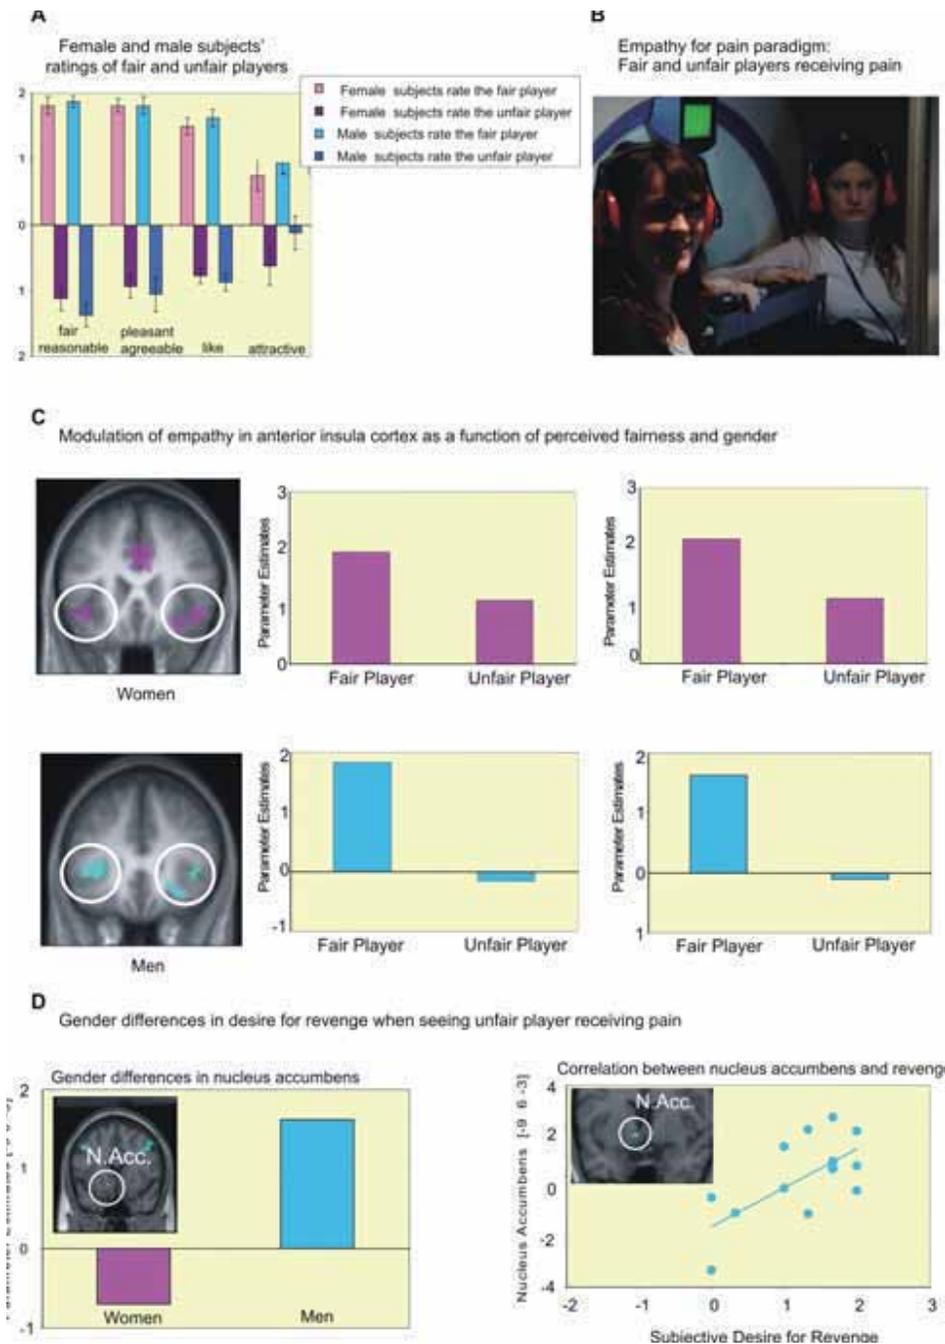

PLATE 82 Modulation of empathic brain responses by perceived fairness (adapted from Singer et al., 2006). (A) Female (pink) and male (blue) subject's postscan ratings of perceived fairness, agreeableness, likeability, and attractiveness of the two confederates, who had always played fairly and unfairly, respectively, in a preceding monetary economic trust game. (B) Setup of the empathy-for-pain paradigm with the subject lying in the scanner and one fair and one unfair player (both confederates) sitting on either side of the scanner. Electrodes, which were attached to one of their hands, delivered painful or nonpainful stimulation as previously indicated by flashes on a screen in front of them. (C) Empathic brain activa-

tion in bilateral frontoinsula cortex when males (blue) and females (pink) perceived either the fair or the unfair player suffering pain. Although both men and women showed empathic brain activity in frontoinsula cortex when they perceived a fair player in pain, only women did so when they perceived an unfair player in pain. (D) Enhanced activation in nucleus accumbens in men, but not in women, when they perceived unfair as compared to fair players suffering pain. The strength of this activation correlated positively with men's, but not women's, degree of subjectively expressed desire for revenge. (See figure 67.2.)

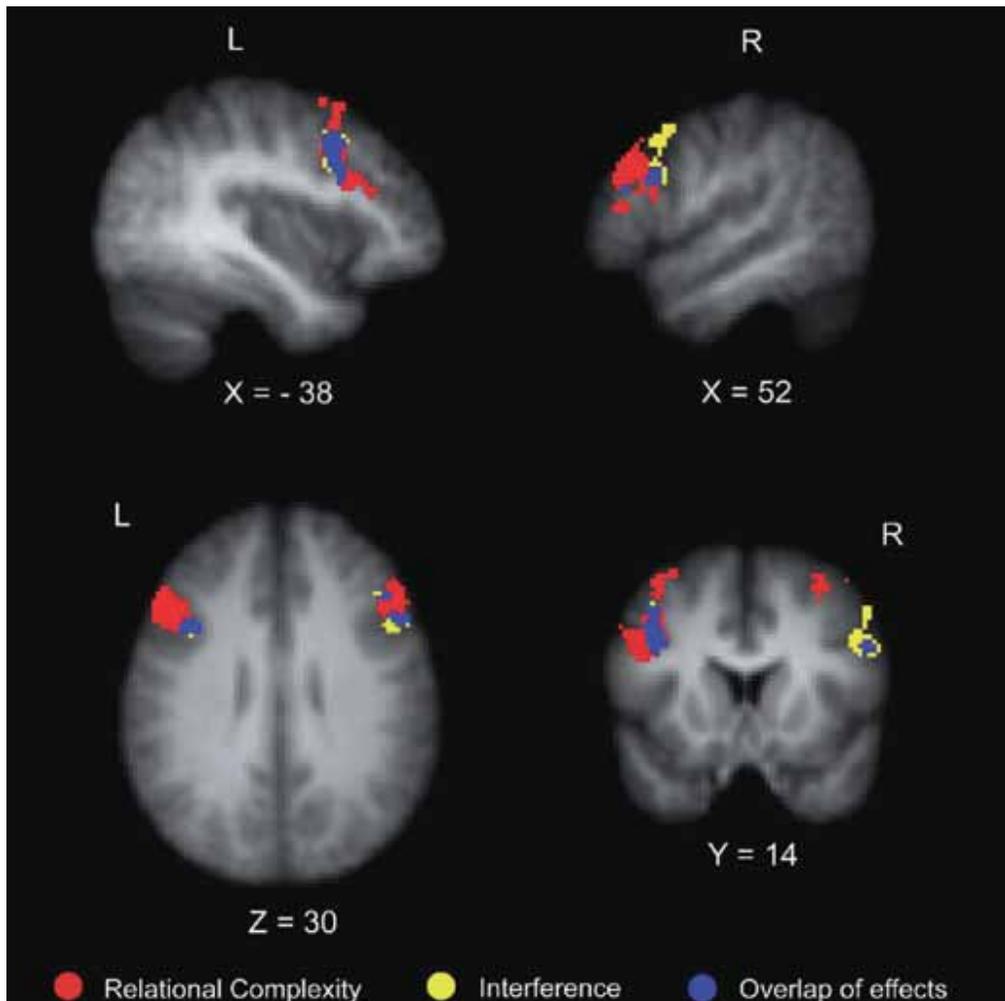

PLATE 83 Neuroimaging results from Cho and colleagues (2009). Regions showing the main effects of relational complexity (shown in red), interference (shown in yellow; small volume corrected, uncorrected cluster-forming threshold $T > 2.3$, corrected cluster extent significance threshold, $p < .05$), and regions where main

effects overlapped (blue) within an a priori defined anatomical ROI mask of the bilateral MFG and IFG pars opercularis and pars triangularis. R, right; L, left. Coordinates are in MNI space (mm). (See figure 69.7.)

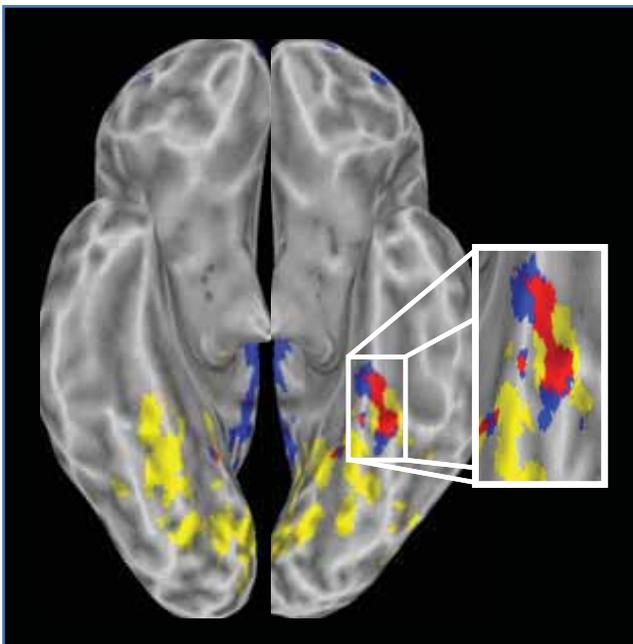

PLATE 84 Overlap between the neural circuitry for perceiving and knowing about color. Shown is an inflated map of the ventral surface of the brain. Regions shown in yellow were more active when subjects performed a difficult color-perception task, relative to performing that same task with gray-scale stimuli. Regions in blue were more active when answering written questions about object color, relative to answering questions about object motor and motion properties. Red shows region of overlap in the left fusiform gyrus for the color-perception and color-knowledge tasks. (Adapted from Simmons, Ramjee, McRae, Martin, & Barsalou, 2007.) (See figure 71.2.)

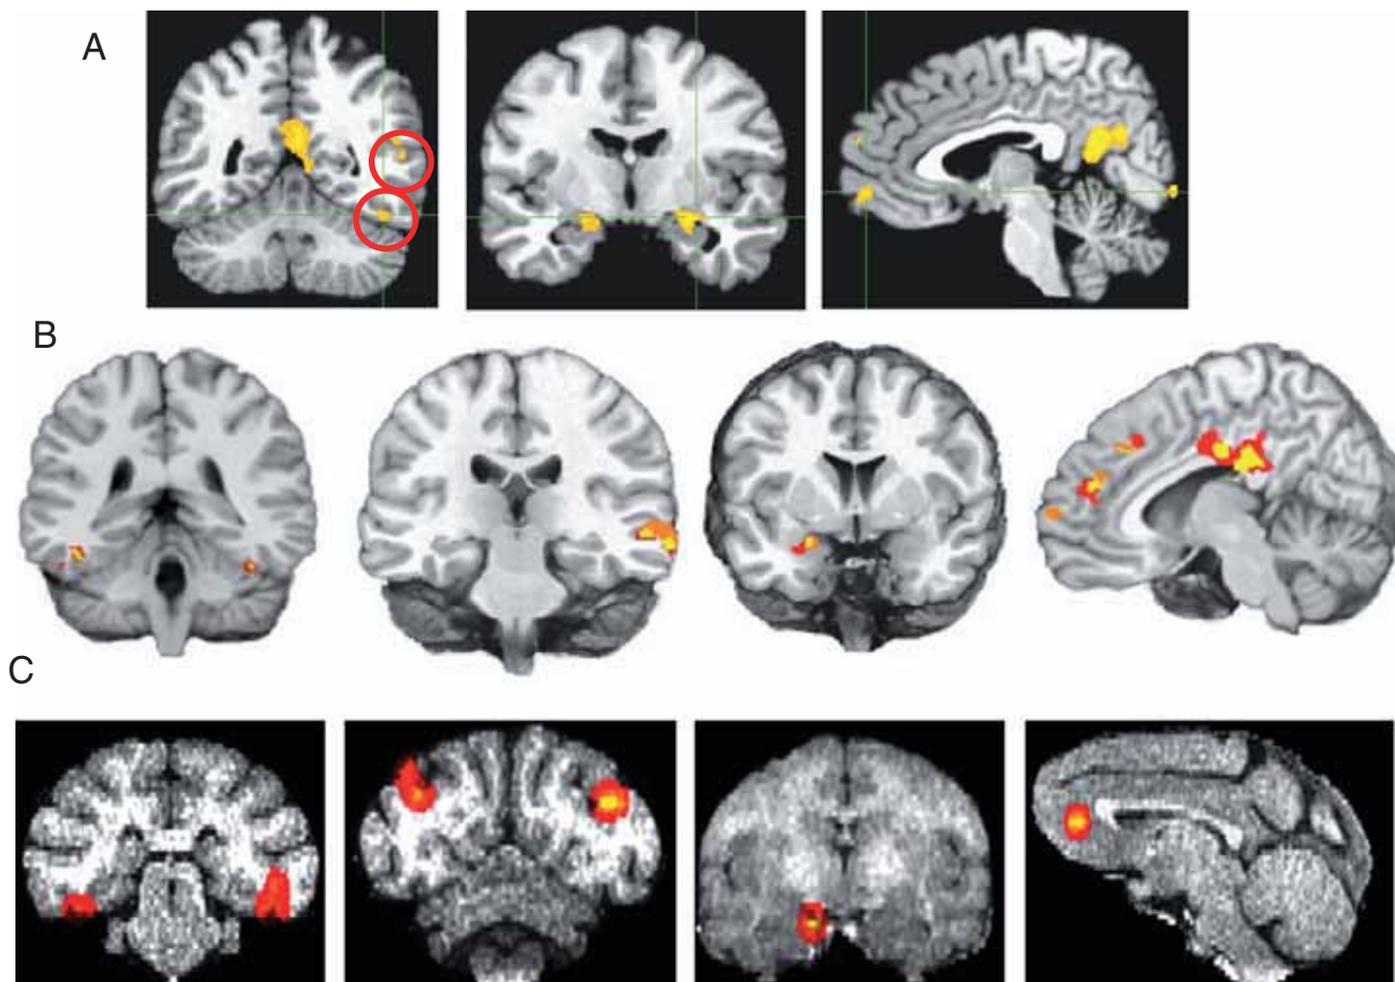

PLATE 85 Correspondence across tasks and species in the location of the neural circuitry for perceiving and knowing about animate entities. (A) Regions shown in yellow were more active when subjects viewed photographs of faces relative to viewing photographs of common tools. Going from left to right, the first image shows a coronal slice through posterior cortex indicating the location of activity in the lateral portion of the right fusiform gyrus (lower red circle) and in the right pSTS (upper red circle). The next coronal image depicts bilateral activity in the amygdalae. The third image shows a sagittal section revealing activity in the medial prefrontal cortex and in the posterior cingulate/precuneus. (Unpublished data from our laboratory.) (B) Brain slices depicting conjunction of regions more active when subjects perceived simple shapes in motion as animate, relative to when they were judged to be inanimate, and when they imagined these stimuli as animate versus

inanimate. Going from left to right, the first image is a coronal slice showing bilateral activity in the lateral fusiform gyrus. The next coronal slice shows the location of activity in the STS, the third depicts activity in the left amygdala, and the last shows activations located in the medial prefrontal and posterior cingulate cortices. (Adapted from Wheatley, Milleville, & Martin, 2007.) (C) Activity in the macaque brain when listening to species-specific calls. Shown are PET scans obtained from a single animal. Going from left to right, the first image shows a coronal slice through ventral regions TEO/TE, the next coronal slice shows activity in the STS, the third slice shows activation in the amygdala, and the fourth slice shows an activation located in Area 32 on the medial surface of the brain. (Adapted from Gil-da-Costa et al., 2004.) (See figure 71.3.)

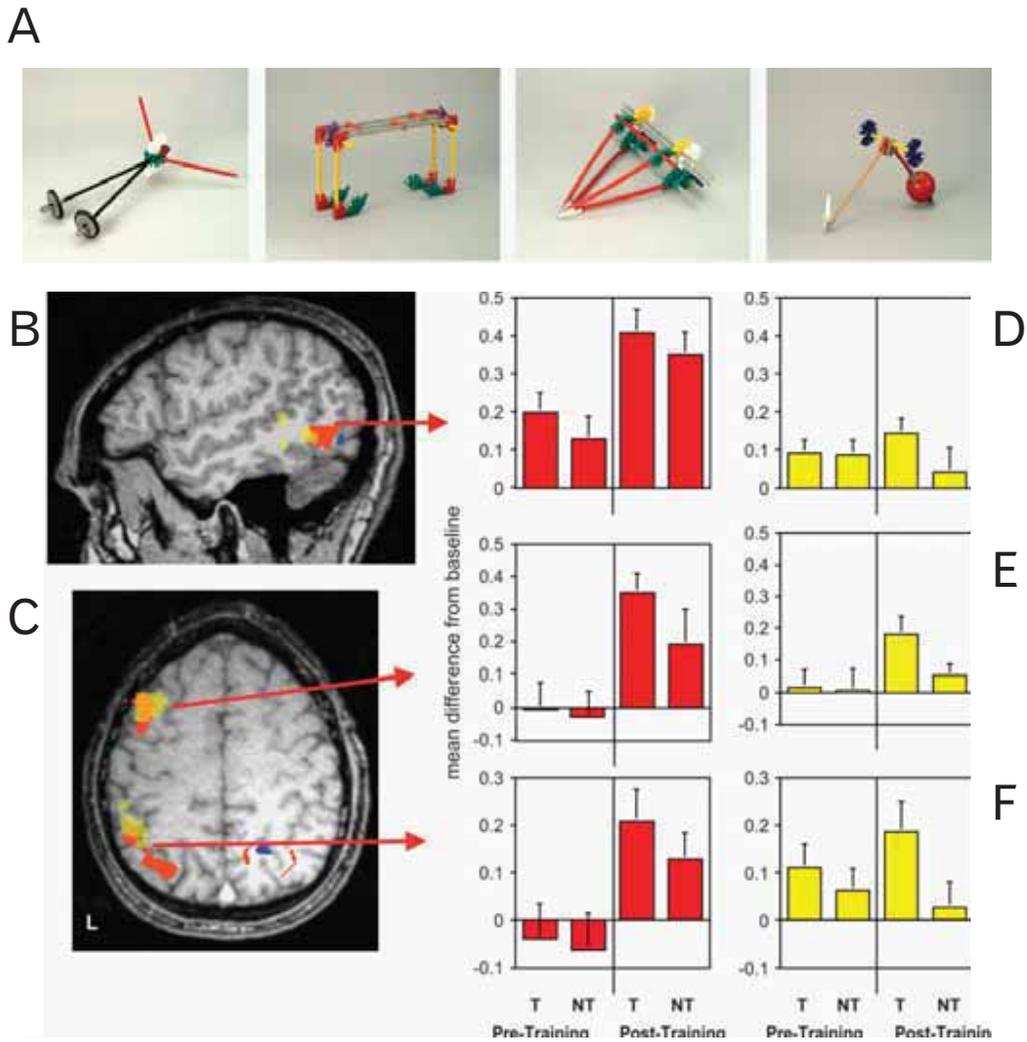

PLATE 86 (A) Examples of novel objects designed to perform specific toollike functions. (B) Sagittal section showing the location of learning-related activity in the left middle temporal gyrus. Regions in red were more active after training than before training. Regions in yellow, which overlap with regions in red, were more active for trained (*T*) objects than for not-trained (*NT*) objects. (C) Axial section showing the location of learning-related activity in the left premotor/prefrontal cortex and intraparietal cortices. (D, E, F) Histograms showing the difference between novel-object-matching

and scrambled-image-matching baseline task in the middle temporal gyrus, left premotor, and intraparietal regions, respectively. Red bars represent brain regions that showed increased activity for object matching after but not prior to training; yellow bars represent regions that demonstrated greater activity for trained objects than not-trained objects after but not prior to training. (Adapted from Weisberg, van Turenout, & Martin, 2007.) (See figure 71.4.)

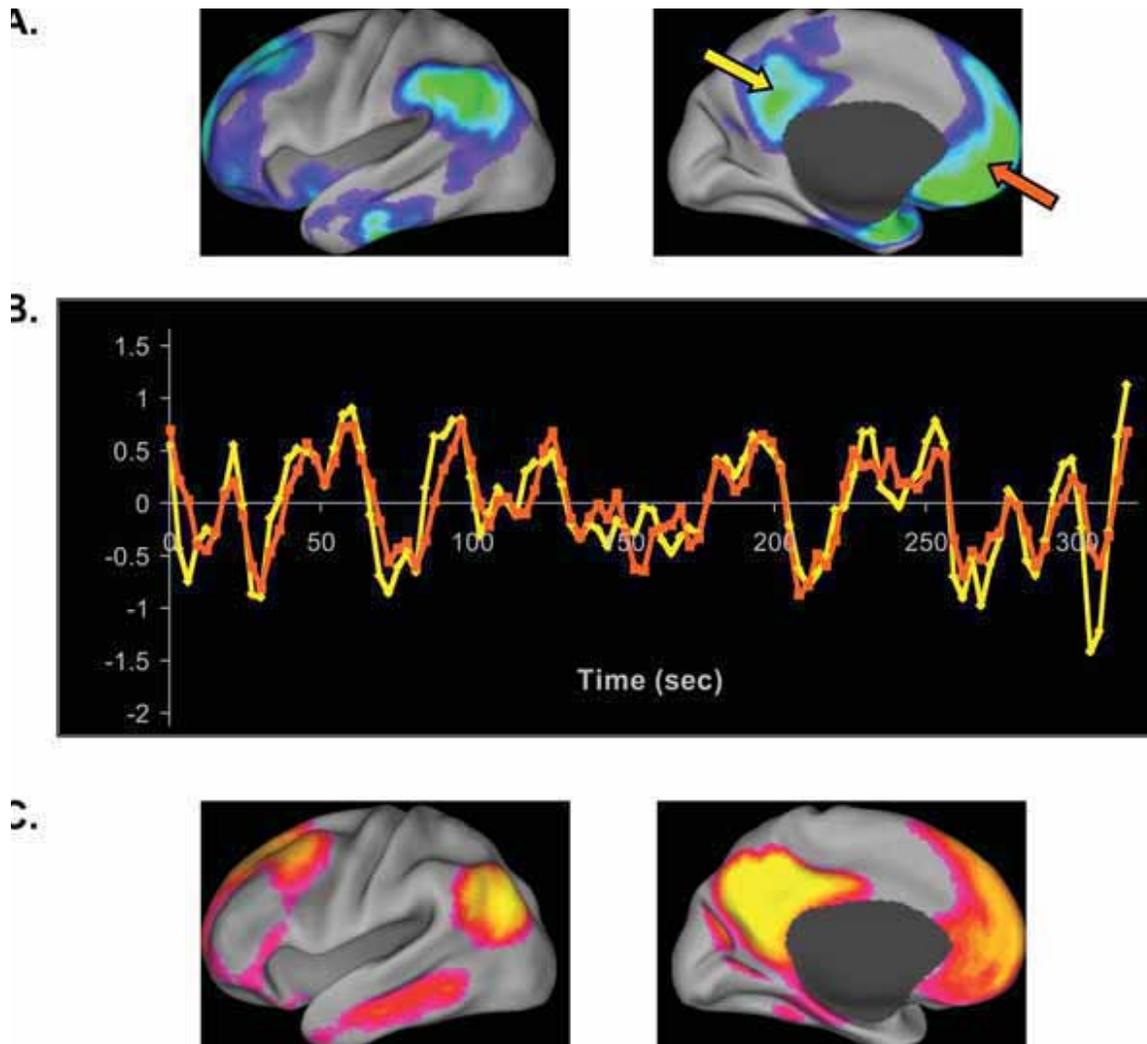

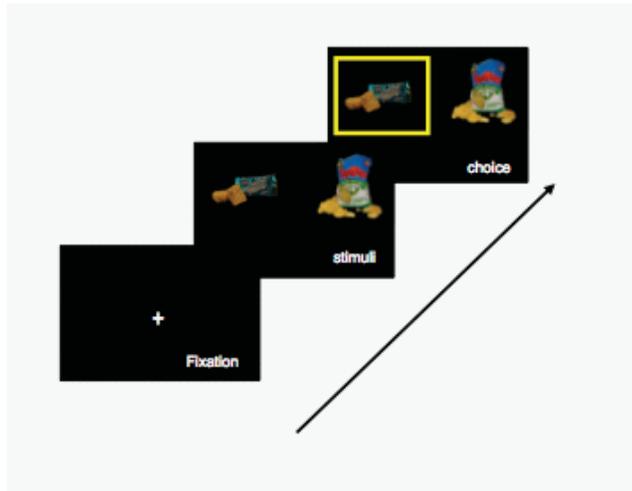

PLATE 87 Performance of a wide variety of tasks has called attention to a group of brain areas (*A*) that decrease their activity during task performance (data adapted from G. Shulman et al., 1997). These areas are often referred to as the brain's default mode network after our initial work on them (Raichle et al., 2001). If one records the spontaneous fMRI BOLD signal activity in these areas in the resting state (arrows, *A*) what emerges is a remarkable similarity in the behavior of the signals between areas (*B*), a phenomenon originally described by Biswal and colleagues (1995) in the somato-motor cortex and later in the default mode network by Greicius

and colleagues (2003). Using these fluctuations to analyze the network as a whole (M. Fox et al., 2005; Vincent et al., 2006) reveals a level of functional organization (*C*) that parallels that seen in the task-related activity decreases. These data provide a dramatic demonstration that the ongoing organization of the human brain likely provides a critical context for all human behaviors. (These data were adapted from our earlier published work: M. Fox et al., 2005; Gusnard & Raichle, 2001; Raichle et al., 2001; G. Shulman et al., 1997.) (See figure 73.1.)

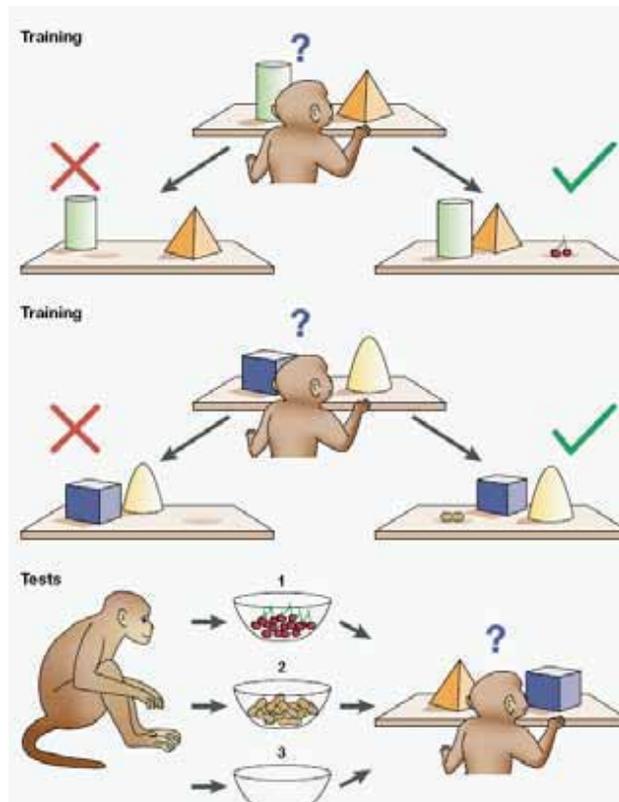

PLATE 88 Examples of simple binary stimulus choice tasks. (A) Binary food choice from Karjbich, Armel, and Rangel (under review). (B) Devaluation choice task from Izquierdo, Suda, and Murray (2004). (With permission from Baxter & Murray, 2002.) (See figure 74.1.)

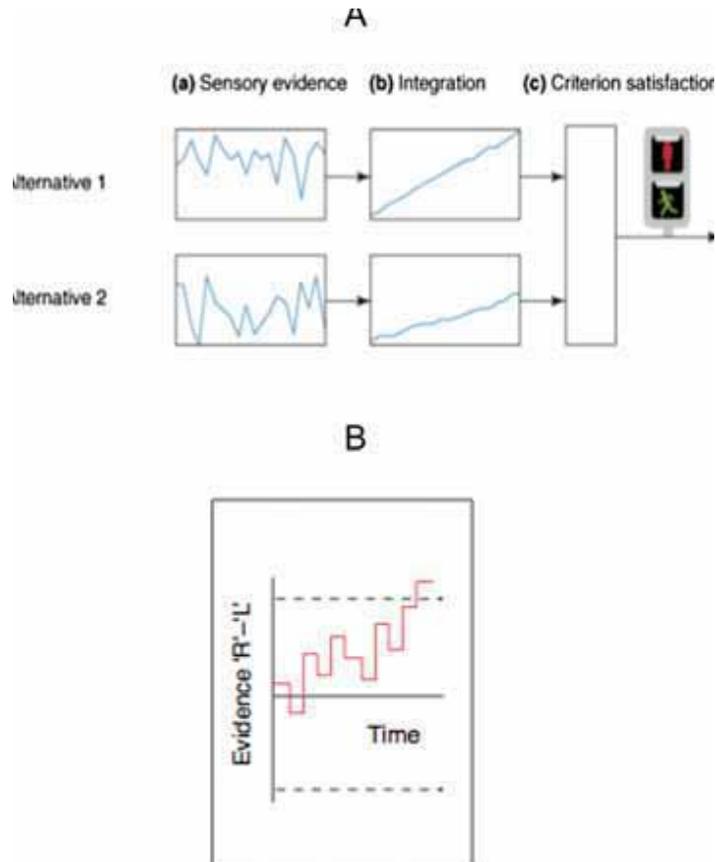

PLATE 89 Models of the value comparison process. (A) Illustration of the main components of the race-to-barrier models. (Adapted with permission from Bogacz, 2007.) (B) A typical run of the random walk model. The step function represents the accumulated relative value of the “right” target. The process starts at a middle point and stops the first time this variable crosses one of the thresholds (depicted by the bracketed horizontal lines). “Right” is chosen

when it crosses the upper threshold; “left” is chosen when it crosses the lower one. Time advances in discrete steps. The size of every step is given by a Gaussian distribution with a mean that is proportional to the true direction of motion. This noise is meant to capture the variability in the valuation processes. (See figure 74.2.)

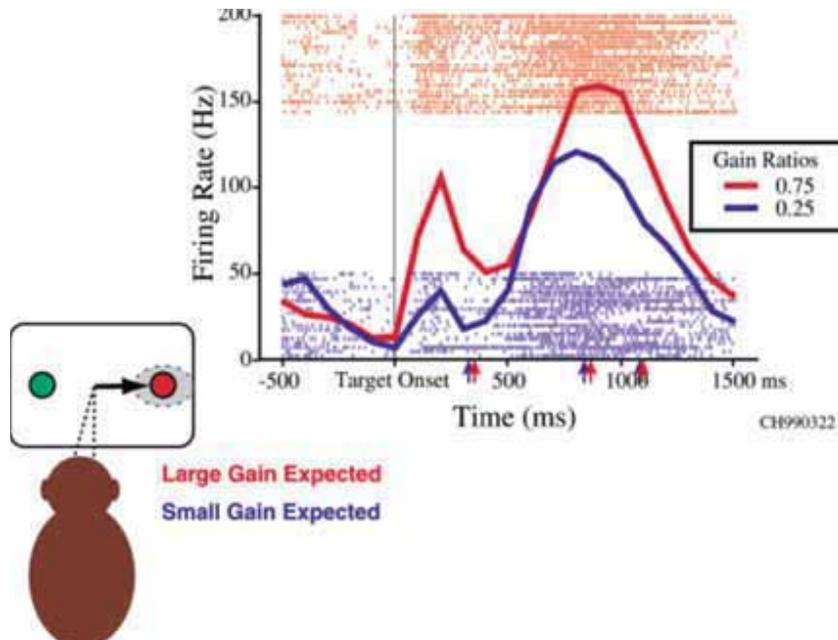

PLATE 90 Same movement, different values. (From Glimcher, 2003.) (See figure 75.1.)

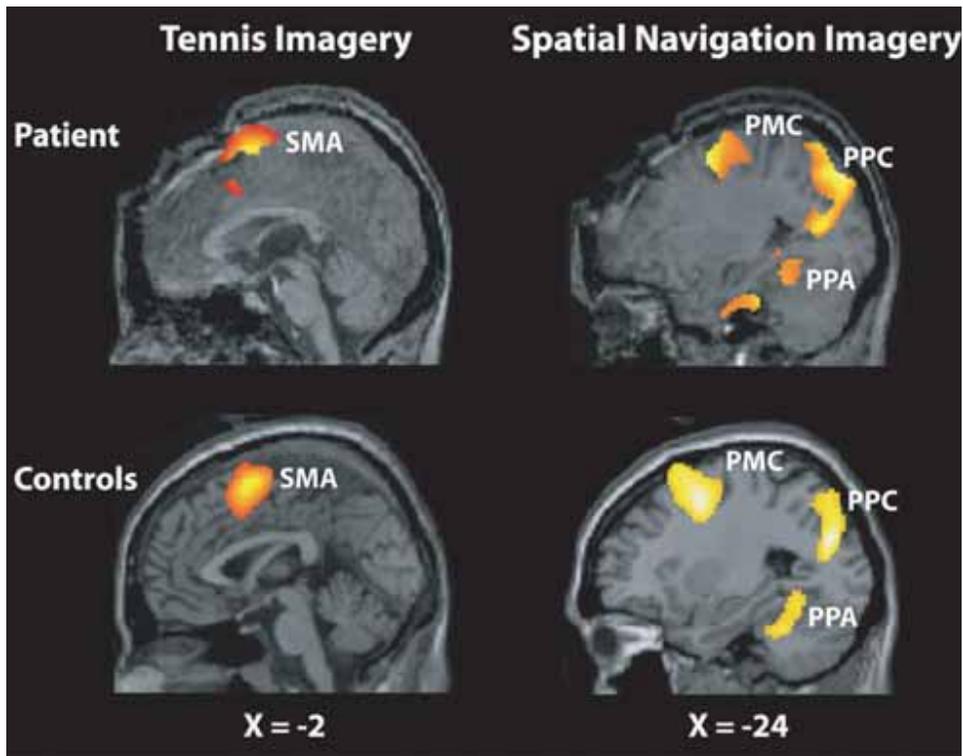

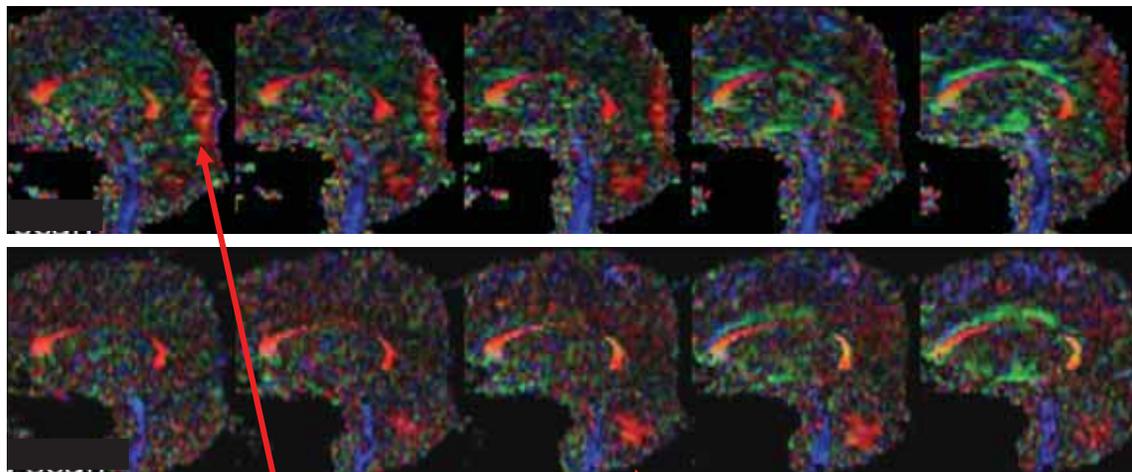

PLATE 91 Command following in vegetative state (Owen et al., 2006). A 23-year-old woman with clinical exam consistent with VS, five months after severe traumatic brain injury with only brief periods of visual fixation, was asked to imagine playing tennis or

walking throughout her own house. The regionally selective brain activation patterns obtained from functional magnetic resonance imaging measurements for each condition were identical to those of normal controls. (Reproduced with permission.) (See figure 78.2.)

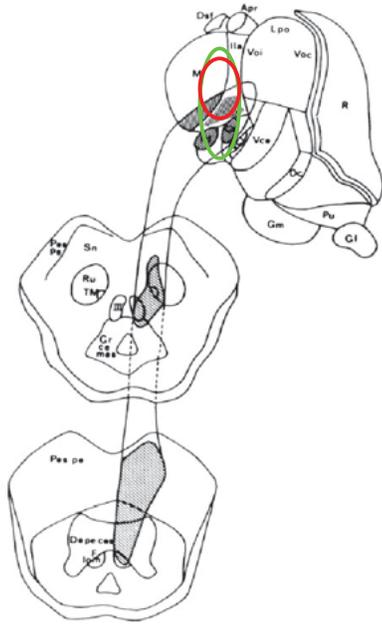

Parasagittal Medial
Parietal-Occipital

Midline
Cerebellum

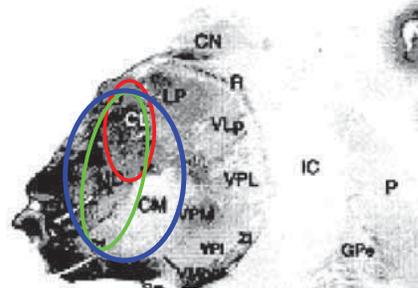

PLATE 92 Diffusion tensor imaging studies of patient with late recovery (19 years) from MCS (Voss et al., 2006). Fractional anisotropy maps showing fiber tracks: red, fibers with left-right directionality; blue, fibers with up-down directionality; green, fibers with anterior-posterior directionality. Top images show volume loss of the corpus callosum throughout the medial component and regions

in parieto-occipital white matter with prominent left-right directionality. Bottom row images show fractional anisotropy maps obtained 18 months later that demonstrate reduction of left-right direction in parieto-occipital regions with increased anisotropy noted in the midline cerebellum. (See figure 78.3.)

A. Anatomical localization of focal subcortical injuries producing acute coma, persistent vegetative state and minimally conscious state

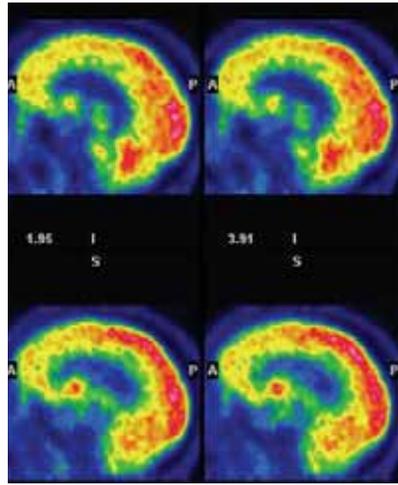

B. Regional neuronal cell loss in central thalamus across range of functional outcomes

- Moderately disabled
- Severely disabled
- Vegetative

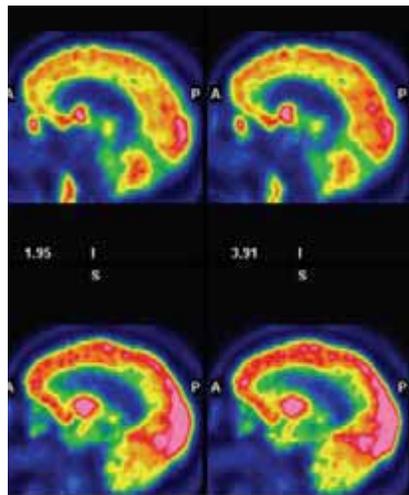

PLATE 93 Contributions of the central thalamus to disorders of consciousness. (A) Focal injury patterns in the central thalamus associated with coma, vegetative state, and minimally conscious state. (B) Regional neuronal cell loss in central thalamus across the range of function outcomes. Moderately disabled (red); neuronal loss in median dorsalis, rostral central medial, central lateral and

paracentral nuclei. Severely disabled (green): includes moderately disabled regions plus neuronal loss from median dorsalis, caudal central medial, parafascicular nucleus. Permanent vegetative state (blue): all of above and centromedian nucleus. (Figure elements adapted from Castaigne et al., 1981, and Munkle, Waldvogel, & Faull, 2000.) (See figure 78.5.)

CBIC Weill-Cornell

OFF

ON

PLATE 94 Changes in cerebral metabolism associated with zolpidem administration in severe brain injury. Two sets of parasagittal images of fluorodeoxyglucose positron emission tomography studies obtained in an awake, severely brain-injured patient are shown obtained one day apart. The OFF images show the resting metabolic profile in an awake state and demonstrate qualitative downregulation of metabolism in the anterior forebrain (frontal,

prefrontal cortex), basal ganglia, and thalamus. The ON images show the resting metabolic profile in an awake state 45 minutes after administration of the drug zolpidem. A marked qualitative increase in metabolism is observed in the anterior forebrain, basal ganglia, and thalamus. In addition, overall metabolic activity across cerebral structures is increased. (See figure 78.7.)

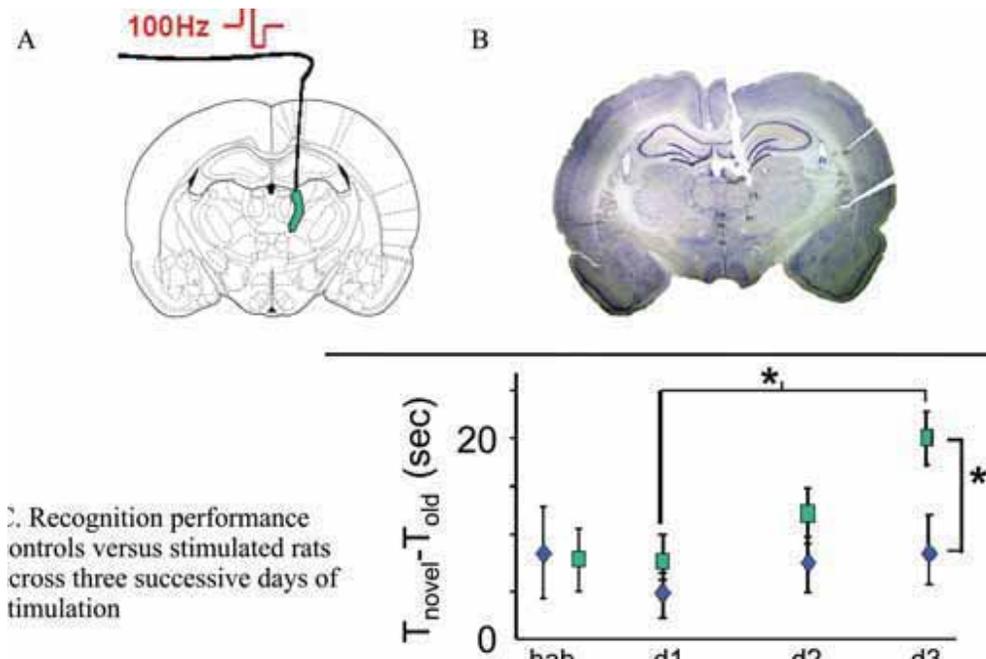

PLATE 95 Facilitation of recognition memory with continuous electrical stimulation of the rat central thalamus (Shirvaskar, Seth, Schiff, & Herrera, 2006). (A) Electrode placement in the central thalamus. (B) Representative gross histological section. (C) Com-

parison of sham-stimulated controls and stimulated rat cohorts on object recognition task across three successive days of stimulation. Stimulated rats show increased performance and accumulation of effects. (See figure 78.9.)

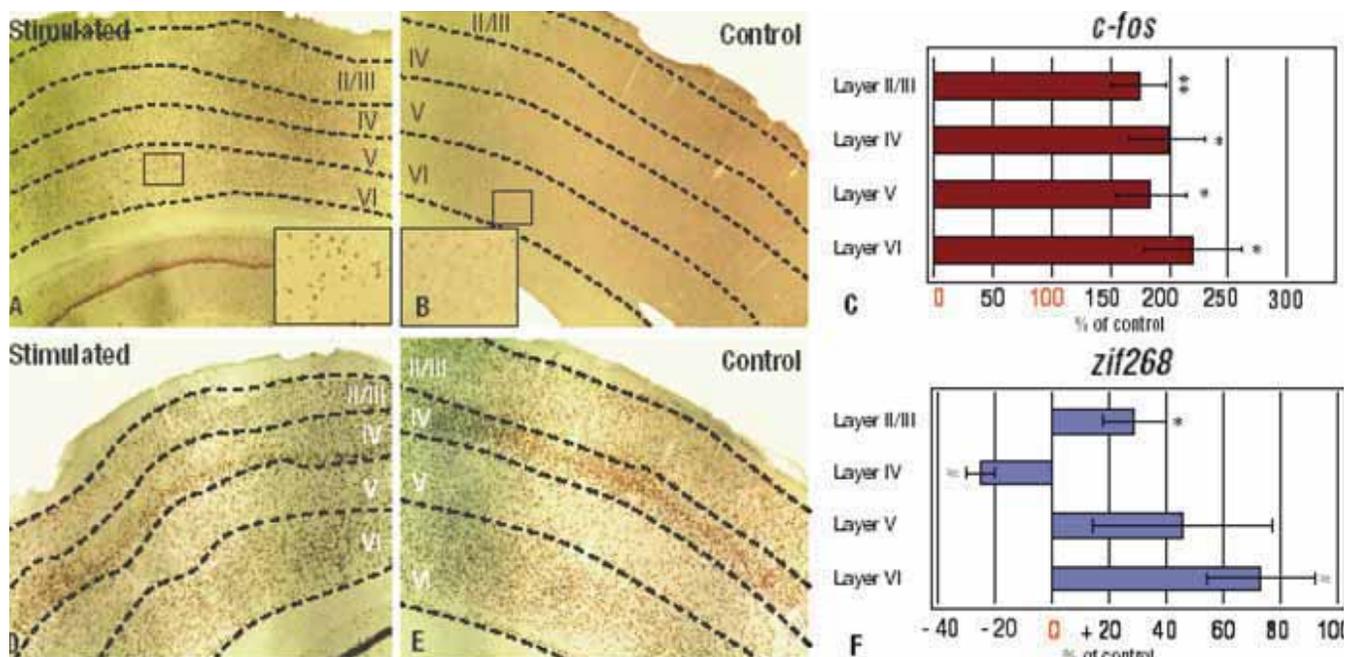

PLATE 96 Gene expression changes in the motor cortex following central thalamic electrical stimulation. Gene expression changes associated with 30 minutes of electrical stimulation of the central thalamus in two immediate early genes, *c-fos* and *zif268*, are shown (Shirvaskar et al., 2006). A broad increase of *c-fos* across cortical lamina is seen, consistent with increased synaptic activity. A laminar

specific pattern of changes in *zif268*, a memory-related gene, may link to accumulation effects seen in figure 78.9 and possibly to carryover effects observed in human-subject DBS study shown in figure 78.8 (see text and Shirvaskar et al., 2006, for further details). (See figure 78.10.)

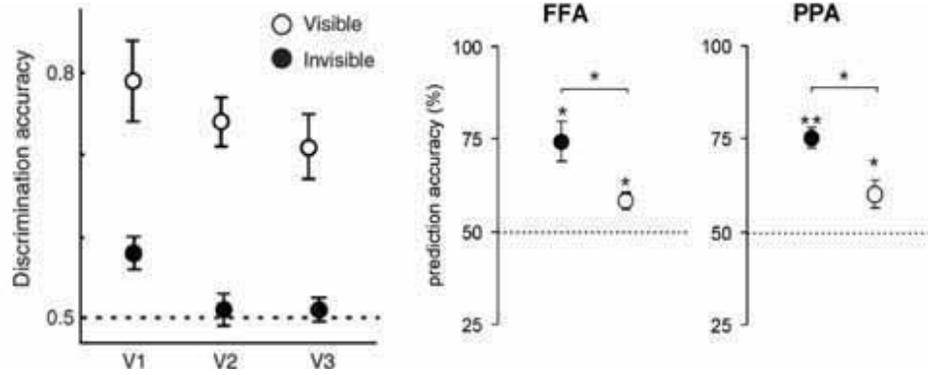

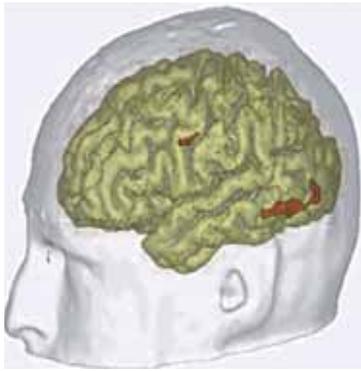

PLATE 97 Activation of sensory cortices by invisible stimuli. *Left panel:* Masked and invisible words nevertheless evoke activation (shown in orange, superimposed on an anatomical image of the brain) of the fusiform gyrus. See Dehaene et al. (2001) for further details. *Middle panel:* Activity measured using BOLD contrast functional MRI in human V1–V3 can be used to discriminate the orientation (right or left tilted) of a grating stimulus. Open symbols representing mean decoding accuracy for a group of subjects (error bars, one SE) for visible stimuli; closed symbols for similarly oriented stimuli rendered invisible by masking. The orientation of these invisible stimuli can still be discriminated at a rate significantly better than chance in human V1. See Haynes and Rees

(2005a) for further details. *Right panel:* Performance of support-vector-machine (SVM) classifiers for pairwise classification of face and house presentations from fusiform face area (FFA) and parahippocampal place area (PPA). Average prediction accuracies across participants for visible faces versus houses are denoted by filled circles (\pm SEM) and for invisible faces versus houses by empty circles. The dotted lines denote chance level (50%). $*p < 0.05$; $**p < 0.005$; n.s. = non significant ($p > 0.1$). Above-chance performance for invisible stimuli indicates that information is still present in higher visual areas sufficient to discriminate stimulus category. See Sterzer, Haynes, and Rees (2008) for further details. (See figure 80.1.)

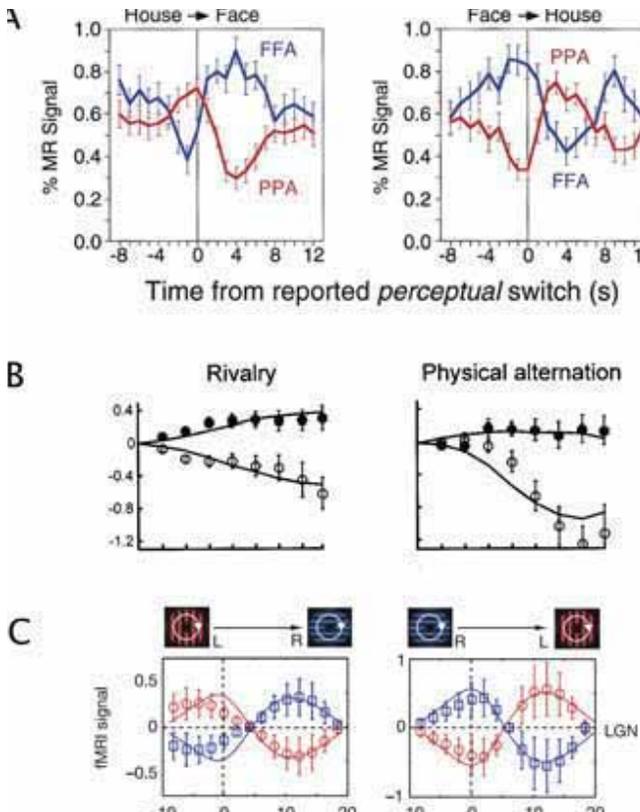

PLATE 98 Fluctuations in activity in visual pathways associated with visual awareness during binocular rivalry. (A) Fusiform face area. Activity measured using functional MRI from human fusiform face area (FFA) and parahippocampal place area (PPA) is plotted as a function of time relative to a perceptual switch from house to face (left panel) or face to house (right panel). It is apparent that activity in the FFA is higher when a face is perceived during binocular rivalry than when it is suppressed, and activity in the PPA is similarly higher when a house is perceived than when it is suppressed. For further details see Tong, Nakayama, Vaughan, and Kanwisher (1998). (B) Binocular rivalry in primary visual cortex (V1). Activity measured using fMRI from human primary visual cortex is plotted as a function of time after a perceptual switch where the subsequent perception is of a high-contrast stimulus (solid symbols) or low-contrast stimulus (open symbols). The left-hand panel plots activity following a perceptual switch due to binocular rivalry, while the right-hand panel plots activity following a deliberate physical switch of monocular (nonrivalrous) stimuli. V1 activity therefore corresponds to perception during binocular rivalry, and the amplitude changes are similar to those seen during physical alternation of corresponding monocular stimuli. For further details see Polonsky, Blake, Braun, and Heeger, (2000). (C) Rivalry in the lateral geniculate nucleus (LGN). Activity measured using fMRI is plotted as a function of time for voxels in the LGN selective for left-eye stimuli (red symbols) or right-eye stimuli (blue symbols) around the time (vertical dotted line) of a perceptual switch between left- and right-eye views (left panel) or right- and left-eye views (right panel). Reciprocal changes in signal in the different eye-selective voxels as a function of perceptual state can be readily seen. For further details see Haynes, Deichmann, and Rees (2005). (See figure 80.2.)

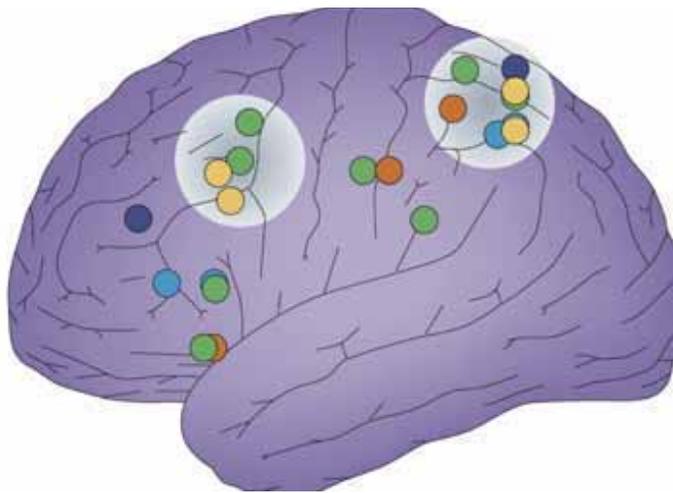

PLATE 99 Parietal and prefrontal correlates of visual awareness. Foci of parietal and prefrontal activity measured using functional MRI and associated with switches in the contents of consciousness independent of changes in physical stimulation are plotted on an anatomical brain image in a standard stereotactic space. Studies shown identify the neural correlates of perceptual switches during rivalry (Lumer, Friston, & Rees, 1998; Lumer & Rees, 1999),

during bistable perception generally (Kleinschmidt, Buchel, Zeki, & Frackowiak, 1998), associated with stereo pop-out (Portas, Strange, Friston, Dolan, & Frith, 2000), or associated with change detection (Beck, Rees, Frith, & Lavie, 2001). Clustering of activated foci (white circles) are apparent in superior parietal and dorsolateral prefrontal cortex. (See figure 80.3.)

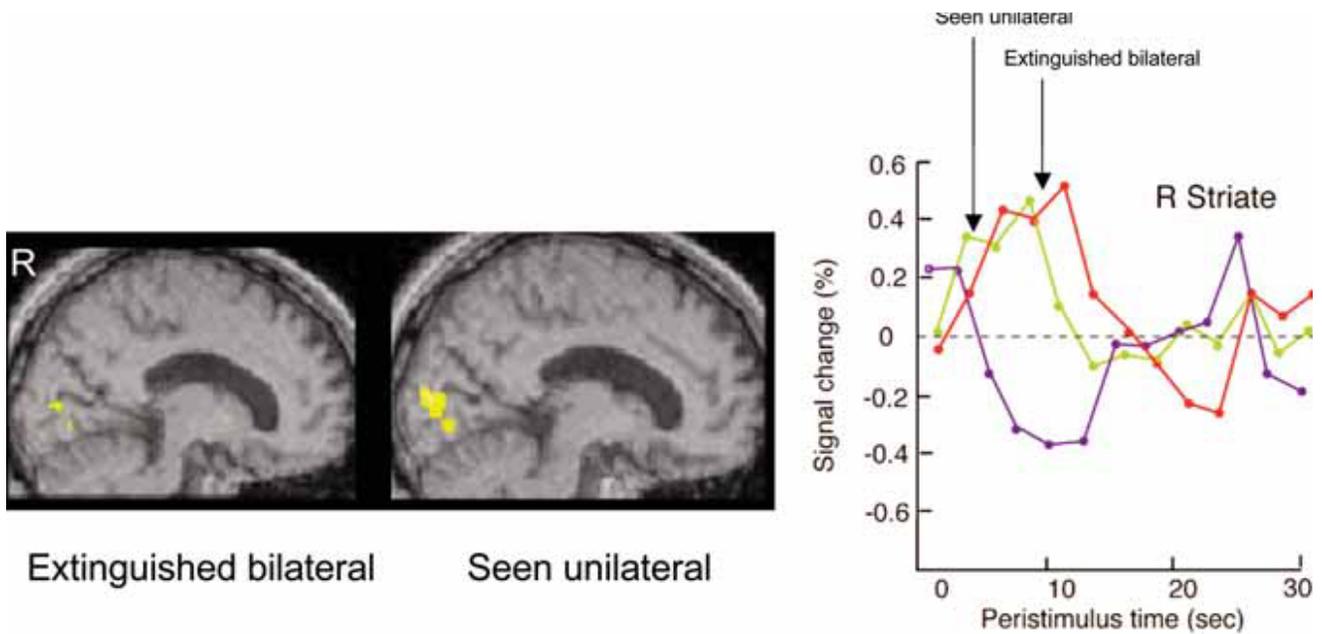

PLATE 100 Activity in ventral visual cortex is not sufficient for awareness. *Upper left:* Activity evoked by an unseen and extinguished left-visual-field stimulus (see text for description of visual extinction) in striate and extrastriate cortex in a patient with parietal neglect. Differences in activity comparing bilateral extinguished with unilateral right stimulation is overlaid on two sagittal slices of a T1-weighted anatomical scan. For further details see Rees and colleagues (2000). *Upper right:* BOLD activity from the right striate (V1) focus of activation shown in the left panel is plotted as a function of peristimulus time for bilateral extinguished stimuli, unilateral left-visual-field stimuli, and unilateral right-visual-field stimuli. Note the similarity of the BOLD time courses for the bilateral extinguished stimuli (in which a stimulus is present in the left visual

field but not reported by the individual with parietal extinction) and for the left unilateral stimulation (in which a stimulus is both present in the left visual field and reported). This indicates that stimuli that do and do not reach awareness may produce similar levels of activation in similar cortical locations, in this case following parietal damage. *Lower panel:* Activity in the fusiform face area evoked by a face (versus a house) stimulus presented in the neglected left hemifield of a patient with parietal neglect and left visual extinction. Thus, after parietal damage, activation in the ventral visual pathway for unseen stimuli can be sufficient to distinguish the category of stimulus presented. See Rees and colleagues (2002) for further details. (See figure 80.4.)

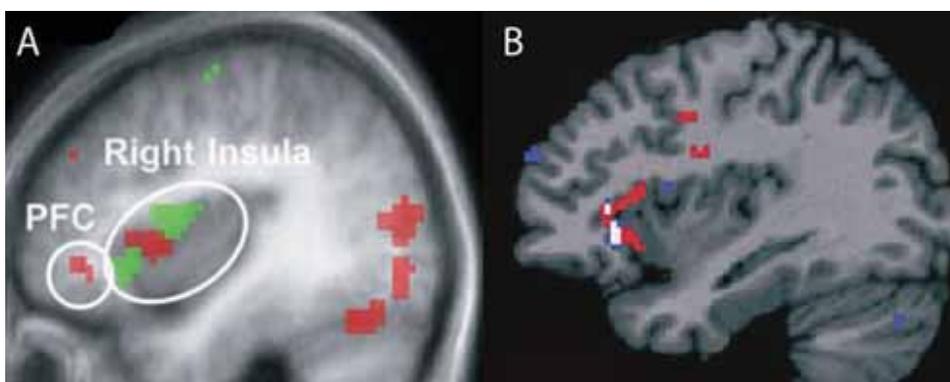

PLATE 101 Functional MRI data supporting simulation theory. (A) Brain areas active during the observation of pain in another (red) and the feeling of pain in oneself (green) (Singer et al., 2004). (B) Brain areas active during the observation of disgust in another (blue) and the feeling of disgust in oneself (red); overlap in white (Wicker et al., 2003). (See figure 82.3.)
